PREFACE

The 18th International Society of Scientometrics and Informetrics Conference is held on 12–15 July 2021 and organized by KU Leuven in close collaboration with the university of Antwerp under the auspices of ISSI the International Society for Scientometrics and Informetrics.

Due to the constraints imposed by the COVID-19 pandemic situation and the resulting risks for planning and organising a full-fledged conference with physical presence of attendees, the organisers decided to go virtual this time. This decision warranted a smooth organisation without unpredictable events and unnecessary modifications and adjustments during the preparation process. However, organising a virtual event of this size has posed a true challenge for the organisers. We were very pleased that despite the various different time-zones in the world, we could organise part of the conference, notably all keynotes, invited talks and plenary sessions as well as the workshops and tutorials and, last not least, all ceremonies as live events. The special tracks and the usual "parallel sessions" had, however, to be organised using pre-recorded on-line video streams. Making a virtue of necessity, we can provide all talks and the discussion for three months after the conference and thus make the conference a hopefully sustainable event.

The goal of ISSI2021 is to provide an international open forum for scholars and practitioners in the domain of informetrics, bibliometrics, scientometrics, webmetrics and altmetrics to discuss new research directions, advanced methods and theories, and to highlight the best research in this area. In order to achieve this goal, we asked researchers worldwide to submit original research manuscripts, particularly full papers, research-in-progress papers or posters, to propose and organise tutorials and workshops, with a special emphasis on the future of this area and on its interdisciplinary links with other fields. We succeeded in attracting a sufficient number of contributions to organise two special tracks, one on bibliometric approaches to measure and evaluate interdisciplinary research (IDR) organised by KU Leuven and one on the bibliometrics of social sciences and humanities (SSH) organised by our partner at University Antwerp. University Antwerp also took the opportunity to introduce their project of publishing on a new handbook on "Research Assessment in the Social Sciences".

We would like to thank the three keynote speakers, who have accepted our invitation, namely Katy Börner from Indiana University in Bloomington (USA), Albert-László Barabási from Northeastern University in Boston (USA), and David Sweeney, Executive Chair of Research England (UK).

Despite the pandemic-induced constraints, we could accept about 230 contributions, roughly two thirds of which are full and research-in-progress papers and nearly one third is present in pre-recorded poster sessions.

The assignment of contributions to session topics was facilitated by the organisation as a virtual event since time constraints did not influence the schedule. We have chosen the following major themes.

- Research evaluation & bibliometrics in support of science policy
- Effects of research funding
- Patent analysis
- Individual-level bibliometrics
- Collaboration and mobility
- Domain studies and regional issues
- Open Science, Open Access and editorial impact
- Gender and equality studies
- Webmetrics, altmetrics and media impact of research
- Advanced methods in citation analysis
- Data sources and data processing
- Document and journal analysis
- Network analysis

Furthermore, six workshops deal with the tracing of epistemic change, with creation and application of models, cited reference analysis, national and institutional research assessment, and collaborative archive and data research environment. This is completed by two tutorials. The organisers look forward to the future publication of the outcomes of these workshops.

All accepted presentations and posters are incorporated in the conference proceedings. The first part comprises invited and full papers as well as research-in-progress papers, while the second part is devoted to posters.

At this place, we would like to express our thanks to all participants and contributors for their understanding for the constrains due to the special situation and their active support. Our thanks are due to the ISSI board for its trust and support. We also thank the Leuven Congress Office – PC for their enormous effort and dedicated work and MEEPLE for providing the online platform. In particular, we thank Liesbeth Michiels, Marie-Laure Bettens and Ann Moerenhout.

On behalf of the organisers and the programme committee of ISSI2021
Wolfgang Glänzel

INDEX OF PAPERS
(FULL PAPERS AND RESEARCH IN PROGRESS)

INDEX OF POSTERS

Do hijacked journals attract dishonest authors?

Anna Abalkina[1]

[1] *abalkina@gmail.com*
Free University of Berlin (Germany)

Abstract

This research in progress studies academic misconduct as it related to hijacked journals. There is a common belief in the literature that naïve authors submit papers to fake journals. This study demonstrates that there is a group of dishonest authors who are attracted by the fast publication with no peer review process that is offered by hijacked journals. The results show that the average share of plagiarism in an examined sample of 500 papers was 21.0%. Plagiarism was not detected only in 28.2% of the papers. These results raise concerns not only about cyber-criminals but also about authors who exploit hijacked journals to improve their publication records.

Introduction

Hijacked journals create a challenge for academic publishing. Hijacked journals represent a type of cyber-crime. Hijacked journals mimic legitimate journals (Lukić 2014; Bohannon 2015; Dadkhah 2015; Jalalian & Dadkhah 2015; Asadi et al. 2017; Shahri et al. 2018) in order to cheat potential clients. These cloned journals exploit the titles and ISSNs of original journals and fraudulently collect fees from authors.

There is a common belief that the potential clients of such journal are naïve authors who are not able to distinguish between honest and fraudulent journals (Watson 2015; Dadkhah& Borchardt 2016). However, is this true? In other words, are naïve authors the only group of authors who submit their articles to hijacked journals? This question has not yet been investigated in the literature. There is an alternative hypothesis that some authors choose to exploit hijacked journals and submit their articles in order to increase their publication records. There is evidence of some plagiarism cases in hijacked journals and of the recycling of already published texts to replenish the archives of fraudulent journals (Abalkina 2021). Dadkhah et al. (2016) detected some cases of the circulation of texts between predatory and hijacked journals. Abalkina (2020) demonstrated cases of translation plagiarism in papers submitted to the hijacked *Journal of Talent Development and Excellence*.

In this study, I argue that dishonest authors constitute another group of clients who submit their articles to hijacked journals. Dishonest authors are attracted by fraudulent hijacked journals that offer a fast publication process with no peer review. To test this hypothesis, the texts of papers published in hijacked journals were checked for text similarities. Plagiarism is considered to be one of the most serious forms of academic misconduct (Resnik et al. 2015). Authors who violate academic ethics can be considered dishonest. Plagiarism detection in articles submitted to hijacked journals can shed light on the behaviour of the authors who submit to such journals.

This study is important for several reasons. First, there is a rising concern about the proliferation of hijacked journals and fraudulent publishers (Dadkhah & Borchardt 2016; Memon 2019). Second, recent evidence suggests that cyber-criminals compromise information from the webpages of peer-review journals and their content in international citation databases (Al-Amr 2020). Such behaviour constitutes a significant challenge for the academic community. Third, a considerable amount of literature has developed around the topic of academic misconduct and plagiarism in scientific papers (Fanelli 2009; Pupovac & Fanelli 2015). However, these studies do not take into account possible violations of academic ethics in hijacked journals. Fourth, research has shown that the high level of competition in academia, as well as the 'publish or perish' strategy, can increase the number of publications in predatory journals (Kurt 2018). Publishing in hijacked journals can be another possible way for academics to improve their publication records and cheat their universities.

Selection of hijacked journals

The hijacked journals were selected from several sources. First, I used the lists of hijacked journals found on the online websites https://beallslist.net/hijacked-journals/ and https://predatoryjournals.com/hijacked/. Second, I used the lists of hijacked journals found in Jalalian & Dadkhah (2015) and Abalkina (2021).

Third, I searched the SCImago website, which contains the profiles of academic journals and allows comments by users. Several hijacked journals were selected according to the comments of users regarding hijacked journals.

All the websites of identified hijacked journals were checked for their availability because hijacked journals do not work for a long time, and their domains usually expire after several years. I have made a list of 85 cloned websites that were available as of March 2021.

Selection of articles

The selection of articles to check for plagiarism is challenging. There is evidence that the archives of cloned journals are replenished by texts from hijacked and predatory journals (Abalkina 2021). To select the papers that were submitted to the hijacked journals but were not added by hijacking themselves, I selected only the last three issues of hijacked journals. This method increased the probability of selecting papers that were submitted by authors. I selected each tenth paper of each issue to check for plagiarism. I randomly chose the first paper (from one to ten) and then downloaded each tenth paper. If the total number of papers was less than ten, I chose each fifth paper. In the case of the *Journal of Talent Development and Excellence*, each twentieth paper was downloaded due to the extreme number of papers in each issue of this fraudulent journal.

Plagiarism detection

I used Urkund (Ouriginal) to detect plagiarism in the papers published in the hijacked journals. The study by Foltýnek et al. (2020) confirmed the efficiency of Urkund in detecting text similarities. Since the software detects all possible text similarities (Weber-Wulff 2019), a manual check is needed to eliminate the published paper itself, the references, citations, and standard phrases, for example, the description of statistical models, as well as false positive results. A manual check is also needed to detect the issue date of the text donors to take into consideration reverse plagiarism. After the manual check of text similarities, the final percentage of non-originality was calculated. As of March 2021, I have analysed a sample of 500 papers (approximately 60%).

Results

This study in progress found that 1,150 authors that contributed to 500 papers in the hijacked journals were predominantly from developing or emerging countries, especially from India (see Figure 1). However, this authorship by scientists from India (71,1%) is explained by the fact that a large number of hijacked journals are aimed at authors from India. Each tenth author of the sample papers originated from Indonesia. Authors from Russia and Kazakhstan shared 3rd and 4th place. There was also evidence of plagiarism in papers authored by post-Soviet scholars and published in hijacked journals (Abalkina 2020). Interestingly, the coauthors of most papers originated from the same country, and international collaboration can be considered an exception.

The analysis of text similarities in the hijacked journals showed that the level of plagiarism in the sample was high. The current average level of nonoriginal text is 21.0%; this number will be adjusted at the end of the study.

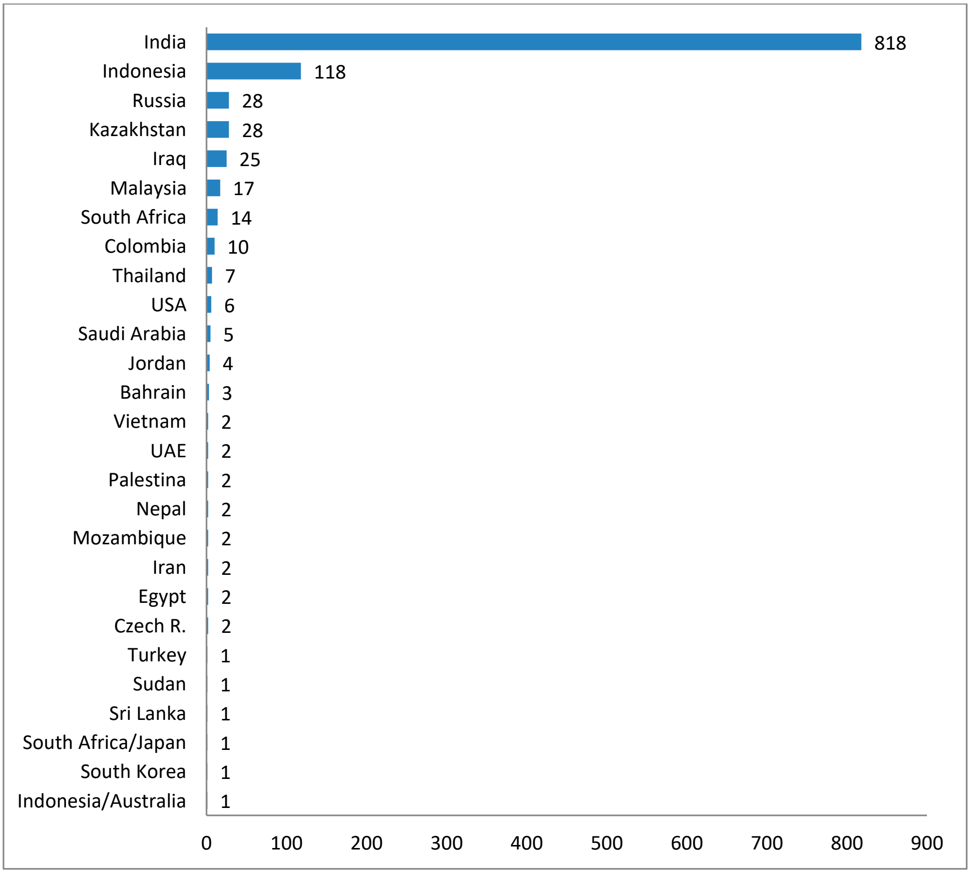

Figure 1Distribution of affiliation country of authors

Several types of plagiarism were found in the articles under investigation:

- Blatant plagiarism. Approximately 18.2% of papers had text similarities at the level of 50% or more;
- Plagiarism with rewriting. This is the case when the text of other authors is adopted, and synonyms are used;
- Plagiarism from papers with a different set of coauthors. This happens when text similarities are detected in papers with an overlapping set of coauthors;
- Self-plagiarism.
- Data fabrication. Several cases of data fabrication were also detected. In these cases, authors have changed the data in the plagiarized texts to keep them updated.

The text donors represent a variety of sources: master's degree theses, PhD theses, working papers, papers from both legitimate journals and predatory and hijacked journals, books, newspapers, and Internet pages.

Limitations

Both self-plagiarism and a low level of other-author plagiarism can be explained not only by the dishonesty of the authors but also by a low level of awareness of academic ethics principles and citation rules by such authors. This aspect warrants further investigation by interviews with the authors.

Conclusions

The following conclusions can be drawn from this study of plagiarism in hijacked journals. First, this study confirms the hypothesis that the authors are not as naïve as it is commonly believed in the literature. The absence of strict requirements for publication and plagiarism checks allows authors to publish texts with a significant amount of plagiarism. Thus, these findings of the current study suggest that fraudulent journals attract dishonest authors.

Second, the hypothesis of the presence of honest authors who have been deceived by hijacked journals is also not excluded. However, the share of articles without plagiarism is currently only 28.2%; this figure will be adjusted after the end of the study.

Acknowledgements

I thank Valeria Morozhnikova for her assistance with data collection. I gratefully acknowledge financial support from Ludwig Maximilian University of Munich where this study was initiated.

Abstract

This study is about public-private research collaboration. In particular, we want to measure how the propensity of academics to collaborate with their colleagues from private firms varies over time and whether the typical profile of such academics change. Furthermore, we investigate the change of the weights of main drivers underlying the academics' propensity to collaborate with industry. In order to achieve such goals, we apply an inferential model on a dataset of professors working in Italian universities in two subsequent periods, 2010-2013 and 2014-2017. Results can be useful for supporting the definition of policies aimed at fostering public-private research collaborations, and should be taken into account when assessing their effectiveness afterwards.

Introduction

The ability of industry to exploit the results of academic research is a distinctive competence of advanced economies. Policies aimed at developing such ability are among the priorities of an increasing number of governments (Fan, Yang, & Chen, 2015; Shane, 2004). Public-private research collaboration is one of the main modes to realize knowledge transfer. Understanding the motivations underlying joint cooperation is an important step towards formulating policies and initiatives aimed at increasing the frequency of collaboration.

The main objective of this work is to investigate to what extent frequency of public-private research collaboration change over time, alongside the main drivers underlying the academics' propensity to collaborate with industry. Decision makers then would be able to formulate incentive schemes based on those drivers that show not only more weight but also more stability. A critical step in the study is the identification of the main drivers that could influence the propensity of academics to engage in research collaborations with industry. Previous literature suggests that they are to be found in the individual characteristics of the academic and the environment he or she works in (Zhao, Broström, & Cai, 2020; Llopis, Sánchez-Barrioluengo, Olmos-Peñuela, & Castro-Martínez, 2018; Abramo, D'Angelo, & Murgia, 2013), although personal characteristics seem to be more important than those of the environment (D'Este & Patel, 2007).

Most works on the topic are based on surveys, which poses limits on the scale of observations (Zhao, Broström, & Cai, 2020; Weerasinghe & Dedunu, 2020; Llopis, Sánchez-Barrioluengo, Olmos-Peñuela, & Castro-Martínez, 2018; Thune, Reymert, Gulbrandsen, & Aamodt, 2016). To overcome these limits, we adopt instead a bibliometric approach, analyzing the co-

authorships of publications. Co-authorship in fact should be the outcome of a real research collaboration, though exceptions cannot be excluded (Katz & Martin, 1997).
We aim to answer the following research questions:

- Does the intensity of public-private research collaboration varies over time?
- Does the typical profile of academics collaborating with the private sector change over time?
- Do the main individual and contextual drivers of the academics' propensity for research collaboration with the private sector change over time?

To address these questions, we apply an inferential model on a dataset of professors working in Italian universities in two subsequent periods, 2010-2013 and 2014-2017. It must be noted that we investigate the scientific output of research collaboration, therefore output at time *t* refers to a joint research project conducted at time t-τ, where τ represents the time lapse needed for the new knowledge to be encoded in written form and having it published in a scientific journal. This is it be kept in mind in general when interpreting results of time-series or before-after analyses, and especially when setting up frameworks to assess the effectiveness of policies aimed at fostering public-private research collaborations.
In the next section we review the literature on the factors determining private-public research collaboration. In Section three we present the methodology and data. In Section four we show the results of the analysis. Section five concludes the work.

Literature review

The underlying reasons for academics to engage in research collaborations with industry differ from those of the industrial partner. The latter mainly aims to access knowledge to be further developed for commercial exploitation (Bekkers & Bodas Freitas, 2008; Perkmann et al., 2013). The former is mostly attracted from direct economic and financial benefits that the industrial partner can offer (Garcia, Araújo, Mascarini, Santos, & Costa, 2020) and, to some extent, also by a noble purpose: the so called "mission" motivation, i.e. advancing the societal role of universities (Iorio, Labory, & Rentocchini, 2016). The intensity of public-private research collaboration must be sensitive then to the changing financial needs of academics, to the incentive schemes adopted by national and regional governments and by the research organizations they work at, and to the effectiveness of industry-liaison offices which act as catalysts for collaboration.
From the academic standpoint, the propensity to collaborate with industry varies along the career cycle, although the impact of age seems non-linear (Weerasinghe & Dedunu, 2020). In fact, collaboration propensity seems stronger at the early career stage and weaker in the later stages (Bozeman & Gaughan, 2011; Ubfal & Maffioli, 2011). In fact, younger academics are in more need of financial resources, and to show their ability to activate and manage collaborations, which is positively evaluated for career progress (Bayer & Smart, 1991; Traoré & Landry, 1997).
Gender also plays an important role. Because of gender homophily women show greater difficulty in developing their social capital, including collaboration networks (Boschini & Siogren, 2007). As compared to males, female academics engage less in research collaboration with industry (Tartari & Salter, 2015), mainly because they are less interested (Calvo, Fernández-López, & Rodeiro-Pazos, 2019).
There occurs a positive correlation between research performance and collaboration (Mansfield, 1995; Mansfield & Lee, 1996; He, Geng, & Campbell-Hunt, 2009; Lee & Bozeman, 2005; Schartinger, Schibany, & Gassler, 2001), as companies are likely to search for top players to engage in their research projects (Balconi, & Laboranti, 2006).

The tendency to diversify one's own research activities may underly curiosity for novelty and unexplored, and reveal more appropriate for engaging in cross-sector research (Abramo, D'Angelo, & Di Costa, 2019).

Environmental factors must have an influence as well on the academic's propensity for joint research with industry. The relative importance that the university poses on technology transfer creates a culture and motivational stimuli more or less harbinger of research collaboration with industry (Di Gregorio & Shane, 2003; Giuri, Munari, Scandura, & Toschi, 2019). Also, the extent of financial resources made available for research affect the propensity to search for private sources (Giuri, Munari, Scandura, & Toschi, 2019).

The attitude and inclination of academic colleagues towards cross-sector research projects, will have an influence of one's own behavior, through a mechanism of social comparison (Tartari, Perkmann, & Salter, 2014). The size of the university plays a role in determining the types of collaboration by the research staff. If a critical research mass is not there, academics would likely tend to engage in extra-muros collaborations (Schartinger, Schibany, & Gassler, 2001).

The demand by industry for collaboration, and therefore the concentration of private R&D in the territory of the university, affects the possibilities for cross-sector collaboration (Berbegal-Mirabent, Sánchez García, & Ribeiro-Soriano, 2015).

Finally, the research production function varies across scientific disciplines (Abramo, D'Angelo, & Murgia, 2013a), therefore discipline effects on the intensity of university-industry collaborations are expected.

Data and methods

The field of observation consists of professors of Italian universities, conducting research in the so-called hard sciences. We exclude the social sciences and arts & humanities because for these the coverage of bibliographic repertories is still insufficient for reliable representation of research output. In the Italian university system all professors are classified in one and only one field (named the scientific disciplinary sector, SDS, 370 in all). Fields are grouped into disciplines (named university disciplinary areas, UDAs, 14 in all). We observe research production in 201 SDSs falling in 10 UDAs, where publications in international journals serve as a reliable proxy for overall research output.

To investigate whether the collaboration rates and determinants of academic engagement in joint research with industry change over time, we conduct a longitudinal analysis dividing the observed period into two subsequent four-year subperiods, 2010-2013 and 2014-2017.

The analysis dataset consists of all assistant, associate and full professors, on staff for at least three years in 2010-2013 or 2014-2017, with at least one Web of Science (WoS) indexed publication in the relevant period. These are 31634 professors in the first period and 31392 in the second.

The bibliometric dataset is extracted from the Italian Observatory of Public Research, a database developed and maintained by the present authors, and derived under license from the Thomson Reuters WoS. Beginning from the raw data of the WoS and applying a complex algorithm to reconcile the author's affiliation and disambiguation of the true identity of the authors, each publication (article, article review and conference proceeding) is attributed to the professors that authored it (D'Angelo, Giuffrida, & Abramo, 2011).[1] Collaboration with industry is evidenced by the presence of at least one private company[2] in the address list of publications authored by the professor in the dataset.

[1] The harmonic average of precision and recall (F-measure) of authorships, as disambiguated by the algorithm, is around 97% (2% margin of error, 98% confidence interval).

[2] Identified through the manual scrutiny and unification of all bibliographic addresses with "Italy" as affiliation country.

We will first verify if the share of professors collaborating with industry in the two periods increases or not and if the "profile" of those engaging in such collaborations has changed over time. Then, we will use a logit regression in order to understand if the main drivers of academic engagement in public-private research collaboration changed in weight, in the two periods. The logit regression relies on a dummy dependent variable (Y) assuming: 1, if professor *i* co-authored at least one publication with industry; 0, otherwise. As for covariates suggested by previous literature that are likely to affect the propensity of professors to engage in research collaboration with industry, we will consider the following, grouped in two clusters.

Individual covariates

- Gender (X_1), specified by a dummy variable (1 for female; 0 for male);
- Age ($X_{2\text{-}5}$), specified with 5 classes, through 4 dummies (baseline "Less than 40");
- Academic rank ($X_{6\text{-}7}$), specified by 2 dummies (baseline "Assistant professors");
- Total publications authored by the professor in the period under observation (X_8);
- Level of specialization of the scientific activity of the professor, specified by 2 dummies:
  - ✓ "Highly diversified" (X_9), 1 if the papers falling in the prevalent subject category of the professor[3] is less than 40% of total publications; 0, otherwise;
  - ✓ "Highly specialized" (X_{10}), 1 if the papers falling in the prevalent subject category of the professor is more than 75% of total publications; 0, otherwise;[4]

Contextual covariates

- Environment-Peers behaviour (X_{11}), specified by a dummy variable (1 in case of a colleague in the same university and SDS of the professor, co-authoring publications with industry; 0, otherwise)[5];
- Institutional control (X_{12}), specified by a dummy variable (0, for public universities; 1, for private ones);
- University scope (X_{13}), specified by a dummy variable (1, for "Polytechnics" and "Special Schools for Advanced Studies, SS"; 0, otherwise);[6]
- University size in the ADU of the professor ($X_{14\text{-}15}$), specified with 3 classes through 2 dummies ("Big", for universities with a research staff in the UDA of the professor, above 80 percentile in the national ranking; "Medium", with a research staff between 50 and 80 percentile);
- University location ($X_{16\text{-}19}$), specified with 5 geographical macro-areas, by 4 dummies (baseline "Islands").
- Period (X_{20}), specified by a dummy variable (0, for 2010-2013; 1, for 2014-2017)

In order to control for the research discipline effects, we also consider other 9 dummies related to the ten UDAs under observation.

[3] For a thorough explanation of the bibliometric approach to discriminate specialized from diversified research, we refer the reader to Abramo, D'Angelo, and Di Costa (2017).

[4] The chosen thresholds (40% for X_8, and 75% for X_9) allow for equal partitions of the dataset (one third of of highly diversified professors, and one third of highly specialized ones).

[5] For this variable we do not exclude those publications where the scientist under observation is a co-author. Such publications are fruit of cross-sector and, at the same time, of "intramural" collaborations, where the peers effect is in place.

[6] The Italian Minister of University and Research (MUR) recognizes a total of 96 universities as having the authority to issue legally recognized degrees. Of these, 29 are small, private, special-focus universities, of which 13 offer only e-learning, 67 are public and generally multi-disciplinary universities. Three of them are Polytechnics and six are *Scuole Superiori* (Special Schools for Advanced Studies), devoted to highly talented students, with very small faculties and tightly limited enrolment per degree program. In the overall system, 94.9% of faculty are employed in public universities (0.5% in *Scuole Superiori*).

The logit regression was applied separately to the two period under observation. In detail, values of the variables referred to the first period are measured at 31/12/2009, while the ones of the second period are measured at 31/12/2013.

Results

In the first period, professors with at least one publication co-authored with industry represented 17.2 percent of the 2010-2013 dataset (Table 1). In the second period, their share raised to 25.5 percent. Among the 27,323 professors on staff in both periods, 10.0 percent collaborated with industry in both periods; 8.1 percent collaborated in the first period only, and 16.0 percent collaborated in the second period only. Overall, the share of professors on staff in both periods, and who collaborated with industry in the first period was 18.1 percent; in the second period, 26.0 percent.

The other two subsets considered in Table 1 (A not B, B not A), consist respectively of professors who left the academia in the second period, and who joined it in the second period. Among the former, the share of those who co-authored at least one publication with industry in 2010-2013 was 11.3 percent. Among the latter, the share almost doubled (21.6%).

We can say then, that i) the share of professors on staff in both periods, collaborating with industry increased by 8.0 percent; and ii) the new entries (in the second period) showed a propensity to collaborate with industry which almost doubled that of professors approaching retirement.[7]

Table 1. Breakdown of professors in the dataset

Set*	No.	Category	Share
A	31643	Collaborating	17.2%
B	31392	Collaborating	25.5%
A ∩ B	27323	Collaborating in both periods	10.0%
		Collaborating only in the second period	16.0%
		Collaborating only in the first period	8.1%
		Never collaborating	65.8%
A not B	4320	Collaborating with industry	11.3%
B not A	4069	Collaborating with industry	21.6%

** "A" = professors in the 2010-2013 dataset; "B" = professors in the 2014-2017 dataset*

Table 2 reports the typical profile of university professors collaborating with private companies, identified by the concentration index on each individual and contextual trait.[8] The left side refers to the profile emerging from the data of the first four-year period; the right side, to the second one.

2010-2013, the typical academic active in research collaboration with industry is male, 40-45 years old, a full professor, with highly diversified research activity. This professor operates within a group of peers who likewise collaborate with industry, and belongs to a medium-sized public university, typically a polytechnic or SSs located in northwestern Italy.

In 2014-2017, the profile is very similar. The only significant differences are in the age of the academic and size of their home university. As for the age, the prevailing trait is below 40 years old: in other words, in the second period, interaction with industry extends to and features academics younger than other aged colleagues. As for the size, the shift is from medium to big, but in both period the association is not statistically significant. Other traits remain unchanged,

[7] Almost all professors present only in the first period, were not there in the second period because of age limits. In Italy, it is quite rare that a professor quits academia for other reasons (Abramo, D'Angelo, & Rosati, 2016).

[8] The concentration index is the ratio of two ratios. Example: for the group variable "gender", the prevailing trait "male" shows a concentration index of 1.058 for 2010-2013 data, since males compose 71.66% of total researchers co-authoring publications with industry, and 67.75% of the total population, therefore 71.66/67.75=1.058.

although variation in the absolute value of the concentration index reveals a weakening/strengthening of the characteristic trait between the two periods.

Since this purely descriptive analysis does not take into account the simultaneous effects of all covariates on the independent variable, in the following we conduct an inferential analysis using a logit regression model, as illustrated in the previous section.

Table 2: Profiling of the Italian academic co-authoring publications with industry

	2010-2013			2014-2017

Table 3 shows the average values of the model variables, at overall level, for the two periods under investigation. Some significant differences between the two periods, for individual covariates, deserve an underlining:

- Average age of professors increased, in particular the incidence of the elder courts (for example, the over sixties' share raised from 12.6 percent to 14.3 percent of total);
- Average number of publications per professors increased (from 14.60 to 19.37);
- The propensity to diversify research activity increased. Highly diversified academics raised from 14.3 percent to 19.1 percent. Specularly, the share of specialized researchers decreased from 31.3 percent to 25.2 percent).

We remind the reader that the two datasets partly overlap, with about 87 percent of professors belonging to both. As a consequence, variations between the two periods can be explained partly by a behavioural change of incumbent professors, and partly by different attitudes and interests of younger newly hired professors as compared to their older peers who retired. In fact, in the second period, the share of associate professors, and more noticeably of full professors, dropped in favour of that of assistant professors. In spite of that, the average age of faculty increased, in particular that of the elder courts (the share of over sixty years old professors raised from 12.6 percent to 14.3 percent). Thanks to the new entries and exits, gender unbalance improved, as the share of female professors raised from 32.3 percent to 33.9 percent. In fact, in the subset "B not A" of Table 1, the share of females is 37.6 percent, while in the subset "A not B", it is 25.3 percent.

Table 3: Average values of the regression model variables in the two periods under investigation

Variable group			2010-2013	2014-2017

	X_{19}	Northwest	0.239	0.244

Findings of the logit regressions applied to the whole dataset to investigate the drivers of academic engagement in public-private research collaboration, are reported in Table 4.

The model estimation appears satisfactory. The mean VIF is 2.42, with maximum (7.23) for the covariate "University size – Big" (X_{15}), which excludes the presence of multicollinearity that could disturb the estimation of the coefficients.

The value of under ROC area (AUC) is 0.747, which indicates good ability of the model to correctly classify professors, discriminating the propensity to collaborate with companies[9] in function of individual traits and context.

The estimated coefficients of the regression model are expressed in terms of odds ratios: the reference value is equal to one and indicates that the independent variable considered has no effect on the dependent variable, i.e. on the probability that a professor has or has not collaborated with private companies. For values above one, the variable instead has a positive marginal effect, and vice versa.

Scrolling data in Table 4, the coefficient of X_{20}, representing the time pattern, immediately jumps to the eye: all others being equal, the propensity to collaborate in the second period increases by over 50% as compared to the first, confirming what has already been shown by descriptive statistics.

In general, all the covariates but very few have a statistically significant effect. In particular, "University type-Polytechnic or SS" (X_{13}) does not show a significant marginal effect on academics' propensity to collaborate with industry.

[9] The AUC analysis evaluates a classifier's ability to discern between true positives and false positives. In our case, the AUC value, between 0 and 1, is equivalent to the probability that the result of the logit classifier applied to a researcher randomly extracted from the group of those who collaborated with industry is higher than that obtained by applying it to a researcher randomly extracted from the group of those who did not collaborate (Bowyer, Kranenburg, & Dougherty, 2001).

† Interaction effect between the variable and the 'Period', indicating if and to what extent the weight of the variable changes in the second period

Confirming previous literature (Weerasinghe & Dedunu, 2020; Tartari & Salter, 2015; Calvo, Fernández-López, & Rodeiro-Pazos, 2019), among the individual characteristics, gender has a non-marginal effect: women show a lower propensity to collaborate with private companies (-11.8%). The last column of Table 4 indicates that such propensity for women tends also to decrease in the second period: the coefficient of the interaction effect with the "Period" variable is negative (-0.070), although statistically not significant. Age as well shows a systematically negative impact on the response variable of the proposed model, with all odds ratios below 1, decreasing over time for older cohorts (over 45 aged), at least according to the sign of the interaction coefficient.

As for the academic rank, it shows a positive effect on the propensity for collaborating with industry, slightly decreasing in the second period: full and associate professors show a higher propensity to collaborate as compared to assistant professors, respectively by 80.9 percent and 35.4 percent.

Regarding the level of research diversification/specialization, a highly diversified scientific profile has 34.6 percent higher probability of collaborating with companies than an "intermediate" profile. Specularly, the dual covariant (highly specialized profile) has a negative impact on the propensity to collaborate (-38%).

Finally, the effect of what can be considered an exposure variable (the number of total publications), although statistically significant, is very limited in both periods (odds ratio 1.012 in 2010-2013, and 1.010 in 2014-2017).

Among all covariates under examination, “Peers collaborating” (X_{11}) presents the highest odds ratio. Confirming the indication of Tartari, Perkmann, and Salter (2014) the presence of colleagues from the same field, actively collaborating with companies, is the most important driver for an academic, even though in the second period its marginal effect substantially decreases. This is shown by the negative and significant sign of the interaction effect in the last column (-0.172). Among contextual covariates, the trait “public” of a university has a positive effect on the propensity of faculty to collaborate, probably because financial resources for research are lower than in private universities. Furthermore, also size matters: all others being equal, in medium and large-sized university the faculty propensity to collaborate is, respectively, 14.7 and 27.3 percent lower than in small-sized ones. As for geographic localization, the coefficients of the four dummies considered indicate an increase in the propensity to collaborate with latitude, i.e. towards northern Italy, where the concentration of private R&D is the highest. For academic researchers, interaction with companies depends on the level of concentration of industrial activities in general and, in particular, of knowledge-intensive industry. As for the time pattern, in the second period the propensity to engage in cross-sector collaborations seems to significantly increase in the south and the center, while it decreases in the north-west (relatively to professors on staff at universities located in the islands).

Conclusions

In the so called knowledge-based economy we live in, knowledge is increasingly becoming a distinctive competence to achieve the competitive advantage of companies, and to sustain the economic growth of nations. Universities, as the loci of new knowledge creation, have undergone in the last decades an increasing pressure to devote a special care to the technology transfer function (Todorovic, McNaughton, & Guild, 2011; Etzkowitz & Leydesdorff, 1995; Etzkowitz, 1983), which has become their third mission, alongside the traditional ones of education and research (Etzkowitz & Leydesdorff, 1995). When we refer to public-private technology transfer we generally think the exploitation by industry of results of research conducted at universities and public research organizations. A quicker and more effective way to pursue the same results is the co-creation of new knowledge through joint public-private research projects. To that aim, a number of incentive schemes have been put into place (Davenport, Davies, & Grimes, 1998; Debackere & Veugelers, 2005).

Understanding the drivers underlying the academics’ propensity to engage in collaboration with industry is critical in formulating and targeting such incentive systems to maximize their effectiveness, especially in such countries as Italy where the current levels of collaboration are suboptimal. Also important is to be aware of how the relative weight of such drivers vary over time, especially when setting performance indicators and reward systems, or when assessing the effectiveness of the policy initiatives.

Disincentives are at play too, first of all transactions costs (Belkhodja & Landry, 2005; Drejer & Jørgensen, 2005), which grow with the cultural and cognitive distance of members of the university-industry research team (Abramo, D’Angelo, Di Costa, & Solazzi, 2011). Furthermore, it has been demonstrated that on average public-private co-authored publications have lower impact than intra-university co-authored publications, and represent a lower share of highly-cited publications (Abramo, D’Angelo, & Di Costa, 2020). Because academics are increasingly subject to evaluation of their scientific activity, this awareness might constitute an additional deterrent.

In this study, we show that in the Italian academia, the share of professors collaborating with industry raised from 17.2 percent in 2010-2013 to 25.5 percent in 2014-2017. This increase is explained partly by a higher propensity to collaborate with industry by incumbents, and partly by the higher propensity of new hired professors as compared to their older colleagues who retired. This evidence can be partly due to the increasing emphasis on the importance of the university's so-called third mission. Researchers are experiencing increasing pressure to open up their research agendas to the needs of the local and national production system. There are no yet specific incentives put in place by the policy maker in this sense, but in the current national evaluation exercise, the entrepreneurial and technology transfer activities of universities are going to be assessed for the first time, in view of their possible use in the performance-based research funding scheme adopted by the Ministry of Universities and Research. At the same time, it is also possible that the increasing recourse to collaboration with private organizations has been caused by the progressive thinning of the resources made available to public research institutions, because of the budget constraints due to the tough economic situation in Italy.

The typical profile of the academic collaborating with industry is unchanged: it is a male, full professors, relatively young, with highly diversified research activity, operating within a disciplinary team made of colleagues with a high propensity themselves to collaborate with industry, and on staff in a public university located in northwestern Italy.

The relative importance of the drivers of academics' engagement in research collaboration with industry remains quite stable. The variations of the marginal effects of such personal traits as gender, age, research diversification and academic rank are quite modest and statistically not significant.

With regard to contextual drivers, the variable showing the highest weight, i.e. the presence of peers with high propensity to collaborate with industry, undergoes a significant reduction. University localization gains weight as well, while the gap between north and south shrinks.

In interpreting results, caution is recommended due to the intrinsic limits of all bibliometric approaches to the analyse of cross-sector collaborations, not all research collaborations lead to an indexed publication, and not all joint co-authored publications reflect a real public-private collaboration.

Follow on research might concern i) the measurement of publications' impact to verify whether there occurs a trade-off between the increase of the frequency of collaborations and the quality of their outputs; ii) a field level analysis to verify to what extent results vary across fields; and iii) the extension of the analysis to broader time periods with panel data.

Future research might also inquire into the geographic proximity effect on the intensity of cross-sector research collaborations, as compared with intra-sector collaborations. Finally, the methodology can be easily applied to other nations, whereby natives can easily distinguish and reconcile public and private affiliations. This would allow cross-country comparisons for a better understanding of the phenomenon.

Abstract

The massive shock of the COVID-19 pandemic is already showing its negative effects on economies around the world, unprecedented in recent history. COVID-19 infections and containment measures have caused a general slowdown in research and new knowledge production. Because of the link between R&D spending and economic growth, it is to be expected then that a slowdown in research activities will slow in turn the global recovery from the pandemic. Many recent studies also claim an uneven impact on scientific production across gender. In this paper, we investigate the phenomenon across countries, analysing preprint depositions in bioRxiv. Differently from other works, that compare the number of preprint depositions before and after the pandemic outbreak, we analyse the depositions trends across geographical areas, and contrast after-pandemic depositions with expected ones. Differently from common belief and initial evidence, in few countries female scientists increased their scientific output while males plunged.

Introduction

Following the COVID-19 outbreak in China and the Far East first, Italy and Europe shortly after, and finally the Americas, governments adopted a body of emergency measures to contrast the pandemic diffusion. Among others, mobility restrictions and social distancing caused simultaneous disruptions to both supply and demand in a globalized world economy. On the supply side, reduction of labour supply because of infections, business closures and slowdown of production because of lockdowns and social distancing, caused a decrease in production. On the demand side, notwithstanding social safety nets introduced by governments, layoffs, loss of income, and worsened economic prospects caused a reduction in household consumption and private investment.

A rapidly growing number of studies investigate the macroeconomic effects of COVID-19 pandemic across countries, sectors in individual countries, as well as on a global scale (Pagano et al., 2020; Ludvigson et al., 2020; Baqaee & Farhi, 2020; McKibbin & Fernando, 2020). According to the World Bank, the massive shock of the COVID-19 pandemic and lockdown measures to contain it have plunged the global economy into the worst economic depression since World War II.[1] The negative effect on economies around the world is expected to lead to a decline in per capita income in about 90% of countries in 2020 (Djankov & Panizza, 2020), not to even mention the long-term social effects.

Due to containment measures, research activities, both public and private, have undergone a general slowdown as well, especially in those disciplines where the presence at work and close interaction with colleagues are necessary. "Levels of self-perceived productivity dropped,

[1] https://www.worldbank.org/en/news/press-release/2020/06/08/covid-19-to-plunge-global-economy-into-worst-recession-since-world-war-ii, last accessed 25 January 2021.

where dry lab scientists were much more likely to continue carrying out their work from home as expected (29% of dry lab scientists, but only 10% of wet lab scientists, reported “at least 80% productivity”)” (Korbel & Stegle, 2020). At many major research universities, non-essential research was halted, “in what amounts to an unprecedented stoppage of academic science in modern memory” (Redden, 2020).

It is widely accepted in economic theory that R&D spending can lead to rates of return well above those expected on standard capital investment (Deleidi et al., 2019). It is to be expected then that a slowdown in research output will slow in turn global recovery from COVID-19.

In this work, we undertake empirical analysis of the impact of COVID-19 pandemic on worldwide research production in life sciences, across macro-geographical areas and distinguishing by gender. We expect that the extent of slowdown in research activities varies across countries and over time, depending on the spread of infections, the extent of social restrictions, and timing of both. Furthermore, the adoption of smart working, especially at universities and public research institutions, alongside the shutdown of schools, caused a considerable increase in the scientists’ workload at home that could impact research production differently across gender. In fact, the more extensive involvement of women in family responsibilities, mainly care for children (Schiebinger & Gilmartin, 2010), might have increased or relieved because of the presence of men at home. Specularly, men might face more distractions and an intensification of domestic responsibilities when confined to the home.

The implications of findings are twofold. First, any forecasts of the impact of research on economic recovery and growth, might be misleading if based on R&D spending during the pandemic. In fact, COVID-19 pandemic did not affect so much overall R&D spending, at least by governments (Radecki & Schonfeld, 2020), while it did affect research productivity, as we will show empirically. Second, if the pandemic unevenly affects research productivity across gender, any research performance evaluation should account for that, in order not to disfavour either gender in their careers and access to resources, and institutions with uneven gender distributions of research staff.

The first empirical studies on the effects of COVID-19 pandemic on research activities focused on the response from researchers to address health issues to minimize its impact. While findings need to be verified at a later stage of the pandemic and in the years to come, from these very first investigations we learn that the volume of publications for this topic noticeably increased (Zang et al., 2020), while their quality seems below the quality average of other articles in the same journals (Zdravkovic, Berger-Estilita, Zdravkovic, & Berger, 2020). Differently from previous publications though, there seems to be a high degree of convergence between articles shared in the social web and citation counts (Kousha & Thelwall, 2020).

Soon after, the focus of scholars extended to investigate the effect of COVID-19 also on scientists’ behaviour and on research activities other than COVID-19-related research. In terms of scientists’ research behaviour, it is evident that the pandemic emergency led to substantial innovation in research collaboration and scholarly communication. The sense of urgency that has pervaded the world scientific community has generated amounts of data sharing and scientific research collaboration at levels that have never been seen before. It has been reported a speed-up of open early-stage research sharing, with a surge of depositions to such preprint archives as medRxiv and bioRxiv to foster large-scale early-stage research communication (Callaway, 2020).

The question of whether pandemic is disproportionately hurting the productivity of female scholars has been posed and empirically confirmed in different research disciplines and from different data sources: among Italian astronomy and astrophysics researchers (Deleidi et al., 2020); among neuro-immunologists (Ribarovska et al., 2021); among corresponding authors in medRxiv, but not in bioRxiv (Wehner, Li, & Nead, 2020); in the physical-sciences repository arXiv and, contrary to Wehner, Li and Nead (2020), in bioRxiv as well for the life sciences

(Frederickson, 2020); in 11 preprint repositories, expanding disciplinary coverage, and especially on COVID-19-related research (Vincent-Lamarre, Sugimoto, & Larivière, 2020). Also, early journal submission data suggest that COVID-19 is disproportionally plunging women's research production.[2]

Given that submission data are not publicly available, in the present study we recur to preprint repositories as data sources. In the past few years, there has been a significant uptake in posting preprint works in such repositories, to accelerate the diffusion of new knowledge. Considering this, and differently from other studies on the subject, we measure the variation in research production during the pandemic, by comparing research production in the pandemic period with the expected one, as extrapolated from the trends, rather than with that in previous period.

The paper unfolds as follows. In the next section we present methods and data. In the third section we present the results of the empirical analysis. The final section is devoted to the discussion and conclusions.

Data and methods

Initially, we have examined the appropriateness of a number of preprint archives to meet our objectives and methodology. We discarded all of them but arXiv or bioRxiv. The reason was that either they are too recent to be able to extrapolate the trends of posting, or the volume of preprints is too small to assure robust elaborations. arXiv is a free online archive and distribution service for unpublished preprints primarily for research in physics, astronomy and mathematics. bioRxiv is the equivalent in the life sciences. We finally chose bioRxiv as the only data source, because arXiv provides authors' affiliations of a very small share of preprints (around three percent), which makes it unsuitable for country-level analyses like the one we intend to conduct.

bioRxiv was launched in 2013 by Cold Spring Harbor Laboratory, a not-for-profit research and educational institution,[3] recently obtaining support by the Chan-Zuckerberg initiative (Callaway, 2017). First depositions occurred in November 2013.

Articles are not peer-reviewed before being posted online on this archive but undergo a basic screening process for checking non-scientific content and plagiarism. Generally, an article may be posted prior to, or concurrently with, submission to a journal so that the authors are able to make their findings immediately available to the scientific community and receive feedback on draft manuscripts.

Before the pandemic outbreak, very few bibliometric studies had used this platform as a data source. Tsunoda, Sun, Nishizawa, Liu and Amano (2019) investigated the evolution of a set of papers posted on bioRxiv and then published in academic journals. Among others, the authors found that only around 40 percent of 2013 - 2019 depositions are then published in peer-reviewed scientific journals. Fraser, Momeni, Mayr and Peters (2019) investigated the citation and altmetric advantage of depositing preprints to bioRxiv. Kenekayoro (2020) recently showed that although the platform is not yet mature enough for reliable analyses, the exponential growth in preprint depositions suggests that this data source will be soon a valuable resource for discovering interesting trends on emerging or dying research fronts.

To observe the effects of the COVID-19 pandemic and of the consequent containment measures on the production of novel scientific knowledge at a short temporal distance from its outbreak, biorXiv appears particularly appropriate. Even assuming editors' acceptance rates unchanged, the use of a traditional bibliometric platforms (such as Scopus, WoS, Google Scholar,

[2] https://www.insidehighered.com/news/2020/04/21/early-journal-submission-data-suggest-covid-19-tanking-womens-research-productivity, last accessed 25 January 2021

[3] https://www.biorxiv.org/about-biorxiv

Dimension or the like) would in fact require a longer time window considering the average publication time of an article in a journal, and its indexing in bibliographic repertories.

Moreover, bioRxiv provides free and unrestricted access to all preprints posted on the server. This applies also to machine analysis of the content. Metadata is made available via a number of dedicated RSS feeds and APIs resources. For the purpose of this research, we used a wget script for retrieving all publication metadata in XML format. Data extraction took place on 16 December 2020. After retrieving all XML files related to the original deposition (version 1)[4] of all preprints on the bioRxiv server, we implemented a parser in Python for extracting relevant information from each XML file. More in detail, we extracted: date of deposition, doi (record digital identifier in bioRxiv), author first names and last name, author position, corresponding author, institution name and country, and subject area.

Since the full set of processed XML files from bioRxiv is deposited each month with delivery completing typically in the first days of the subsequent month, we can be confident that the dataset contains all depositions up to 31 November 2020.

The full retrieved dataset is made of 106,050 preprints, showing a quadratic growth along years up to the 2020 pandemic: 77 depositions in 2013, 848 in 2014, 1704 in 2015, 4590 in 2016, 11191 in 2017, 20512 in 2018, 29018 in 2019, and 38110 in 2020. The overall distribution by bioRxiv subject area is shown in Table 1.

For the identification of the gender of each author we queried the “Gender API” platform[5] by the “first name”+”affiliation_country” pair. Since the level of standardization of bioRxiv retrieved data was not very high, some initial effort was needed for manually cleaning and reconciling fields, mainly for removing umlauts and other non-ASCII characters in first names as well as for reconciling country names.

Table 1. Share of total bioRxiv depositions by subject area

Subject area	Share	Subject area	Share
Neuroscience	17.8%	Immunology	3.2%
Bioinformatics	9.1%	Plant Biology	3.2%
Microbiology	9.0%	Developmental Biology	3.0%
Genomics	6.1%	Systems Biology	2.5%
Evolutionary Biology	5.9%	Bioengineering	2.4%
Cell Biology	5.2%	Animal Behavior and Cognition	1.5%
Genetics	4.9%	Physiology	1.4%
Biophysics	4.4%	Epidemiology	1.4%
Ecology	4.4%	Pharmacology and Toxicology	1.0%
Cancer Biology	3.6%	Synthetic Biology	0.9%
Molecular Biology	3.5%	Scientific Communication and Education	0.7%
Biochemistry	3.5%	Other	1.3%

Results

Spatiotemporal analysis of the pandemic impact

The bioRxiv monthly depositions in Figure 1 fit a quadratic trend up to the end of spring 2020,[6] with a peak in June 2020. After that, we observe an abrupt inversion of the curve, indicating a disruptive effect of the pandemic on research production.

[4] Authors can deposit a revised version of an article at any time prior to its formal acceptance by a journal.

[5] https://gender-api.com/ last accessed 25 January 2021

[6] The diagram shows the quarterly moving averages, to filter chance fluctuations.

To better appreciate the spatiotemporal dynamics of depositions before and after the pandemic outbreak, we stratify the data by geographical area. To start with, we identify the corresponding author of each preprint, the relevant affiliation and the corresponding geographical macro-area.

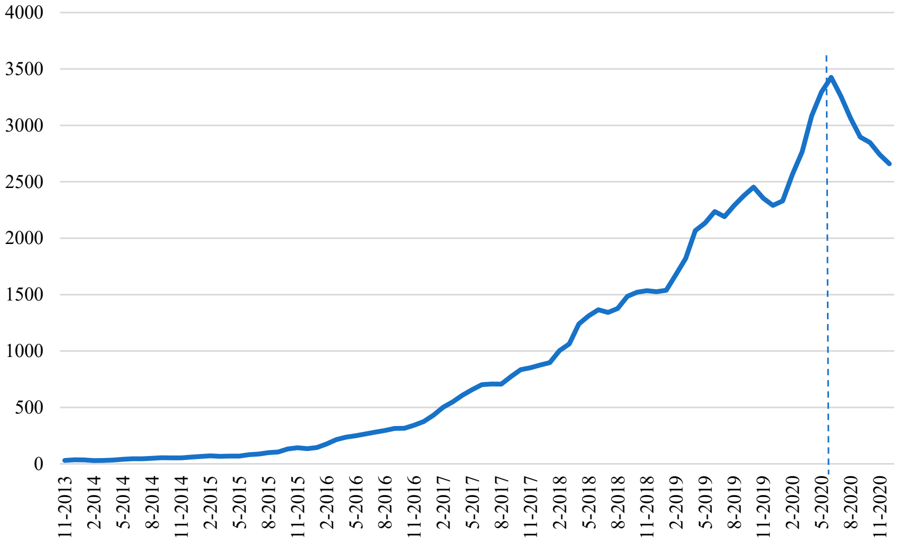

Figure 1. Time series of overall bioRxiv preprint depositions

Out of 106,050 preprints, 97,891 (92.3%) show at least one corresponding author (124,593 in total, as few publications have more than one). 101,647 corresponding authors (81.6% out of total) are provided with an affiliation[7], which can be unequivocally localized in a country and then in a geographical macro-area.

Figure 2 shows the plots of the time series depositions in three macro-areas: Europe, North America (including Canada, USA, and Greenland) and Far East (including China, Japan, Korea and Taiwan). The dot lines represent the quadratic interpolation of the yearly moving average, as measured from November 2013 to April 2020 for the Far East, and to June 2020 for Europe and North America. In order to better visualize the curve inversion in the last period, the plot starts from 2016.

The abrupt inversion of the trend is more noticeable in Europe and North America than in the Far East. The time series reflect the timing of pandemic outbreak in the different geographical areas, occurring first in the Far East but with relatively weaker effects.

It is important to notice that the average number of corresponding authors per preprint hardly changes after the pandemic outbreak (1.27 up to June 2020; 1.29 afterwards. Therefore, all trends observed with reference to the corresponding authorships remain valid for the preprints as well.

[7] Corresponding authors with multiple affiliations are counted multiple times (155,369 total affiliations).

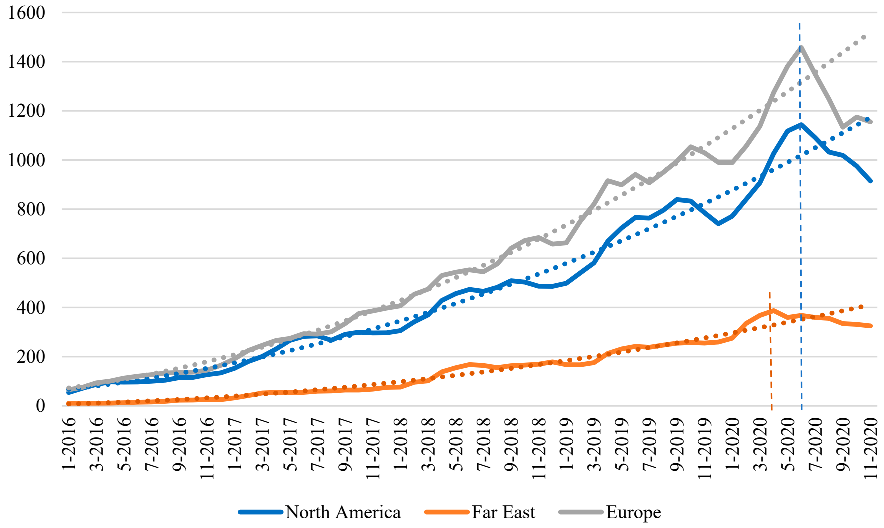

Figure 2. Time series of bioRxiv preprint depositions by macro area of the corresponding author (2016-2020 data)

Table 2 shows the percentage variations between observed and expected number of depositions in the period from September to November 2020.[8] The expected number of depositions is calculated as the product of the trend by the monthly seasonality coefficients derived from the time series.[9] We observe a drop in the number of depositions vìs-a-vìs the expected values of -17% at world level, with a maximum in Europe (-21%) and a minimum in the Far East (-8.8%).

Table 2. Observed and expected bioRxiv preprint depositions by macro-area of affiliation of the corresponding authors (September-November 2020 data)

	Observed	Expected	Variation	Confidence interval*
North America	2927	3356	-12.8%	[-9.1%;+15.5%]
Far East	994	1090	-8.8%	[-10.2%;+26.7%]
Europe	3523	4461	-21.0%	[-5.3%;+7.4%]
World	8543	10288	-17.0%	[-4.0%;+7.4%]

** Min and max monthly variations recorded for September-November 2014-2019 data*

The recorded variation is outside the confidence interval[10] at world level, for Europe and North America, but not for the Far East.

If we consider the first author in place of the corresponding author, we obtain the plot of Figure 3, showing a pattern similar to Figure 2, the only difference being the absolute values, because in a publication there is only one first author, but there could be more than one corresponding author.

[8] We chose this latest subperiod, because it is less affected by the inertia of depositions related to research projects started well in advance of the pandemic outbreak.

[9] With respect to the world level trend, every month presents average systematic variations, ranging from a minimum of -11.6% in December to a maximum of +5.5% in March in the overall period observed.

[10] Given by the min-max error of the estimate, i.e. the min-max variation between observed and expected values for September-November time series data.

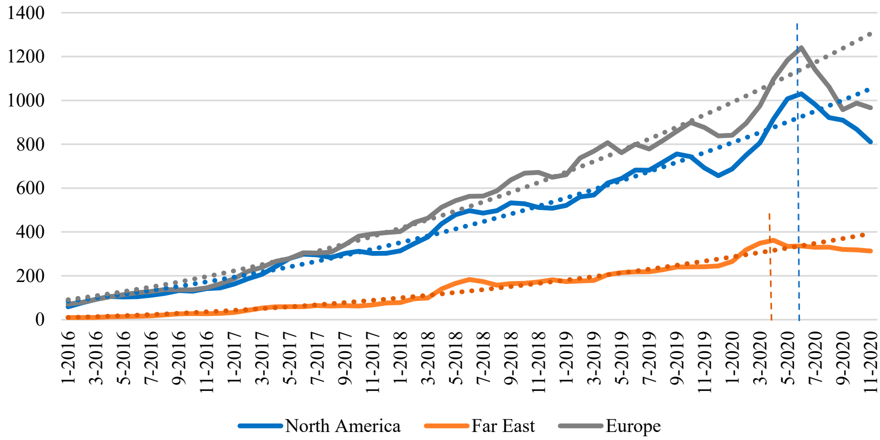

Figure 3. Time series of bioRxiv preprint depositions by macro-area of affiliation of the first author (2016-2020 data)

A gender analysis of COVID-19 impact on research production

We repeat the previous analysis further stratifying the dataset by country and gender. To discriminate gender, the first name of the author is needed alongside the country of affiliation. We discard all corresponding authors to which the Gender-API is not able to associate a gender with an accuracy equal or above 90 percent.[11] The dataset for this analysis consists of 77,156 corresponding authors, representing 61.8 percent of 24,593 total corresponding authors in bioRxiv, and 75.9 percent of those (101,647) are provided with an affiliation that can be unequivocally localized in a country.

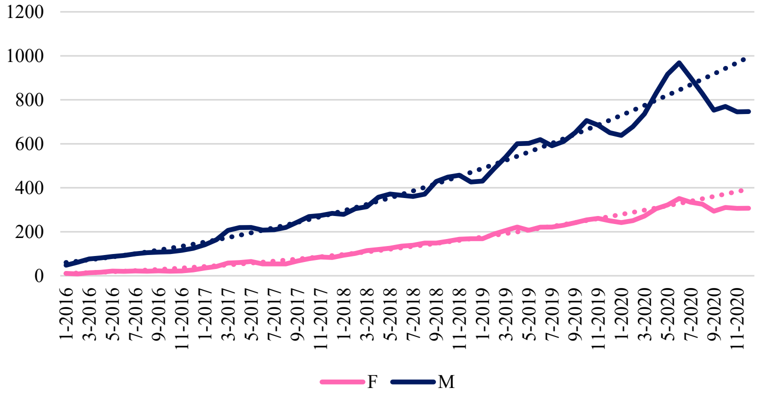

Figure 4. Time series of bioRxiv preprint depositions by gender of corresponding authors affiliated to European research organizations

[11] The authors are aware of the low accuracy of Gender_API in gender prediction of Asian and, in particular, Chinese names (Zhao & Kamareddine, 2018). However, it is the application of the threshold (90%) on the accuracy of the gender prediction to limit the extent of errors and distortion of results. In fact, 56.4% of Chinese corresponding authors have been assigned a gender and are included in the analysis as compared to 74.7% of the whole population.

Figures 4 to 6 show the time series for preprints posted by corresponding authors affiliated respectively to European, North American and Far Eastern research organizations. The reader should not be misled by the eye: when comparing the "expected" and "observed" curves around the pandemic outbreak, it seems that the plunge in production in Europe and in the Far East is much more severe for men than for women, while it is more or less the same in North America.

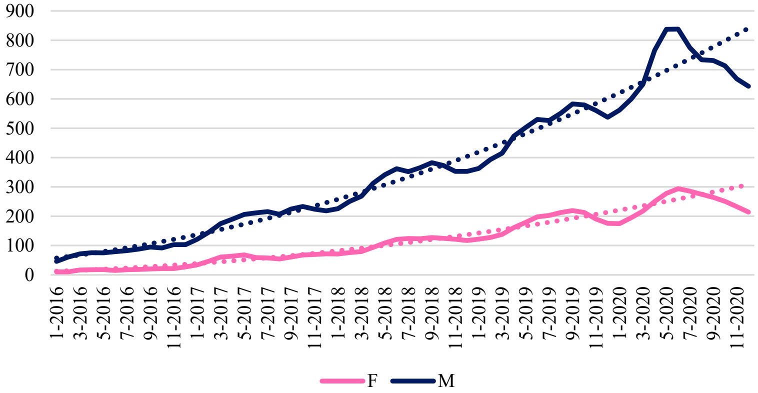

Figure 5. Time series of bioRxiv preprint depositions by gender of corresponding authors affiliated to North American research organizations

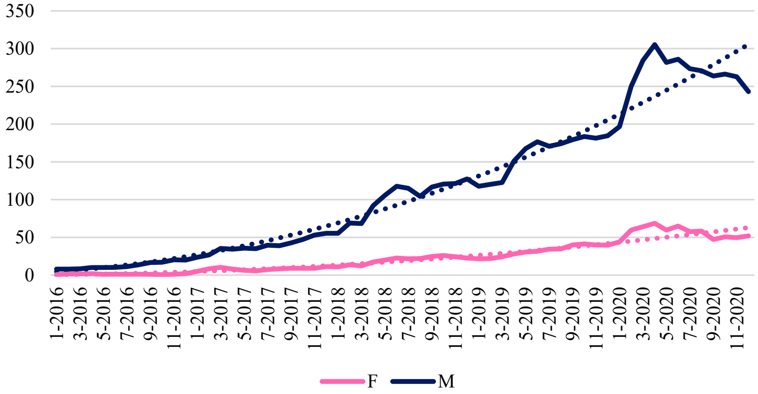

Figure 6. Time series of bioRxiv preprint depositions by gender of corresponding authors affiliated to Far East research organizations

A more in-depth analysis though, which takes into account also the seasonality of depositions, reveals that for North America (Table 3) the plunge in depositions is more conspicuous for women (-12.0%) than for men (-8.9%), similarly to the Far East (-6% vs +1.6%). In Europe instead, it is men who experienced a worse decrease in depositions (-18.8% vs -17.0%).

Table 3: Observed and expected bioRxiv preprint depositions by macro-area and gender of corresponding authors (September-November 2020 data)

	Gender	Observed	Expected	Variation
North America	F	752	855	-12.0%
	M	2139	2347	-8.9%
Far East	F	152	162	-6.0%
	M	799	786	+1.6%
Europe	F	931	1121	-17.0%
	M	2310	2845	-18.8%

We delve the analysis at country level considering the U.S., China, and the top eight European countries per number of depositions. Findings in Table 4 confirm the unbalance showed in Table 3 in the U.S., where female scientists reduced the output of their research activities at a higher rate than their male colleagues, -13.6% vs -9.3%. The same occurs in China, but to a less extent: -5.5% for females vs -3.0% for males. In Europe, contrasting evidences emerge. In France, Italy, Netherlands, and Switzerland it is women who are hurt more, while in Germany and Spain the opposite holds true. Quite surprisingly, in both countries female scientists raised their depositions with respect to the expected ones, respectively by 10 percent and 45 percent, while males decreased theirs by 15 percent and 9 percent. In Sweden and U.K., gender differences are hardly noticeable. It must be said that the more fine-grained the analysis the less robust the results, because of the lower number of observations. Nevertheless, what emerges at continental level is often untrue at country level, where the interplay of different containment measures, women's role in society, and family-related infrastructure unveil quite different realities.

Table 4: Observed and expected bioRxiv preprint depositions by gender of the corresponding authors in the U.S., China, and the top eight European countries per number of depositions (September-November 2020 data)

Country	Gender	Observed	Expected	Variation
United States	F	665	769	-13.6%
	M	1919	2117	-9.3%
China	F	111	117	-5.5%
	M	402	414	-3.0%
France	F	123	168	-26.6%
	M	276	344	-19.8%
Germany	F	199	181	+9.9%
	M	509	596	-14.6%
Italy	F	34	47	-28.4%
	M	98	110	-10.8%
Netherlands	F	39	60	-35.5%
	M	136	147	-7.3%
Spain	F	73	50	+45.4%
	M	127	140	-9.1%
Sweden	F	32	45	-28.5%
	M	64	92	-30.6%
Switzerland	F	47	65	-27.7%
	M	184	188	-2.1%
United Kingdom	F	214	309	-30.7%
	M	507	734	-31.0%

Conclusions

The human impacts of COVID-19 infections, and pandemic-related limitations and impediments are vast. These include disruptions to researchers that, as we showed, differ by nation and gender. In this work, we have investigated the impact of pandemic on research output. Results confirm what was expected that is a general plunge in preprint depositions, following the pandemic outbreak, consistent in timing across geographical areas: in China and the Far East first, in Europe and North America then. Probably, we will never see the consequences of the slowdown in scientific production caused by COVID-19 pandemic, in terms of published articles, as journal editors can simply raise their acceptance rates to keep the volumes unchanged. Most likely, we will witness lower average quality of publications. Evidence of that can be assessed in the years to come. Editors though might give now a precious contribution to scholars in the field by providing them with data on submission variations after the pandemic outbreak.

Contrary to what most people might expect, and early studies have announced, that female scientists are hurt more by pandemic due to the increase in family care workload, we could observe that this holds true at world level while significant exceptions occur at country level. The important lesson to be learnt is that world level analyses often hide significant differences across countries, especially when country-specific variables play a significant role in determining the outcomes.

Why gender differences occur across countries would require further investigation by scholars knowledgeable about the single country under observation. As for Italy, results are not surprising to us. In Italy women's relative share of involvement in family responsibilities, mainly care for children but also for parents and parents-in-law, is more extensive than in average EU countries. In Italy, for example, only 24 percent of the children go to kindergarten,[12] not allowing parents to be full-time occupied (Istat, 2019). Percent of population ages 65 and older (often associated with high levels of morbidity) is 24 in Italy, among the highest in the world (PRB, 2020). According to a recent survey, the majority of Italians totally agreed on the statement: "The most important role of a woman is to take care of her home and family" (EU, 2017).

Findings might be of interest to scholars in scientometrics, in the economics of innovation, and in sociology. The pandemic effects on research can inform policy makers when dealing with economic forecasts, gender equality issues, research evaluation exercises, and the assessment of the effectiveness of relevant policies and initiatives.

We appreciate several limitations embedded in our study. The field of analysis is limited to the life sciences, therefore findings and conclusions cannot be generalized to other disciplines. Data extraction was conducted during the pandemic, whose expiration is hopefully expected to occur in the next few months. Therefore, the extent of the effects that we tried to grasp is to be confirmed by future updates. It is the intention of the authors to extend the period of investigation to June 2021, in order to provide the ISSI conference participants with up-to-date and more robust findings. We also intend to extend the analysis to all authors of publications.

Finally, future research might entail investigation on the pandemic impact on research collaboration behaviour. It is to be expected in fact that intra-muros collaborations must have lost their advantage over extra-muros, as physical presence and personal contacts were inhibited by containment measures.

Abstract

Scientific collaboration within a research unit (team, laboratory, group, etc.) has caught scientometricians' attention. Science of team science recently emerged to use science to understand the best ways researchers are jointly organized to perform science in order to increase their performance as well as to suggest relevant strategies to support effective science teams. This paper contributes to this field of science by analyzing to which extent internal collaboration outputs of a research unit is influenced by its size, i.e. number of academics. Therefore, 120 accredited units composed of about 1,500 researchers located within four universities in Morocco are analyzed in this paper. A cross-matrix of members' co-publications is built for each unit. An index of intra-collaboration and an internal co-publication indicator are calculated to assess both size and internal research output at the unit's level. Furthermore, the Lorenz curve is being used to draw equality/inequality of the internal co-publication with respect to unit's size. The results indicate low internal co-publications for larger research units with an inequality in the distribution of these publications in favor of small size units.

Introduction

The analysis of scientific collaboration allows putting forward patterns, organizing modes, obstacles and opportunities for effective and impactful research at all levels of collaboration. Scientific collaboration represents a social component of modern science (Glanzel and Schubert, 2005; Wuchty et al., 2007; Milojevic, 2010). It is observed on several levels: micro (individual), meso (unit, institution, etc), and macro (national, international, field, etc). Since the publication of the first works by Hooke *et al.* in 1665 on the topic (see Beaver & Rosen, 1978), it is recently a matter of science of team science (Hall et al., 2018; Liu et al., 2020).

The complexity of team collaboration requires adopting appropriate tools to measure and evaluate targeted specific collaboration' facets. As pointed out by Glanzel and Schubert (2005) and Melin and Persson (1996), co-authorship is a particular outcome of collaboration. It can be used as a proxy to study collaboration. Persson et al. (2004), Wuchty et al. (2007) and Larivière et al. (2014), all found that co-authored publications were more frequently cited than sole publications, which results in increasing outputs' impact and quality. Furthermore, these co-publications have a positive impact on scientific productivity at the individual, institutional, and national levels, as well as on socio-economic partnerhips (Helga et al., 2009, Lebeau et al., 2008). This strong correlation is independent of the context (Lee and Bozeman, 2005, Haslam et al, 2008, Defazio et al, 2009, Abramo et al., 2011, Bouabid, 2014).

In this rich literature on scientific collaboration, the majority of studies is particularly oriented towards inter-institutional, international, national collaborations or in specific scientific disciplines (Kumar, 2015; Savic et al., 2015; Wuchty et al. 2007; Jones et al., 2008). Intra-institutional collaboration has also caught academic attention. In a comprehensive literature review by Kumar (2015), two such studies were conducted by Newman (2004) and by Pepe and Rodriguez (2010). Bellanca (2009), De Stefano et al. (2011) and Birnholtz et al. (2013) analyzed intra-institutional collaboration of the University of York (UK), University of Salerno (Italy), and two campuses of Cornell University (USA) respectively.

Besides addressing research performance at a micro-level as well as at a macro one, a number of researchers studied it at the meso-level: research unit or laboratory, as the first 'cell' for scientific collaboration. Indeed, the research unit is put forward as the basic unit for its role as a site of idea emergence, knowledge creation, diffusion and discovery (Bonaccorsi and Daraio, 2005; Carayol and Matt, 2004; Von Tunzelmann et al., 2003; Horta and Lacy, 2011).

All these works at research unit level as the one by Sandstrom and Van den Besselaar (2019) examined the effect of the unit size on the unit's whole output (papers), productivity and impact, without distinguishing internal co-publications. Partitioning the outputs to bring internal co-publications out is crucial because being formally organized together in a unit, members are supposed to team up for collaborative outputs. Indeed, as advocated by Sandstrom and Van den Besselaar (2019), the performance - productivity and citation impact - of a research group relies on its capacity to combine and use different competencies in a creative way.

Bringing out internal co-publications at the research unit is the first contribution of this paper, introducing in this regard a new quantitative method based on a purposely cross-matrix shaping internal co-authorship. Its second contribution is that it addresses intra-collaboration at a unit's level within the context of a developing country, which very few researches have dealt with. Indeed, except the research by Aparecido et Kannebley (2019) in Brazil - to the best of our knowledge - all the others were conducted in developed countries (Bonaccorsi et al. (2006) in an Italian context, Carayol and Matt (2006), in a French context, Cook et al. (2015), in a UK context, Sandstrom and Van den Besselaar (2019), in a European context, Brandt and Schubert (2013), in a German context, Verbree et al. (2015), in a Dutch context, De Saá-Pérez et al. (2017) and in a Spanish context. Shin et al. (2013) found that collaboration patterns differ across systems: researchers in developed countries are more collaborative than their peers in developing ones.

For greater performance and visibility of university research, the Ministry of Scientific Research in Morocco launched an initiative in 2006 for the structuration of the scientific landscape. This structuration constitutes the first milestone towards reaching critical unit size and then research performance. Thus, universities have adopted a common national platform that sets criteria for organizational research units: (i) *Team* of at least 3 professors, (ii) *Laboratory*, of at least 3 research teams or 9 professors, and (iii) a *Center* as a group of teams and laboratories. The process of structuration has allowed the transition to a more formal system where research units are necessarily accredited by the University Council based on prior-defined eligibility criteria. After at least two successive accreditations of four years each, does this initiative have a positive impact on intra-collaboration output?

Data and methods

This research analyzes the unit's intra-collaboration of academics being part of accredited research units after a four-year period following their accreditation cycle of the period 2008-2011. It covers the Faculties of Sciences (*FS*) performing research in the fields of science, technology, engineering and mathematics, within four Moroccan universities out of twelve[1]:

- Mohammed V University in Rabat (*UMV*) ;
- Ibn Tofail University in Kenitra (*UIT*) ;
- Mohammed First University in Oujda (*UMP*) ;
- Moulay Ismail University in Meknès (*UMI*).

The present research focuses only on *Laboratories* as research units, to which we refer later as unit, since the *Team* unit (an average of 3 academics in all institutions under study) is not large enough to allow an objective and rational analysis of intra-collaboration.

Our sample included these four universities composed of 120 research laboratories out of a total of 175, and 1,500 academics out of a total of 1,701, which accounted respectively for 36% and

[1] The three main criteria for this choice among other universities were age, size and geographical location.

33% of all universities in the field of science, technology, engineering and mathematics (see table 1). Moreover, these four universities count for 44% of the total PhD fellows at universities. Descriptive information is given in table 1 regarding the weights of the 4 universities in terms of the numbers of research units, academics (full professors), and PhD fellows.

Table 1: Number of research units, academics and PhD fellows in the 4 universities under this study, and in all universities with their evolution over a decade from 2009 to 2018. Values in parentheses indicate the share of the 4 universities out of all universities

		2009	2018	Change (18/09)

	Total	7,243 (38%)	12,600 (37%)	74 (%)

STEM: Science, Technology, Engineering and Mathematics, MED: Medical sciences, SSH: Social science and Humanities

In terms of disciplines, the fields of physics and environment were the most represented compared to other scientific fields (Figure 1). It is worth informing that all research units are mainly disciplinary-focused, with an organization more linked to departmental structures (which are teaching units) at the university, except for the environment' field.

After identifying the accredited units in the different disciplines, we proceeded to retrieving the name and surname of each academic in these laboratories. Then, we listed the academics' names in a particular manner in a matrix, which we call "intra-collaboration matrix", as shown in Figure 2. For example, for a unit with *n* academics, the intra-collaboration matrix is built by placing the academics' names in rows, from bottom to top, numbered from *1* to *n-1,* then crossing them by placing the academics' names this time in columns from left to right, academics' names starting by the n^{th} remaining academic and counting down to academic number *2*. The matrix allows crossing all unit's academics to plot their respective internal co-authored and sole papers. The intra-collaboration matrix is symmetrical.

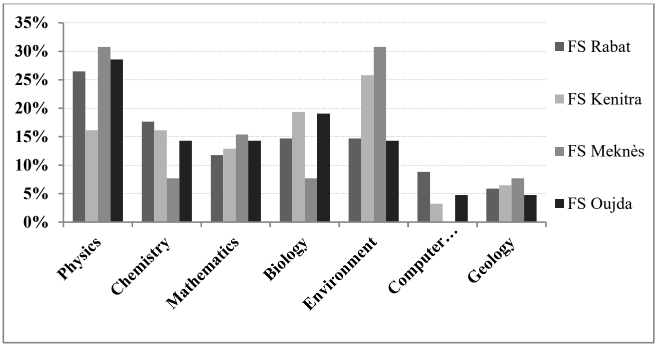

Figure 1: Distribution of accredited research units according to scientific disciplines

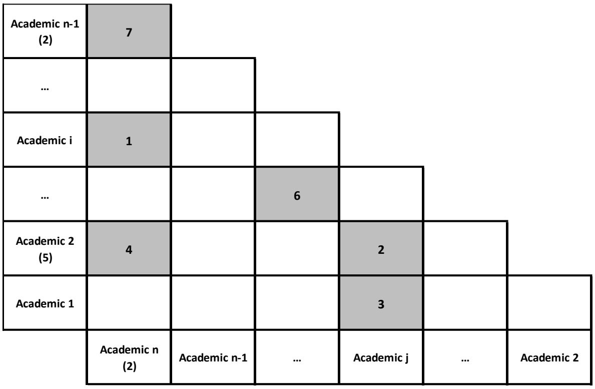
To read the matrix in figure 2, as an example, the academic *2* has 4 co-authored publications with academic *n* and 2 with academic *j*. The numbers between parentheses in the cells, in the left column and the lower row, refer to sole publications of the academics in the unit. A sole publication refers here to a publication made by an academic without any co-authoring with their unit members, which may be a single authored or a co-authored publication with a third party outside the unit. As an example, academic *2* has 5 publications alone without any co-authorship within her/his research unit, besides her/his 6 internal co-publications.



Academic n-1 (2)	7					
…						
Academic i	1					
…			6			
Academic 2 (5)	4			2		
Academic 1				3		
	Academic n (2)	Academic n-1	…	Academic j	…	Academic 2

Figure 2: Example of intra-collaboration matrix for a unit with *n* academics

In this matrix, gray cells represent the number of co-publications of the same unit and number of co-authors. As an example, the academic *2* has 2 co-authors (academic n and academic j), 6 co-authored publications and 5 soles papers.

This analysis uses all types of publication in the Web of Science database (Clarivate Analytics) over a four-year period after the accreditation cycle period of 2008-2011. The four-year timespan ensures the elimination of the yearly fluctuations in the publishing process. Each publication of the corpus had the affiliation of at least one of the studied institutions. The data was retrieved in a format with all the fields of the database records. After refining the raw data, the corpus is about 1,500 publications, containing the exact affiliations, names and surnames of the academics belonging to these research units. Out of which, 49.4% are internal co-publications and 50.6% are sole publications.

Results and discussion

Research unit size measure

To quantify the research unit size, we suggest the grouping index that refers to the average number of academics in a unit within a scientific field or an institution. This index is calculated for each institution (faculty) and for each field. It is defined as the sum of the number of academics per unit for all units, divided by the number of units in a given institution or a field:

$$I_g = \frac{\sum_{i=1}^{m} n_i}{m}$$

where m: number of research units in an institution or a scientific field,
$n_{i:}$ number of academics in unit i.

The grouping index values for the four institutions are reported in Table 2 with respect to each scientific field. It shows that the largest grouping occurred at the Faculty of Meknes with more than 14 academics per unit, reflecting a strong research collectivity. Small unit size (less than 10 academics per unit) is found at the faculty of Rabat (an average of 9.9), knowing that the threshold required for constituting an accredited unit is nine academics. Moreover, at the Faculty of Rabat, there is a significant gap between the minimum and the maximum values of the grouping index *Ig*.

Table 2: Average values of the grouping index *Ig* of academics by university

	FS Oujda			FS Rabat			FS Kenitra			FS Meknes			Mean
	Min	**Mean**	**Max**	**Min**	**Mean**	**Max**	**Min**	**Mean**	**Max**	**Min**	**Mean**	**Max**	**Field**
Physics	8	11.3	14	4	7.7	12	6	7.2	9	12	11.5	18	**9.1**
Mathematics & Computer Science	10	11.3	13	9	11.0	14	7	9.4	13	16	20.5	25	**11.7**
Geology	-	15	-	4	12.0	20	6	7.5	9	-	6.0	-	**10**
Chemistry	12	13.7	16	5	11.3	16	6	5.6	12	-	17.0	-	**10.3**
Biology & Environment	10	13.0	17	4	10.0	21	6	9.9	15	9	14.6	20	**11.2**
Mean		**12.4**			**9.9**			**8.5**			**14.1**		

Regarding the scientific fields, it can be noted that in the field of physics, academics are the least grouped ones, with an Index of about 9. On the contrary, mathematics and computer science is the field where academics tend to gather more in a research unit, irrespectively of the institution (almost 12 academics per unit).

Intra-collaboration measure

To explore the intra-collaboration outputs, we consider three indicators: (i) the intra-collaboration index, (ii) the number of cells with co-publications (cells in gray color in Figure 3) and finally, and (iii) the sum of the number of co-publications within these cells. Then, the Lorenz curve is used to depict both the last two indicators.

The index of intra-collaboration for each matrix is defined as the number of cells where there are co-publications (cells in gray color in Figure 4) divided by the number of cells in the upper (or lower) part of the matrix (without the diagonal). We only consider the upper or the lower part of the matrix because the co-publications matrix is always symmetrical.

In a mathematical form, we write this index as follows for the unit *i*:

$$I_i = \frac{c_i}{(n_i(n_i - 1))/2}$$

c_i: number of cells with co-publications,

n_i: number of academics in unit i.

This size-normalized index ranges from a value of *1* when all cells are in gray color, meaning that all academics have co-publications among them, i.e. full collaboration, and a value of *0* when there is no co-publication between the unit's academics, i.e. *"loneliness"*, as expressed by von Tunzelmann et al. (2003).

Figure 3 shows the intra-collaboration index according to the size of the research unit for all the studied units. We note that the intra-collaboration index is lower and decreases when the size increases. Some years later, the research structuration process of grouping more academics is not yet reaching collaborative publishing outputs. The reason is that achieving this goal requires that the unit goes through several stages in its life cycle, during which compatibility and interconnection at work, besides incentive and infrastructure, need to take place as key factors of collaboration (Hara et al., 2003). Yet, these stages require much time while the process of structuration is relatively recent. Enough time is also required to support strong individual relationships, which are found to allow the establishment of trust and contribute to a better transfer of information and ideas between researchers (Jha and Welch, 2010). Horta and Lacy (2011) have supported the evidence that greater intensity of communication between individuals and groups is a key factor for fostering creativeness and research results. Moreover, according to the survey conducted by Achachi et al (2016), the majority of researchers in a developing countries context stated that affinity is a fundamental vector to build and improve collaboration between them. This demonstrates that intra-collaboration does not immediately increase with unit size, but rather increases gradually with other factors such as relationship (affinity and compatibility), work methodology, writing style and interconnection at work, shared goals, incentives, etc.

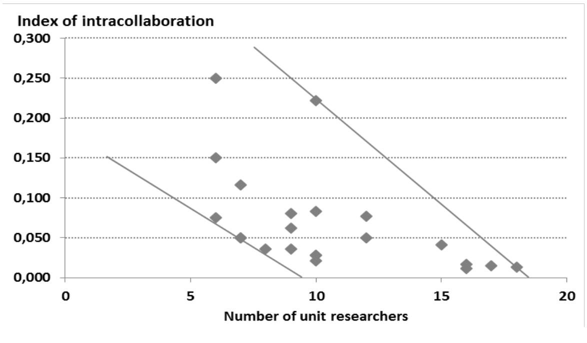


Figure 3: The intra-collaboration index with respect to the number of academics in the research units

Internal co-publications

To understand better this reverse evolution of the intra-collaboration according to the research unit size, the Lorenz curve is used to depict equality or inequality of the internal co-publications according to unit size. Figure 4 shows this relationship for all units by setting a threshold of three gray cells in the collaboration matrix to be represented. Both curves, of the number of gray cells and the total number of internal co-publications in these cells, illustrate clearly the inequality in the distribution of internal co-publications according to the size of the research unit. For total internal co-publications, 40% of the population in large-size units on average holds only 10 % of the internal co-publications (figure on the right). Nevertheless, 20% of the academics - all in small-size units - holds 50% of these papers (figure on the right). The inequality is higher when counting total internal co-publications than the number of gray cells. This finding corroborates previous empirical evidences in developed country contexts, that is size does not matter much for a unit performance (Von Tunzelmann, 2003). It may even have a negative effect on productivity regardless of the context (Qurashi, 1991, in an Indian context; Seglen and Aksnes, 2000, in a Norwegian context; Bonaccorsi et al., 2006, in an Italian context; Cook et al., 2015, in a UK context; Sandstrom and Van den Besselaar, 2019, in a European context). At best, productivity evolves in an inverted-U curve with size, up to an optimal size - between 5 and 9 members - then decreases again (Qurashi, 1993; Von Tunzelman et al., 2003; Verbree et al. 2015; De Saá-Pérez et al. 2017).

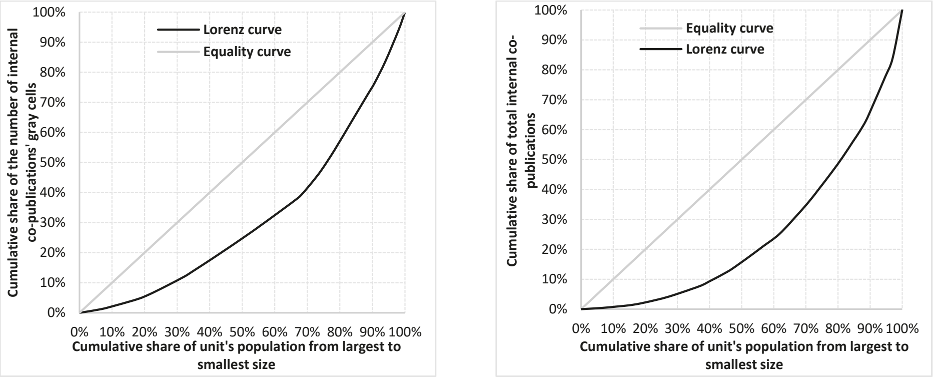

Figure 4: Distribution of Cumulative internal co-publications as a function of the cumulative unit's size (number of academics)

The observed low internal co-publication may also be because research units are built on a field specialization basis with mainly disciplinary focus. Indeed, all units under study were devoted to a specific scientific field, where unit members had similar specialization, called vertical specialization. While this scheme of unit organization seems to favor collaborative work among its members (Laudel, 2002), in the Moroccan context, it is likely supporting competitive attitude among them as they are working on the same - or almost the same - research topics. This competitive attitude is enhanced by the career promotion requirement. Perhaps, horizontal specialization, i.e. multi- or inter-disciplinary research activities, may be suitable for these research units to perform better. Indeed, Schubert (2014) put forward that "even if a certain specialization strategy is globally optimal, it does not need to be optimal for the individual research group".

Despite the academics grouping initiative implemented in universities since 2006, internal co-publications aren't found to increase with research unit's size. The main obstacles challenging research units are the lack of funding, common logistic support, 'teamwork' culture, visibility and impact of the academics' work. As a result, academics are likely to prefer other forms of collaboration, particularly international collaboration, that bring substantial funding and more recognition and visibility. The international collaboration is often developed through individual initiatives rather than formal and institutional policy or agreements (Bouabid 2017, in developing country; Bordons et al. 2013, in developed country). Likewise, Waast (2010) and Achachi et al. (2016) stated that international collaboration is preferred because it is seen to help in keeping the scientific level of researchers up-to-date, but also providing important financial support and scientific recognition.

Two other major factors appear as shortcomings to the internal unit's publishing are: (i) the lack of postdoctoral position in the university landscape and (ii) the teaching overload. With regard to the first shortcoming, academics at university in the Moroccan context are all full Professors, under three categories, from the highest: Professor of the Higher Education, Professor Habilitated for research (Associate Professor) and Assistant Professor. Postdoctoral position is not permitted by law at Moroccan universities, while this category of research personnel plays a key role in the research unit outputs (Carayol and Matt, 2006) besides both academics and PhD fellows. Furthermore, Horta and Lacy (2011) concluded that units' output is positively impacted by the type of its organization when including both academics, postdoctoral and PhD fellows, while it is negatively impacted when this organization is being limited to academics and doctoral fellows only. Cook et al. (2015) provided additional evidence that post-doctorates are more productive than PhD fellows and achieve more impact.

Regarding the second shortcoming, teaching duty, particularly in an undergraduate level, is found to reduce scientific outputs of academics. Units are typically multi-functional: mainly engaged in teaching and research activities. While Lepori et al. (2016) noticed a sort of balance of these two activities in most university units they studied, Horta et Lacy (2011) advocated that academics should be relieved from exclusively teaching undergraduates, since it negatively impacts their productivity. Expectedly, internal co-publications in Moroccan units, are low because the teaching duty is very high. Indeed, with a ratio of students to teaching staff in the faculties of science of 31.3 (and 54.5 at the whole university) in 2017, it is too far behind those of developed countries such as (in the same year): France (16.1), Germany (11.7), Italy (20.9), Netherlands (14.6), Portugal (14.7), Spain (11.7), USA (15.3).

Conclusion

This paper brings some evidence on the extent to which the research unit size at universities affects its scientific internal co-publications. These empirical findings support that in the Moroccan context - a developing country context, the policy initiative, which started recently, of grouping more academics into research units, doesn't yet result in higher collaborative outputs: internal co-publications. This finding is in line with several other researches in developed countries' contexts. Using Lorenz curve on internal co-publications, this paper demonstrates that internal co-publications are not in favor of large units, suggesting that this initiative does not seem yet to stimulate collective work resulting in co-publications. The grouping initiative is likely in its early stages to build real units, which are marked by favoring information exchange and communication between its members, but not reaching yet the upward stage of improving internal collaboration outputs. Since the formal institutional organization or research is so recent, the 'culture' of affinity, interconnection and individual relationship, are not well spread yet, and requires more time to become effective.

Since internal co-publications are found to be unequal with respect to the unit size, the science policy is asked to put forward other prerequisites to reach unit performance, such as invigorating the culture of 'teamwork' in the whole research landscape and to explore optimal unit size rather than simply extending it. Science policy towards university should be clear when it comes to research vs. educational orientation, which fundamentally governs the formal institutional organization and its performance in both research and teaching.

Abstract

Government investment in basic research is generally divided into two categories: funding to external organisations—such as universities—and funding to internal organizations. While an extensive body of literature has been devoted to universities' contribution of basic science, much less is known about that of governmental research centers. This paper analyzes the contribution of federally funded research and development centers (FFRDCs) to US science, with a focus on the contribution of the research & development laboratories (RDLs) to scholarly papers, scientific impact, disciplinary specialization and collaboration patters. Results show that these RDLs account for an increasing part of US papers—representing more than 25% of US papers in some specialties of physics—and that their relative impact is higher than that of average US papers. They are also found to vary substantially in their collaboration patterns, with percentages of international collaboration on publications from these organizations oscillating between 18% and 85%.

Introduction

Government investment in basic research produces benefits that counteract the forces that lead the private sector to underinvest in such research (Rosenberg, 2009). Governments differ in how they organize publicly funded scientific research. In general, this spending is divided between funding distributed to performers outside of the government, such as universities and private firms (i.e., extramural R&D), and funding to government research facilities (intramural R&D). National governments establish intramural research facilities, often termed "public research institutes" or PRIs, for a variety of reasons. Intarakumnerd and Goto (2018) assert that newly industrialized nations tend to establish PRIs to strengthen their national innovation systems and accelerate their pursuit of technological competitiveness, while developed nations use PRIs for a wider range of purposes. A significant motivation for creating and maintaining PRIs is to conduct research that would not normally be undertaken in industry or academia. Military research is a typical activity for many PRIs. National defense is provided almost uniquely by national governments. While some military research may be outsourced to industry and even to academia, extramural mechanisms may compromise secrecy and government influence over the direction and nature of the research performed. Another common activity of PRIs is fundamental, curiosity-driven research, especially when that research requires a significant investment in instrumentation and infrastructure. Universities and firms seldom have the incentive, resources, or expertise to maintain very large and specialized scientific instruments, such as radio telescopes and particle accelerators. Those facilities are operated commonly either by public agencies, or by extramural performers with significant funding and oversight from government.

Few studies of PRIs exist in the published literature. Recognizing this, the OECD launched a study in 1989 on government research laboratories, with a follow-up study conducted in 2011

(Sanz-Menéndez et al., 2011). In the United States, Bozeman and Crow (1998) published a series of examinations of federal government research laboratories. Cruz-Castro et al. (2020) and Zacharewicz et al. (2017) produced a series of scholarly works looking at organizational and managerial issues in public research organizations, and Hallonsten (2017) recently conducted a review of what he terms the "third sector of R&D" (encompassing government research laboratories but including non-governmental research institutes). This study focuses on a specific form of PRI in the United States: nationally owned research laboratories operated as federally funded research and development centers (FFRDCs). The FFRDC is an organizational form different from most PRIs in other nations. These institutions are typically formed and owned by the U.S. federal government, but operated by academic, industrial, and special-purpose entities under bespoke agreements with specific agencies (known as the FFRDC's "sponsor"). As a result, these PRIs straddle the boundary between intramural and extramural government laboratories. They retain the status of a governmental entity, but with many of the attributes of a non-governmental organization.

The United States spends more on research and development as a nation than any other country—estimated at $580 billion in 2018 (National Center for Science and Engineering Statistics, 2020). Of that amount, slightly below 10 percent is performed at federal government research organizations. The scale of the U.S. R&D enterprise accommodates a wide range of organizational types—especially forms of public-private partnerships. Since the 1980s, such partnerships grew more common as a mechanism for sharing and creating knowledge by leveraging the respective capabilities and perspectives of government agencies, universities, and private firms (Carayannis & Alexander, 1999; Carayannis et al., 2000). The FFRDC is an early example of this type of government-university-industry partnership. FFRDCs evolved from their origin in World War II to a significant part of the U.S. public R&D enterprise, accounting for approximately 36 percent of the research performed at federal facilities in 2018.There are three categories of FFRDCs: R&D Laboratories (RDLs), Study and Analysis Centers (SACs), and Systems Engineering and Integration Centers (SICs). Of those, (RDLs) are the major producers of multi-disciplinary scientific knowledge. Study and Analysis centers tend to produce technical reports that are highly tailored to the interests of their sponsoring government agencies, and less frequently produce more generalizable knowledge appropriate for publication in the scholarly literature. Systems Engineering and Integration centers conduct substantial applied research and develop new methods for system development and validation, but these projects are also designed to meet specific government needs. For this study, we focus on FFRDCs that are considered as R&D laboratories, as they have the workforce, facilities, and latitude to conduct quasi-academic research across the physical, social, and life sciences. This research in progress analyzes the place of FFRDCs in the US basic research landscape. We first assess the relative importance of FFRDCs in US science, from both the output and impact points of view. We then analyze their disciplinary specialization, as well as their collaboration patterns at the international level.

Methods

Data for this paper was obtained from the Web of Science (WOS) database, covering the Science Citation Index Expanded, the Social Sciences Citation Index, and the Arts and Humanities Citation Index, over the 1973-2018 period. The name variations of each 24 FFRDC analyzed were retrieved from the institution and department fields of the WOS, leading to a conversion table of 195 name variations at the level of institutions and 7,919 at the level of departments.[1] Using this conversion table, we retrieved 441,636 distinct papers (articles, notes and reviews), and 484,447 FFRDC-paper combinations (including multiple counts of papers in case of collaboration between FFRDCs). Each paper was assigned the subfield of the journal in which it is published according to the NSF field and subfield classification of journals (Hamilton, 2003), and this classification scheme was used for the field-normalization of their number of citations (Waltman et al., 2011). Full counting of papers was used and networks were created with UCINET and Netdraw.

Results

Over the 1980-2018 period, the RDLs contributed to 410,699 papers, representing 3.7 percent of all papers with a US address. This percentage has been rising thoroughly over the period, from 3.4 percent in the 1980s to 3.9% in the 2010s, even as the share of FFRDC performance of US basic research (measured by funding amount) declined from 13% in the 1980s to 5.7% in the 2010s (NCSES, 2021). RDLs vary in output, however. Four laboratories have contributed to more than 1000 papers per year on average over the last four decades: Lawrence Berkeley National Laboratory (58,872 papers), Los Alamos National Laboratory (54,209 papers), Oak Ridge National Laboratory (48,812 papers) and Argonne National Laboratory (43,911 papers). At the other end of the spectrum, others have not been as active in basic research, such as the Software Engineering Institute (33 papers retrieved) and the Center for Advanced Aviation System Development (3 papers retrieved). On average, RDLs have contributed to more than 18,000 papers throughout the period. The scientific impact (average of relative citations) of RDLs is also above the world average as well as the US average. In the 2010 decade, RDL papers have, on average, been cited twice as much as the average papers of the disciplines in which they published. The lead RDL in this regard is Sandia National Laboratories, a FFRDC sponsored by the Department of Energy’s National Nuclear Security Administration. Despite its status as a RDL focused on weapons research, Sandia illustrates the significance of basic research in supporting its sponsor’s mission (National Research Council, 2013). We also observe that the average impact of RDLs and of US papers are going in opposite directions: while that of RDLs is increasing slightly, US papers are, on average, less and less cited, from 52% above world average in the 1980s to 34% in the 2010s. The contribution of RDLs to basic research varies by domain. There are 17 specialties, however, in which they globally account for more than 10 percent of all US papers over the 2010-2018 period (Figure 1). Their contribution is remarkable in Nuclear Technology, Nuclear and Particle Physics and Solid State Physics, where they participated to 42, 31 and 25 percent, respectively, of all US papers published during the period. Other areas with an important relative contribution to US science are related to earth and space science, as well as other areas of applied physics, chemistry and engineering. The disciplinary specialization varies by RDLs, however (Figure 2). While most RDLs are active in specialities of Physics, Chemistry and Engineering and drive the aggregated trends observed in Figure 1, we observe that the Frederick National Lab for Cancer Research is, unsurprisingly, active in various fields of health sciences, and that the Software Engineering Institute is focusing on Computers. Similarly, the National Center for Atmospheric Research and the National Solar Observatory are focusing on Meteorology and Atmospheric Sciences.

[1] The cleaning of the Software Engineering Institute (SEI), however, proved to be more difficult. This FFRDC is based at Carnegie Mellon University, and researchers from the Institute often sign the name of the University without indicating their affiliation to SEI. Therefore, our results from SEI underestimate its contribution to basic research.

Table 1. Number of papers and average of relative citations of RDL FFRDCs, by decade, 1980-2018.

FFRDC	Number of papers				Average of relative citations			
	1980s	1990s	2000s	2010s	1980s	1990s	2000s	2010s

Figure 2. Network of specialization between RDLs and specialties, for specialties that represent at least 2% of a FFRDC's total papers, 2010-2018.

RDLs exhibit strong differences in their international collaboration patterns (Table 2). While the vast majority of papers from astronomical observatories are in international collaboration, this percentage is much lower for large facilities such as Lawrence Berkeley National Laboratory, Oak Ridge National Laboratory, and Argonne National Laboratory, and even lower in the cases of Lincoln Laboratory and Savanah River National Laboratory. The main international collaborator is also varying by laboratory, with Germany and China being the main collaborators of 9 and 8 laboratories, respectively.

Table 2. Percentage of papers in international collaboration and main international collaborator, by RDL, 2010-2018.

FFRDC	Top internat. collaborator	% of papers in internat. collaboration
National Radio Astronomy Observatory	Germany	84.6%
National Optical Astronomy Observatory	Germany	78.7%
Fermi National Accelerator Laboratory	UK	75.6%
SLAC National Accelerator Laboratory	Germany	70.6%
Thomas Jefferson National Accelerator Facility	Italy	64.6%
National Solar Observatory	Germany	63.0%
Jet Propulsion Laboratory	France	60.7%
Brookhaven National Laboratory	China	59.1%
Lawrence Berkeley National Laboratory	Germany	57.1%
National Center for Atmospheric Research	UK	56.5%
Argonne National Laboratory	China	54.3%
Lawrence Livermore National Laboratory	Germany	47.5%
Princeton Plasma Physics Laboratory	China	47.3%
Los Alamos National Laboratory	Germany	45.9%
Oak Ridge National Laboratory	China	45.5%
Ames Laboratory	China	45.0%
Frederick National Laboratory for Cancer Res.	China	43.1%
Pacific Northwest National Laboratory	China	37.7%
National Renewable Energy Laboratory	China	31.6%
Idaho National Laboratory	France	25.7%
Sandia National Laboratories	Germany	24.4%
Lincoln Laboratory	Germany	18.8%
Savannah River National Laboratory	Japan	17.8%

Conclusion

The contribution of RDLs to basic research in the US is sizeable and increasing. Results show that RDLs account for an increasing part of US papers—representing more than 25% of US papers in some specialties of physics—and that their relative impact is higher than that of average US papers. They are at the heart of research in nuclear physics, and contributing in an important fashion to several disciplines of earth and space sciences. Despite their strong US national component—their research focus can be considered to be of strategic importance for the country—an increasingly large proportion of their papers is co-authored with international colleagues, and Germany and China represent the largest collaborators. RDLs vary dramatically in their collaboration patterns, with percentages of international collaboration oscillating between 18% and 85%. On the whole, this research in progress paper shows that the RDL FFRDCs, which often host unique scientific instruments, have an important contribution to US science, and complement research performed in universities and industrial research centers. Further research will investigate the national and international collaboration networks of RDLs, their citation linkages—the organizations cited in RDL publications, and the organizations that cite RDL work—and the relationship between their scientific activities and the funding and priorities of their sponsoring agencies.

Abstract

This research in progress analyses the scientific output of the beneficiaries of one of the most important post-doc mobility programmes in Spain, the José Castillejo call. This research has two main objectives: a) to analyse the volume of international collaboration with the host countries at the medium and long term and b) to test the hypothesis stating that articles written in collaboration with the host countries present greater scientific impact (in terms of citations per document) than those not signed in collaboration. For the period 2009-2017, we retrieved the data on the beneficiaries of the programme and identified their publication set in Web of Science Core Collection (using ORCID codes as input data), obtaining 17,182 registers. A set of regular expressions using the statistical software R allowed us to attribute the output to the beneficiaries with an accuracy rate of 91.58%. The analysis concludes that there are statistically significant differences in citations per document, which favour documents in collaboration. We also find that collaborations persist far beyond the medium term. Several further research issues derived from the initial results are also detailed in this contribution.

Introduction

Scholars' mobility has been largely studied in academic literature (Czaika and Orazbayev, 2018; Kim, 2017; Pheralli, 2011). However, the individual effect of mobility among scholars is yet to be examined. Recent works have evidenced its beneficial effects in terms of scientific performance, including the creation of social and professional networks, improving their scientific production and impact, and foster their prestige (Aksnes et al, 2013; Fanfmeng 2016; Horta, Jung & Santos, 2019, Su, 2011). Still, these results have only been proven for very specific populations and countries. While mobility among Spanish scholars has been addressed in previous literature (De Filippo, Sanz & Gomez, 2009), the impact of government mobility programmes is still understudied. In some countries, talent and government mobility programmes have been proven to have a positive effect on the beneficiaries' careers and research outputs (Liu, Wang & Xu, 2020). This paper (work-in-progress) provides preliminary results of the impact of Spanish governmental mobility programmes in the scientific performance of its beneficiaries, both during the mobility period and afterwards.

For this purpose, we study the scientific production of all the beneficiaries of two public mobility grants: postdoctoral mobility in foreign centres" programme and the "José Castillejo grant for mobility in foreign centres", which together cover the 2009-2017 period. Although the positive effects of these two programmes are manifest for academic career progression in the Spanish system –mobility is one of the criteria of Spanish University System Quality Observatory of the National Agency for Quality Assessment and Accreditation for progressing as an academic or researcher–, the material results of the mobilities have been overlooked. The beneficiaries of the mobility programmes have the opportunity to spend between 3 and 6 months in a foreign University. Prior literature suggests that this opportunity would lead to international collaboration, and higher citation rates and productivity (Aksnes et al, 2013; Su, 2011).

This preliminary study examines the beneficiaries' academic performance during and after the research visit. We use the beneficiaries' production in the Web of Science (WoS) and name disambiguation techniques to attribute each WoS' document to its author. Author disambiguation has been and still is an evolving field in bibliometric studies (Smalheiser & Torvik, 2009; Ferreira, Gonçalves & Laender, 2012; D'Angelo & Van Eck, 2020). The approach of this paper is to classify WoS' documents taking only the affiliation value without using any other information of the metadata such as the author's email, cited references, or other papers' metadata. Inspired by Torvik (2015), we create a name variations dictionary of each beneficiary using automated methods and apply it to the affiliation value of the downloaded WoS' documents.

Preliminary results shown here do not attempt to perform a full analysis of the grants' beneficiaries' performance against no beneficiaries, but to examine patterns among beneficiaries themselves. We find that the percentage of collaboration between the beneficiaries and their countries of destiny is lower than expected, but the impact (measured in citations) of those who have mobility collaborations is indeed higher than the impact of beneficiaries who do not collaborate with their destination country. Production differences have not been found between the two groups.

Data and methods

Data

The data utilized in this analysis were obtained from the web of the Spanish Ministry of Science and Innovation. In particular, the data corresponds to the beneficiaries of the two consecutive mobility programmes: the "postdoctoral mobility in foreign centres" programme, which covers the period 2009-2010; and the "José Castillejo grant for mobility in foreign centres", covering the 2011-2017 period –except for 2013 as the grant was cancelled for that year. Information on the names of the beneficiaries, the resolution year, the start and end date of the mobility period and the country of destination were extracted in DF(Data File)1.In total, grants were given to 1763 beneficiaries in the period 2009-2017.

The ORCIDs were collected for each beneficiary through a semi-automatic procedure and inputted in the Web of Science. Only articles available at the WoS' Core Collection SSCI, SCI and A&HCI sub-databases were retrieved. The results' metadata on WoS's unique identifier of the article, affiliation, publication date and year were downloaded for a total of 17182 documents and saved as DF2.

Pre-processing and regular expressions

Beneficiaries' names from resolutions and affiliation values from the WoS' metadata were converted to ASCII. The names' string was converted to title case and variables were generated for the complete, first and second name, first and second surname, and the initial of the first name. These variables were added to DF.1.

The names of the beneficiaries were identified from the affiliation value of the downloaded WoS' metadata. For this purpose, the names of the authors of each paper were extracted from the affiliations' strings. An intermediate table was created for the classification in which each document was represented in a different row, and the authors of each article were separated in individual columns. This table was called DF2.b.

Regular expressions were constructed from authors' name variants. In total, we used seven regular expressions and they were applied in the following order, which has been designed to minimize the error:

1. Surname1.*Name_complete.*
2. Surname1.*Name1.*
3. Surname1.*Name2.*
4. Surname1.*Surname2.*
5. Surname1.*Name1_initial.*
6. Surname2.*Name1.*
7. Surname2.*Name2

Affiliation extraction

The regex were applied to DF2.b so the row and the column of the match was identified for each document. The full process was as follows:

1. One loop was generated for each year of the grant to minimize errors and mismatching.
2. For each loop, all regex were applied in the order described above.
3. Each matched regex was coded in DF2.b. For articles that only had one match –more than one match could be generated by co-authorship, but more usually by very common names and surnames in articles with many authors–, two columns were generated: one with the beneficiary's name as in DF.1, and one with the regex that obtained the match.
4. No-matched documents or documents with more than one match were passed to the next regex and looped again.
5. Finally, the loop generated one database with all matched documents (DF3).

Figure I shows the percentage of documents that were classified with this process by year. The larger numbers for the last years might be due errors in the ORCID search procedure. Overall, ORCID codes were estimated to match the subjects in 92% of the cases (using a 95% confidence level and a confidence interval of 10). With the regex method, we estimated an accuracy rate of 91.58% in the classification with the same parameters used for the estimation of ORCID search procedure.

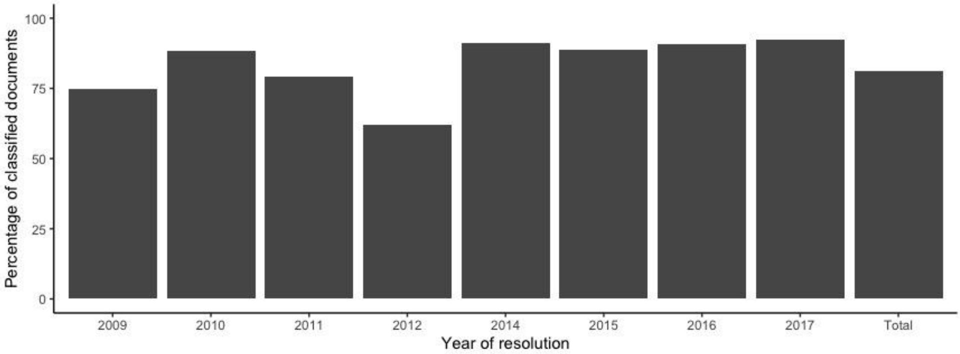

Figure I. Percentage of classified WoS' documents by year and in total.

Identification of production associated with the mobility programme.

The production associated with the mobility programme of each beneficiary was identified using a geographical and a temporal criterion. First, we identified the articles that were written in collaboration with researchers from their destination country using a country dictionary on the affiliations' column of DF3. An important assumption of this step is that articles written in collaboration with researchers from the destination country are likely to have been written during the mobility period or as a result of the collaboration networks developed then.

Secondly, we used the temporal criteria developed in Björk and Solomon (2013) to identify the articles that are more likely to be written during the mobility period considering publishing delay times. Björk and Solomon conclude that the mean period between an article is sent to a journal and published are twelve months (with a standard deviation of 7 months). We calculate two periods. The first approach considers all articles published five months after the start of the mobility in collaboration with researchers from the destination country to evaluate the evolution of the collaborations and the continuity of the networks created. The second method includes all collaboration articles identified before that have been published between five months after the start of the mobility and 19 months after the end of the mobility. This more restricted approach intends to determine the production strictly written during the mobility period. These two approaches will be referred to as Björk and full period respectively.

Results

As can be observed in Figure II, there is an observable decrease in the average percentage of documents in collaboration for the full period. While considering only documents published in the medium term, the collaboration is more stable across concession years.

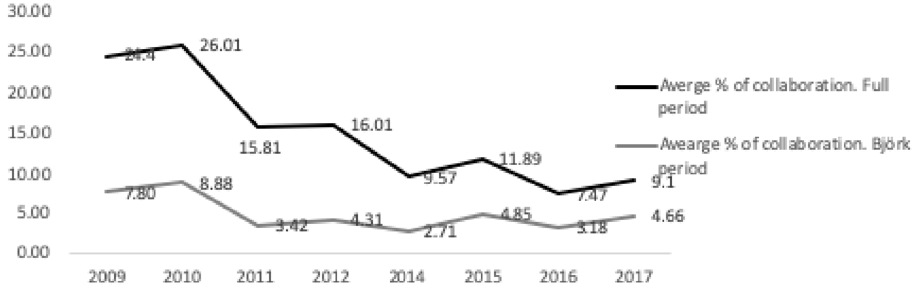

Figure II. Average percentages of collaboration. Full period and medium term

By country, there is an observable shift in the percentages of articles in collaboration. The researchers who made their stays in France, the US and the UK present a strong decrease in the overall percentage of articles in collaboration. Stays in Switzerland, Australia and Portugal are associated, by the opposite, with a growth in the percentages of articles signed in collaboration.

Table I. Compound Annual Growth Rate for the percentages of collaboration (2009-2019 Year of awarded grant).

Country	*N. Docs.*	*Compound Annual Growth Rate (Collaboration %)*
France	1106	-25,69
USA	3954	-23,18
United Kingdom	2767	-12,84
Germany	686	-11,34
Canada	377	-10,63
Netherlands	512	-4,5
Italy	738	-1,01
Switzerland	441	3,26
Australia	564	8,94
Portugal	662	9,58

Removing the documents signed by the researchers when they are affiliated to the stay organization and using values per year, the documents in collaboration (with their host country) present a greater volume of citations than the articles not signed in collaboration. These differences are statistically significant both in the medium and long term (Björk period and full period). The Kolmogorov-Smirnov test shows that the distribution of citations per document are normally distributed across years (Björk period, collaboration [Z=.614; p=.845] Björk period, not in collaboration [Z=.696; p=.717]; full period, collaboration [Z=.653; p=787], full period, not in collaboration [Z=.407; p=.996]). Given the number of authors is very similar each year, we used paired T-test for contrasting the hypothesis that the citations per document are the same for the two groups (articles in collaboration and not in collaboration with the stay country). Citations per document in the Björk period were significantly greater for the articles signed in collaboration (M=40.48; SD=28.37) than for the articles not signed in collaboration (M=19.58; SD=9.58), p=0.025. Citations per document in the full period were significantly greater for the articles signed in collaboration (M=38.96; SD=21.77) than for the articles not signed in collaboration (M=17.45; SD=9.3), p=0.003.

Table II. Citations per document by year. Björk period.

Publication year (Björk period)	*Citations per document collaboration*	*Citations per document NOT in collaboration*
2012	61.73	29.25
2013	52.31	29.05
2014	51.77	27.68
2015	91.01	25.93
2016	24.19	17.05
2017	19.23	12.64
2018	12.66	9.58
2019	10.94	5.46

Table III. Citations per document by year. Full period.

Publication year (full period)	*Citations per document collaboration*	*Citations per document NOT in collaboration*
2012	61.73	29.25
2013	52.37	28.24
2014	56.53	23.21
2015	62.77	20.89
2016	31.81	14.2
2017	20.74	11.27
2018	14.34	8.46
2019	11.44	4.15

Conclusions and discussion

The analysis shows the average of collaborations for the Björk period is low but stable, which means there have been surprisingly few collaborations between the beneficiaries and researchers form the destination countries in all grant resolutions for the this more restrictive period. However, collaborations for the full period show a very different pattern. The higher numbers for the first resolution years show that a considerable number of researchers participating in the research stays show long-term research collaboration with researchers from their host countries.

The documents signed in collaboration, both in the medium and long terms present significantly more scientific impact, measured in citations per document, than the documents not signed in collaboration. Assuming that such collaborations are the one of the stay's outcomes, it can be inferred that the programme is somewhat successful in terms of increasing the impact of the beneficiaries, at least when they engage with scholars from the countries they are visiting.

Despite the clear evidence showing that articles in collaboration show greater citation values, the percentage of articles in collaboration present a steep, linear decrease by award year.

The data analyzed in this study does not allow to conclude any plausible hypothesis but the phenomenon ought to be further studied, since it diminishes the effectiveness of the programme in terms of both collaboration and impact. The slow but noticeable decrease in the percentages of collaboration of the researchers choosing a research organization in France, the UK or the US might be related to a shift in research areas, but this phenomenon together with the increase in the percentage of collaborations in the case of Switzerland, Australia and Portugal might require further research for understanding its causes.

Next steps of this study will also benefit from comparing the results presented here with the analysis of academic performance indicators of researchers that have not been awarded with a mobility grant to address the relative impact of governmental mobility programmes in Spain.

Abstract

In this paper we extend the flexibility of a visual analytic approach featured to performance model's development to include data quality procedures and tests. The resulting environment is helpful to guide the user to an Information Quality-aware development of Performance models. This interactive visual analytics environment offers to the user the possibility to produce and compare information quality-aware indicators.

1. Introduction and background

In the last decade, the rapid increase in the production, communication and evaluation of research have been signs of a transformation. This transformation has changed also the way we conceive and measure performance indicators. Generally speaking, performance is the result (outcome) obtained by an activity and indicators are results of mathematical operations with data. When indicators are used in an evaluation process, they are called metrics. The definition and measurement of performance indicators require the formulation of a performance model., i.e., the description of the conceptual, methodological and data dimensions capable to assess the outcome of given activities of the units under analysis, with respect to some predefined goals. An example of performance model can be an efficient frontier model that describes how well universities produce their scientific and teaching outputs with respect to inputs and other factors (i.e., including staff, public and private funding, and so on).

Despite the various innovations introduced with big data, machine learning and altmetrics, the role of the *user* of metrics, and her interactions in the development and evaluation phase of performance models have not received the great attention they deserve. In addition, important aspects for the usability of data and information, such as the different dimensions of *data and information quality*, have frequently been overlooked, making the developed performance measurement systems rigid, fragile and inconsistent.

Koltay (2016), discussing data quality and research data management, shows that data governance and data literacy are two important constituents to keep into account when developing a knowledge base. “Applying data governance to research data management processes and data literacy education helps in delineating decision domains and defining accountability for decision making. Adopting data governance is advantageous, because it is a service based on standardized, repeatable processes and is designed to enable the transparency of data-related processes and cost reduction. It is also useful, because it refers to rules, policies, standards; decision rights; accountabilities and methods of enforcement. Therefore, although it received more attention in corporate settings and some of the skills related to it are already possessed by librarians, knowledge on data governance is foundational for research data services, especially as it appears on all levels of research data services, and is applicable to big data (Koltay, 2016, p. 303).” Soylu et al. (2017, 2018) describe the added value of visual methods combined with ontology-based data management for query formulation and for making querying independent of users' technical skills and the knowledge of the underlying textual query language and the structure of data. Daraio et al. (2016) show the benefits of an ontology-based data integration approach for data quality in an open environment. Angelini et al. (2020) present the advantages of Visual Analytics for the development of performance models. In this paper we make a step further and extend the flexibility of a visual analytic approach featured to performance model's development to include data quality procedures and tests.

2. Related work

This paper is an extension of a previously published work by the authors (Angelini et al. 2020) that focused on supporting the development of Performance Models through Visual Analytics. Analyzing and steering Data Quality in analytical processes are very relevant activities in computer science and data analysis, where many automatic tools exist that support, to different degree, those tasks. A recent work by Ehrlinger at al. (2019) surveys 667 software tools dedicated to data quality. Among other considerations, the authors report on the large heterogeneity of the tools, with more than half of them working on proprietary solutions, and most of them lacking implementation of important Data Quality dimensions identified in the literature, or not supporting comparability due to the way in which metrics are defined. Interestingly, the authors report a very low presence of visual support for data quality analysis, with existing works focusing more on usability criteria than on supporting the analysis process. Our proposal goes into this direction, to fill this existing gap in the literature.

Few previous works exist that have explored the use of Visualization and Visual Analytics to conduct Data Quality analysis, in particular for supporting the evaluation of research activities. One of the first works is Rajmonda et al. (2005). They present a tool for visual representation of Data Quality called DaVis. DaVis uses a tabular visual representation to show a dataset, highlights inaccuracies and invalid data, and shows difference between versions of a dataset. However, it focuses only on the visual representation and not on providing further analyses lead by visual interactions. Kandel et al. (2012) propose Profiler, a visual analysis tool for assessing data quality issues. Profiler applies data mining methods to flag problematic data and assess the data in context by automatically suggesting a multiple coordinated visualizations environment. The tool is targeted only at tabular data and it still focuses on providing the best visual evidence of problems in the quality of data.

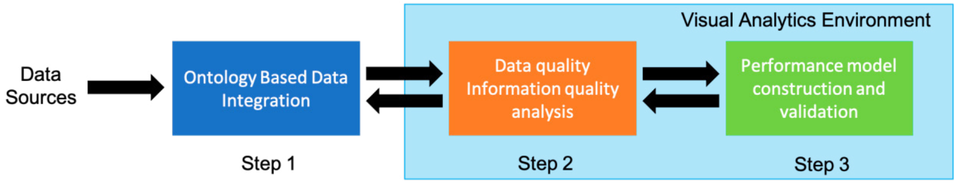
Moving to Visual Analytics approaches, Liu et al. (2018) offer a literature review on Visual Analytics for Data Quality activities, and a framework for conducting data cleansing on four data types (multimedia, text, trajectories and graphs). Gschwandtner et al. (2014) propose a solution for data cleansing of time-oriented data, providing semi-automatic quality checks, visualizations, and directly editable data tables. However, the authors specifically target time-series and do not target the evaluation of research activities. Finally, Bors et al. (2018) present Metrics-Doc, a visual analytic solution for assessing Data Quality that provides customizable, reusable quality metrics in combination with immediate visual feedback. This solution allows for defining specific quality metrics directly into the system (using OpenRefine syntax) and test and identify data quality violations and distribution.

We highlight, as a differentiating point with respect to these approaches, that our proposal is expressively aimed to the evaluation of educational and research activities, considering their specific indicators and semantics that govern this domain. At the same time, our approach shares similar goal in inserting Data Quality features for supporting performance models development.

Daraio et al. (2020) developed a Data Quality approach featured on higher educational data, that may be integrated with research data and other heterogeneous sources through *Sapientia*, the Ontology of Multidimensional Research Assessment. This is what we are implementing in ongoing research.

3. Aim and contribution

This paper exploits Visual Analytics, “the science of analytical reasoning facilitated by interactive visual interfaces” (Cook and Thomas, 2005), focusing on the Data Quality analysis of the measures, indicators, scores that will be used by the analyst as a base for creating and developing a performance model. In this respect, this phase is very important, given the heterogeneity of data sources, the different formats that can still convey similar semantic, and the importance that features selection can have on the definition of a performance model.
Angelini et al. (2020) provide a workflow for a dynamic creating and assessment of a performance model for evaluating research activities. This workflow is based on an ontological modelling of the data sources, instantiated in the *Sapientia* ontology, that align semantically the contents coming from different sources (e.g., Eter, Scopus, Wos and so on). From this step, the Visual Analytics Environment built allows the data exploration and builds on top of it several performance models (e.g., Efficiency models, input/output models) that can be compared and assessed in order to be validated. Figure 1 shows the mentioned functionalities as steps 1 and 3.



Visual Analytics Environment
Data Sources
Ontology Based Data Integration
Data quality Information quality analysis
Performance model construction and validation
Step 1
Step 2
Step 3

Figure 1: Performance models development workflow

The proposal in this paper leverages on this workflow inserting a new intermediate step (see Figure 1, step 2) that implements the evaluation of the quality of data ingested in the system, during the initial data exploration and/or once the analyst selected a pool of features on which construct the desired models (hence the bi-directional arrows for both model construction and data ingestion). For quality we mean both syntactic properties of the data, like the presence of null or incomplete values or the type of data at hand (e.g., categorical, numerical), and semantic properties, like the fairness of specific features (consistency) and their timeliness.
This intermediate step can reinforce the resulting quality of the developed performance models and can facilitate the check of the fairness of the model or controlling the reliability of the resulting rankings with respect to the statistical significance of the supporting data.
Given the specificity of this additional Data Quality task, the resulting Visual Analytics Environment has been expanded with a tailored solution dedicated to this analysis, split into two main parts: an environment dedicated to provide an overview and exploration of classic Data Quality metrics (Data Quality Environment, DQE), and another environment dedicated to Information Quality evaluation, which refers to how the specific feature can support the creation of a performance model and how a feature contribute to it (Information Quality Environment, IQE). Referring to the DQE, it is constructed with both visual paradigms that are familiar to data quality experts (e.g., Pareto charts) and more abstract representations, like matrix-based visualization or radar-charts. A Data Quality overview from the current version of the DQE is visible in Figure 2: this representation, inspired by the work of Angelini et al. (2018), allows a statistical description of the behavior of the numerical data dimensions with respect to a set of Data Quality metrics using a matrix-like representation.
This interactive visualization represents data dimensions on columns and quality metrics on rows. It visually highlights good quality scores (deep blue color) or bad quality scores (white color) for data dimensions on all quality metrics. This results in the creation of an overview on the overall quality of the dataset through a compact visualization that allows exploration and detailed analysis of subset of pairs *quality metric(s)-data dimension(s)*. The area of an element encodes the variability in scores computed for all the data tuples for each pair *quality metric-*

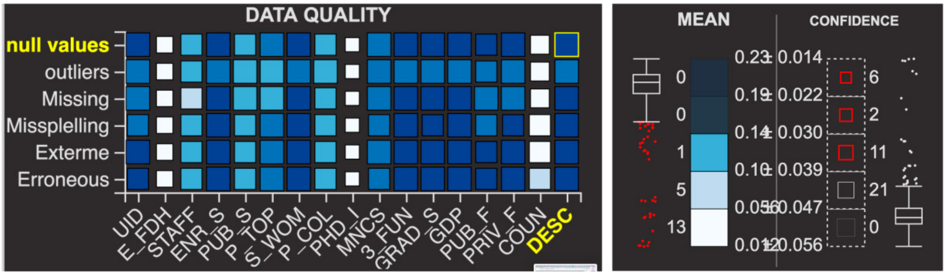


Figure 2: Data quality overview (*left*) with interactive instances exploration panel (*right*)

data dimension. A large area means a narrow confidence interval (stable result with low variability). Conversely, a small area identifies a large confidence interval (high variability).

4. Application to European Higher Education Institutions data (ETER)

On top of the DQE, we are developing also the Information Quality Environment (IQE). We present below some results of the application on the ETER dataset (https://www.eter-project.com/). This dataset is composed by 619 variables about European universities and their activities. In this example, we select the variables that represent the structure and the dimension of the institutions. From these variables we computed the ratios shown in Table 1.

Table 1. Ratios created from the selected variables

Index	Formula	Description
R_1	R&D_EXP / TOT_EXP	Index of funding for Research & Development
R_2	STUD_ENR_I8 / TOT_STUD_ENR	Index of doctorate enrolment
R_3	TOT_EXP / TOT_REV	Index of investments
R_4	COOP_RES / TOT_RES	Index of collaborative research
R_5	GRAD_ISCED8 / STUD_ENR_I8	Index of doctorate graduation in the institution
R_6	(TOT_INC_STUD + INC_STAFF) / (TOT_OUT_STUD + OUT_STAFF)	Index of students and staff mobility
R_7	FOR_ACC_STAFF / TOT_ACC_STAFF	Index of academic foreigners
R_8	CORE_BUDG / TOT_REV	Index of the core funding allocated by the government

Each of these ratios is visualized in the IQE as a *Gauge plot*. Focusing on R_1 (see Figure 4 left), the plot represents the distribution of the ratios (the fraction between the expenditures in Research and Development (R&D) over the total amount of expenditures for one year). From this plot we can say that the institutions on average, spend 23.4% of their total expenditures in R&D, while the upper 5% of the institutions spend more than 60% and the lower 5% of the institutions spend a very little part (around 1%) of the total expenditures in R&D. The analysis can proceed on comparing institutions on this ratio and their R&D expenditures through the use of a *Map plot*. Figure 3 shows the average of the R_1 ratios (on the left) and their R&D expenditures (on the right) aggregated at regional level.

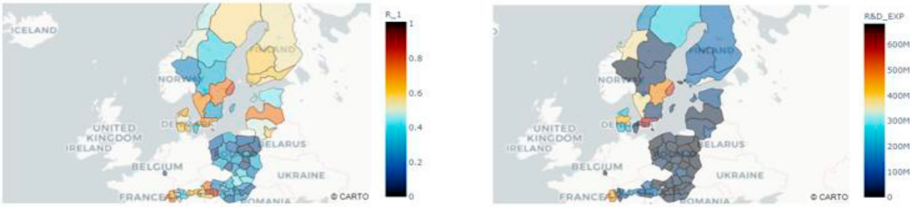

Figure 3: Map plots for R_1 (left) and R&D_EXP (right) variables

We notice that the institutions of Finland, Denmark and Austria are making more efforts (in percentage) in R&D (Fig. 3 on the left), while Polish institutions are expending the less in this field (Fig. 3 on the right).

If we want to compare two variables looking at their correlation, we use the *Heatmap plot* that visualizes the correlation between the target variable (TOT_RES) and all the ratios. See Figure 4 on the right.

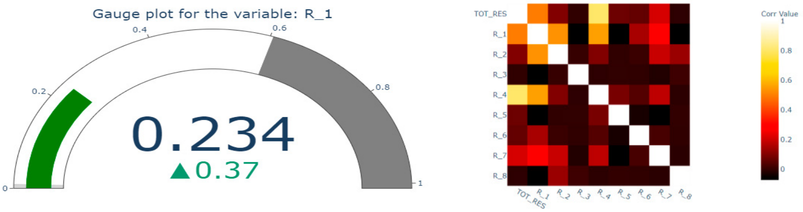

Figure 4: Gauge plot for single variable (left). Heatmap that contains the correlation between the total number of researches and all the ratios (right)

The most correlated ratios with the target variable are R_4 and R_1 ratios, a smaller correlation exists with R_7, while the others are poorly correlated. If we want to see why a variable is highly or poorly correlated to another, we can use the *Scatterplot chart* with the two chosen variables (see Figure 5: TOT_RES variable and R_1 ratios (on the left), and TOT_RES variable and R_2 ratios on the right). By inspecting Figure 5, R_2 results more scattered than R_1.

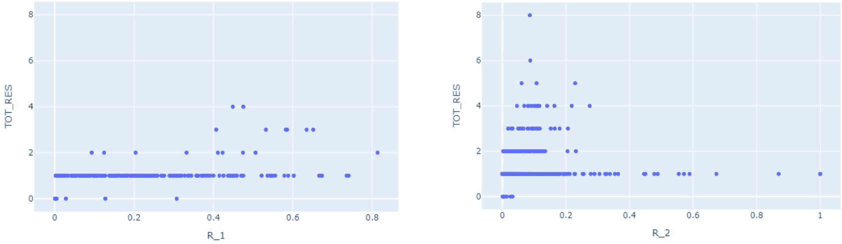

Figure 5: Scatterplots of R_1 and R_2 with respect to the TOT_RES variable

Our IQE includes the *Feature Importance Analysis* (FIA), a multivariate analysis based on the application of *i)* a *Ridge Regression* (with different values of the regularization parameter α) with the chosen features on the target variable, *ii)* Extraction of the *Feature Importance* value, and *iii)* plotting of the *Pareto chart*. An example is shown in Figure 6. While the single variable analysis identified R_1 and R_2 ratios as the best correlated to the TOT_RES variable, the results obtained from the FIA identifies R_4 and R_7 ratios as the most important, with R_4 most prominent (80% of the total importance). Perturbing the regularization parameter, the result does not change much, confirming their validity.

5. Concluding remarks

We are working on finalizing the DQE and IQE, integrating them to fully implement the described workflow. It will better support the creation and evaluation phases, providing insights on information and data quality, able to guide the user toward better performance models. A preliminary version of this environment has been used during a Methodological Course on Data

Quality organized within the training activities of the EU RISIS Project (Research Infrastructure for Science and Innovation Policy Studies (https://www.risis2.eu). Further developments and a novel version will be integrated in a web platform for evaluation activities.

Abstract

Universities underwent a radical change of paradigm in the last forty years. Since Bayh-Dole Act in 1980, they have been accused of having a growing interest in revenue generation activities such as overzealous patenting, participation in patent auctions and morally doubtful patent enforcement. On the point, some prominent scholars argue that the litigation behavior of universities should be monitored, considering the possible similarity with the so- called patent trolls. Patent trolls are a kind of non-practicing entities (NPEs) whose core business is litigate patents with lower quality almost at the end of their life, trying to maximize their revenues at the expense of the potential plaintiffs. While the harms to innovation made by patent trolls are well-known, the involvement of universities in litigation has not been explored by the literature from an empirically point of view. In this work, we collect data on patents held by universities at the United States and Trademark Office (USPTO) and data on infringement lawsuits filed by universities in the years 1990-2019 to study the characteristics of the litigated patents. We find that universities litigate their patents only sporadically (less than 0.4% of their patents have been used in infringement proceedings) and when the patents are particularly valuable. Moreover, we analyse the fields in which universities litigate, considering that trolls mainly ravage in the ICT sector. Our conclusion supports the idea that universities participating in litigation is a growing phenomenon which should be monitored, but their current behavior does not reflect the strategies of the *litigation* NPEs. Further research is needed to consider the whole universities' portfolio to assess which patents they choose to litigate and the evolution of their strategies over time.

Introduction

University, traditionally been perceived as a relevant actor in the innovation ecosystem, gradually changed its role, integrating its teaching and research mission with the commercial assumptions underlying IP law (Etzkowitz, 1990; Ghosh, 2016). Thus, understanding and analyzing the changes which have taken place in the relationship between higher education institutions (HEIs) and intellectual property is relevant to the whole innovation system (Adams, 1990).

In US, universities have been involved in technology transfer activities since the nineteenth century (Meyer-Thurow, 1982), with an upsurge in patenting activities after the adoption of the Bayh-Dole Act; the increase was also sustained by the increasing importance of software and biotechnology, which were emerging sectors in the 1980s, together with the shifting of norms in academia (Firpo and Mireles, 2018; Rai and Eisenberg, 2003). After Bayh-Dole, universities started establishing TTOs to help researchers with patent applications and to manage licensing revenues.

In an attempt to increase revenues generated by licensing and patenting activities, in recent years some universities have started to pursue "overzealous" strategies to protect their existing patents, by enforcing them in courts, selling them to the highest bidder and making arrangements with patent assertion entities (PAEs) (Fusco et al., 2019; Love et al., 2020). As pointed out by the former Harvard president Deren Bok, the "lure of marketplace" might modify and hamper universities' core values (Bok, 2009), giving incentives to universities to patent inventions which might have or not a commercial value but which for sure could be enforced in courts for their "litigation" value (Frye and Ryan Jr, 2020).

Despite the importance of the topic, very few studies on university patent litigation exist. To our knowledge, only Rooksby (2011, 2012) and Firpo and Mireles (2018, 2020) collect and examine data on patent litigations initiated by universities in the US. In particular, Firpo and Mireles (2018) analyze litigation cases filed between 2000 and 2015 by universities, foundations and non-profit organizations, for a total of 585 cases and had the merit of being the first to explore evidence of strategic (troll-like) behavior in university patent litigation. They find that, contrary to patent trolls, universities assert on average relatively young patents (7.5 years old at the time of litigation); however, they also find that there are numerous patent litigated by universities that are in the final years of their term, suggesting that in some circumstances some universities also assert their patent against a technology that has been already commercialized.

In this research, we use a novel dataset which further investigates the participation of universities in litigation in the US. In particular, we collect patent infringement lawsuits involving universities up to 2019 from Darts-IP and US granted (utility) patents at the USPTO where universities appear as assignees, from Patent Views (2018) and the Patent Assignment Database (version 2017). Our results provide evidence of the increasing participation of universities in litigation activities during the last twenty years. Moreover, our econometric analysis shows that universities litigate the most valuable patents of their portfolio and that are not as much as broad as one could expect from PAEs (Fisher and Henkel, 2012). However, the litigation and patenting behaviour of universities should be closely monitored, by investigating differences across technologies (we observe a significant share of patents litigated in the ICT field), and studying the emergence of new universities (included non-US universities) and investigating the change in their monetisation strategies over time.

The rest of the paper is organized as follows. In the next section we discuss the patent commercialization strategies adopted by universities, with particular attention to their "non-orthodox" monetization behavior and we review the present literature about their participation in litigation. Then, we describe the patent and litigation data and facilitate an empirical understanding of university participation in patent infringement litigation in the US in the years 1990-2019. Afterwards, we run an econometric model, in order to analyze the characteristics of patents litigated by universities in the US. Finally, a discussion of the results and acknowledgment of limitation concludes.

University patents commercialization

Prominent scholars extensively studied the surge for patenting which followed Bayh-Dole, looking for the effects on innovation production and on universities as actors for the first time involved in the challenges of commercializing and licensing their inventions (Mowery and Ziedonis, 2002; Mowery et al., 2002).

Bayh-Dole Act has been harshly criticized by some, being defined as a "one size fits all" law which do not consider that patents from diverse field have different necessities and opportunities for commercialization (Mireles and Firpo, 2018). For instance, patents may play a central role in industries such as pharmaceuticals, while in others, such as IT and software, patents might be not as important or even harmful (Burk and Lemley, 2002). Moreover, licenses do not seem so fruitful for universities either, not enough to justify the current scope of Bayh-Dole. Powers and Campbell (2009) demonstrated that 35% of universities in their sample never realized profitability no matter their investment. In addition, a 2013 Brooking Institution extensive study proved that, in 2012, 84% of universities failed to break even in technology transfer, considering the personnel and filing costs (Valdivia, 2013).

The issue of whether society benefits most if universities patent (or not) their inventions is entangled with another debate about whether universities should try to maximize the revenue stream from their patents (Lemley and Feldman, 2020). Jennifer Washburn (2008) defined the benefits of commercialization as "vastly overblown", suggesting that the increasingly aggressive attitude of universities towards IP appropriation not only would dissuade broad public access, but might also encourage monetization as a mission of universities, thus further disincentivizing dissemination of technologies and thwarting rather than facilitating commercial development (Raj, 2004). Moreover, the increasing interest in commercialization would increase universities' interest in acting like "patent seekers, patent enforcers, and patent policy stakeholders" (Eisenberg and Cook-Deegan, 2018). Many university administrators in the US state that revenue generation is a relevant goal of their technology transfer operations, and that this was already the case in the early 2000s (Thursby et al., 2001; Abrams et al., 2009), in part in response to the increasing threat of dwindling public funding (Firpo and Mireles, 2018, 2020). Recent evidence shows that there has been a significant increase in the monetization activity around the related patents, especially in the US, and that university TTOs appear to be "revenue-driven with a single-minded focus on generating licensing income" (Kesan, 2008). University pursuit of licensing to increase revenues generated consequences which go beyond the greater amount of resources invested in TTOs, the orientation towards applied research and exclusive licenses. For instance, looking for even greater revenues, universities have even been tried to organize patent auctions, selling even to PAEs (Ledford, 2013, Cahoy et al., 2016).

Universities and patent trolls: an ambiguous relationship

PAEs are owners of patents who file or acquire patents without having any interest in actually developing the product. The activity of PAEs has been largely analyzed by scholars in terms of patents' acquisitions and litigation, with a special eye on the latter, considering its potentially harmful impact on innovation (Bessen and Meurer, 2013; Chien, 2013; Kiebzak et al., 2016). Allison et al. (2010) showed that almost 50% of the most litigated patents are owned by PAEs, making them the most litigious actor on the market and pointing out the importance of monitoring their behavior (Lemley and Melamed, 2013).

In general, PAEs are accused to focus their business mostly on litigating patents related to product already developed, harming innovation and damaging companies and individuals which do not have enough resources to fight them in court: these are called patent trolls (Chien, 2012; Feldman and Lemley, 2015; Cohen et al., 2019). With the threat of expensive litigation process, patent trolls convince inventors to pay them a license to use the litigated patent, regardless of the supposed infringement being true or not. Thus, trolls extract high costs in the form of impeding innovation and pushing up costs for consumers for goods and services covered by patents (Firpo and Mireles, 2018). At the same time, PAEs are also described as "middleman", bringing technologies from inventors to people who can implement them (Fisher and Henkel, 2012; Steensma et al., 2012) and helping small inventor to monetize their IP assets (Haber and Werfel, 2016); hence, they play a relevant administrative role, identifying relevant technology and collecting royalties, complementing in that way the scarce expertise of some patent holders in the latter activity.

The US Federal Trade Commission report on PAEs (FTC, 2016) proposes to distinguish two kind of entities under the umbrella of PAEs. *Portfolio PAEs* are large patent aggregators that usually hold a great amount of patents which are not necessarily used for litigation purposes; their goal is to promote technology transfer, acting as middleman between demand and supply of knowledge. *Litigious PAEs* are smaller PAEs set up as limited liability companies (LLCs) which sue potential licensees and usually settle quickly after entering into negotiations with them. The litigious PAEs have been often accused of starting litigation with the sole purpose of extracting rent, managing to be profitable even if they assert low quality patents, and are labelled like “patent troll”.

Universities have been related to patent trolls for different reasons. First of all, as patent trolls, universities are *non-practicing entities* which have been accused to sell or license their patents without the interest in transferring the underlying technology (Cordova and Feldman, 2015; Feldman and Ewing, 2012; Love et al., 2020); secondly, they have been recently blamed of acting as trolls, (Lemley, 2016; Firpo and Mireles, 2018), being involved into patent litigation with the sole aim of increasing their revenues.

With respect to the first criticism, recent evidence shows that the market of university inventions, by analyzing US patent transfers where universities appear as sellers, between 2012 and 2017, Love et al. (2020) find tht only 10 percent of them appear to transfer knowhow in addition to the patent assets listed therein. Similarly, XXX shows that Intellectual Ventures (IV), one of the biggest patent holding company in US and notorious PAE, opened up about its relationship with more than 400 universities (whose 60 American), but only two of them eventually led to commercial products.

With respect to the second criticism, it is now evident that universities are involved in the patent ecosystem not only as patent owners and licensors, but also as litigants, chasing lavish monetary rewards. In particular, universities have been accused of being patent trolls also because they can enjoy some of their legal benefits: they do not incur the risk of being counterattacked (Lemley, 2007). Beyond seeking patents not always useful for commercialization, anedoctal evidence shows that universities started to enforce their patents in litigation against firms that have already developed successful commercial products (just as patent trolls would do). Many of these lawsuits have led to very large settlement or damages awards. One such case involves Boston University. Boston University sued more than thirty defendants, including Apple, for infringing a late term patent covering LED technology.

Critics also underline the inconsistency between universities values and the troll-like attitude: universities live on tax subsides, so they are supposed to pursue public good through conversation, research and teaching, excluding morally doubtful activities such as patent litigation. In addition, the money invested in patent litigation might harm universities, because litigation would subtract money and time to university personnel. Patent enforcement might decrease productivity of TTOs as well, generating an extra cost for consultancy with attorneys about strategies for ligation; at the same time, they involve TTOs personnel in document production and witnessing at trial, who would otherwise be busy with marketing, search and negotiation activities, thereby reducing the amount of licensing. Hence, patent litigation might have an adverse effect on university licensing activity itself (Shane and Somaya, 2007).

In our paper, we collect data on US patents held by universities and we analyze their characteristics in order to investigate whether the universities' behavior can be compared to that of patent trolls. In particular, we do expect universities behave as patent trolls if we observe that they litigate patents that are of low-quality but at the same time broad, and so more likely to be infringed.

Data sources and key figures

Dataset construction

The dataset used for this research is created from several sources. First, patent infringement actions involving universities are collected. Second, we match these data with other publicly available databases on US patent data (USPTO); to do this, we rely on different patent databases - Patent Views (Version 2018), Patent Assignment Database (version 2017), EEE-PAT - which we use to identify all patents assigned to universities (and their TTOs) and their characteristics. By limiting our investigation to granted patents filed since 1990, our sample contains 156,492 university patents, of which 107,114 include US universities among the applicants. Third, we rely on the US-OECD patent quality database (version 2019), in order to retrieve information on patent characteristics.

Data on litigation cases were collected from Darts-IP, which provides extensive coverage of IP verdicts across all the most important IP markets over the world, and which allowed us to identify the types of actors (company, university, PAE, person, authority). For this study we collected all patent infringement actions in the United States involving universities (including their TTOs and schools of medicine) as plaintiff, up to December 31, 2019 inclusive. Patent litigation data from Darts-IP contain information about where the cases were filed, the relevant dates, the patent number, the names of plaintiffs and defendants, the outcome (if any), as well as other information associated with the cases. After having collected all the patent infringement cases involving universities, we cleaned and harmonized plaintiffs' and defendants' names, taking into account different spellings and to put together each university with its affiliated research entities (for example, the Arizona State University and Arizona Research Foundation). The final database accounts for 574 infringement actions filed in the US and 813 litigated patents granted at the USPTO, of which 521 are university patents and 292 are patents that are assigned to other types of organization classified as co-plaintiffs of universities in the patent infringement lawsuit. The average number of patents disputed per case is 2.76 and about one third of these cases concern more than two patents.

Descriptive statistics

Aggregate statistics show the increasing number of cases of patent litigation by universities. Figure 1 shows the evolution over time of the number of new patent infringement litigation cases involving universities as plaintiffs from 1990 to 2019 (figures for 2019 may be incomplete due to updating delays), where the year corresponds to the year in which litigation cases start: and shows a constant rate change starting from the late 1990s, with an average annual number of new cases between 20 and 40 in the years 2005-2019, and a noteworthy peak in 2013 when we observe more than 90 new cases.

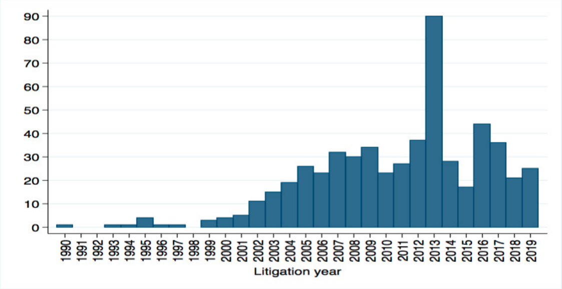

Figure 1. Number of university infringement actions filed in US (1990-2019)

Notes: This distribution is related to all patent infringement actions filed in the US by universities in the period 1990-2019. The litigation year corresponds to the year in which cases start.

Most litigious universities

The 558 identified patent infringement actions involved a total of 93 public and private universities among the plaintiffs; 48 of them were involved in one or two cases, while 15 universities were involved in ten litigations or more (see Table 1). The majority of these are American universities, with the exception of *National Cheng Kung University* (Taiwan), the *University of Strathclyde* (UK) and *Queen's University at Kingston* (Canada). The most active university is *Boston University* with 42 litigation cases, closely followed by the *University of California*, the *Massachusetts Institute of Technology* and the *University of Texas System*, with respectively 37, 32 and 26 cases. Confronting these figures with the ranking of the same universities in terms of patent production, it is possible to observe that, consistently, top performers in patent ranking (such as, University of California, Massachusetts Institute of Technology, University of Texas System etc.) present a higher number of litigation cases, with the exception of Boston University, which is involved in the greatest number of litigations but in proportion has few patents (see Table 1).

Table 1: Top universities, by number of patent infringement suits in United States (1990-2019)

Research institutions	*Country*	*Type*	*No. of cases*	*No. of patents filed*	*Rank pat.*	*Pat. litigated*
Boston University	United States	Private	42	411	55	2
University of California	United States	Public	37	11483	1	49
Massachusetts Institute of Technology	United States	Private	32	4570	3	45
University of Texas System	United States	Public	26	3634	4	16
University of Wisconsin–Madison	United States	Public	23	2611	5	8
University of South Florida	United States	Public	17	935	25	3
National Cheng Kung University	Taiwan	Public	15	463	64	8
Emory University	United States	Private	15	565	44	8
University of Michigan	United States	Public	15	279	98	4
John Hopkins University	United States	Private	15	2016	9	16

Notes: The ranking in the penultimate column is based on the number of patents held by universities at the USPTO since 1990.The last column of the table represents the number of patents (with unique identifier) litigated in the considered time

Technology

Table 2 shows the number of patents held by universities in the US and granted since 1990, and those that have been litigated (0.3%), by technology field according to the 5-sector WIPO classification.

Table 2: Frequencies of US university patents by technology fields

	Litigated patents		*All patents*	
	Nb. (A)	*Percent*	*Nb. (B)*	*Percent*
Electrical Eng.	122	*24.65%*	37,779	*24.03%*
Instruments	118	*23.84%*	35,292	*22.45%*
Chemistry	229	*46.26%*	75,843	*48.24%*
Mechanical Eng.	20	*4.04%*	6,881	*4.38%*
Other fields	6	*1.21%*	1,409	*0.90%*
Total	**495**	***100%***	**157,204**	***100%***

Notes: Only US university patents granted since 1990 are considered and patent infringement actions initiated by universities (as plaintiffs or co-plaintiffs) in the years 1996-201

The largest number of patents filed and litigated by universities in the US is in *Chemistry* (46% of all litigated patents and 48% of university patents), which is also the technological field where they file the largest number of patents (48% of university patents). Interestingly, following the general trend in the patent litigation landscape, while universities litigated only a share of their patents in the ICT sector during the first decade of 2000s, in the last ten years they have increased their presence in this sector (Figure 2).

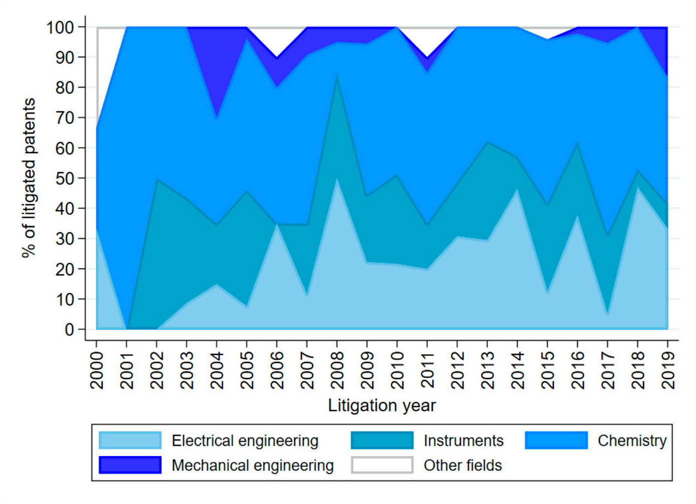

Figure 2. Evolution of the share of litigated patents by sector

Notes. Patent infringement actions initiated by universities (as plaintiff or co-plaintiff) in the period 2000-2019.

Empirical Analysis: litigation decision analysis

In this section we study the litigation strategies of universities in the US by providing a broad-based statistical characterization of patent cases filed in which they appear as plaintiffs. In particular, looking at the main characteristics of the patents under litigation, the aim of this study is to identify the characteristics of litigated patents, with respect to non-litigated patents the universities have in their portfolios.

In particular, we analyse the factors explaining the likelihood of a patent being litigated; in doing so, we consider all university patents filed since 1980 and granted until 2014. We discard from the analysis any patents granted after 2014 because only a few have been litigated later and because they are subjected to a substantial truncation of the number of forward citations which we use as a proxy for technological patent quality. The final dataset contains 134,421 patents, of which 503 have been litigated by universities.

In our econometric exercise, the response variable (*Litigation*) is thus a dichotomous variable whereby litigated patents are designated as "1" while non-litigated ones are coded with "0". Hence a Logit model approach is deemed appropriate here:

$$Prob(Litigation_i = 1) = \mathrm{F}(X_i) = \frac{e^{\beta' X_i}}{1+e^{\beta' X_i}} \qquad (1)$$

In other words, the probability of a litigation is assumed to be a function of a vector of explanatory variables, *X*. Our main variable of interest is the technological importance of the invention (*Fwd_cits*5), which we proxy with the number of citations received by the focal patent in a window of five years starting from the filing date. Citations received by a patent are one indication that an innovation has contributed to the development of subsequent inventions (Henderson et al., 1998). Moreover, we include a set of indicators of patent value (*Claims*, *Bwd_cits*, *Renewals* and *Npl_cits*). In general, the higher the value of these indicators, the higher the expected value of the patent (Squicciarini et al., 2013). *Claims* accounts for the number of claims of a given patent, which define novel features of the invention. Generally, it is associated with the technological breadth or the market value of a patent and reflects a larger risk of conflict with competitors (Tong and Frame, 1994). Similarly, *Renewals* is also a proxy for patent value, indicating the number of years a patent is valid. Since maintaining patent protection over time is costly, we assume that valuable patents pay at least for their own renewal and that the more valuable patents will be renewed for a longer time (Sterzi et al., 2019). *Bwd_cits* looks at backward citations, considering all potential sources of knowledge of a given patent, such as prior patents and scientific works (Harhoff et al., 2003). A low number of backward citations could indicate that the invention is in a relatively new and uncrowded technology area (Harhoff et al., 2003; Harhoff and Reitzig, 2004; Lanjouw and Schankerman, 2004). We thus expect the likelihood of litigation to increase with the number of backward citations. *Npl_cits* measures the size of the non-patented literature cited by the patent, which denotes the technical closeness of an invention to scientific knowledge and is found to be correlated with patent value (Branstetter, 2005).

Patent_scope estimates the breadth of the patent and is measured by counting the number of distinct 4-digit IPC classes the invention is allocated to (Lerner, 1994) and it is thus expected to be correlated with the probability that the patent can be infringed (Lerner, 1994; Fischer and Henkel, 2012).

Next, we control for applicants' country, by including a dummy (*US*) which takes the value of one when at least one university among the applicants comes from the United States. This variable is meant to control for the different costs of trial relative to the cost of settlement for domestic and foreign applicants (universities) and for the disadvantage for foreign universities in detecting infringements in the US market. Moreover, since there are pronounced differences in litigation rates across technology fields and years (Lanjouw and Schankerman, 2001), we also control for technological sector (WIPO 35 technological classes) and grant year fixed effects.

The first column of Table 4 provides the main descriptive statistics of the variables under study. In the overall period observed, litigated patents account for the 0.37% of the whole dataset.

Columns (2)-(5) of Table 4 provide the results of the logistic regression. The different specifications differ little in terms of their explanatory power, where year dummies are included in columns (2) and (3) and technological field dummies are added in columns (2) and (4). Given the values of both pseudo-R^2 and AIC, Column (2) is taken as the reference equation where we control for both annual and technological fixed effects.

Although the overall rate of litigation is low, there is a wide variation across patents in their exposure to litigation risk. First of all, the patent quality is found to be positively correlated with the litigation outcome. All the coefficients of patent value indicators are positive and significant, indicating that a patent's market value increases litigation propensity. On the contrary, the estimated coefficient for *Patent_scope* is non-significant. Overall these results seem to reject the hypothesis that universities behave as patent trolls. As regards the control variables, US patents filed by US universities are more likely to be litigated than patents filed by non-US universities: the odds of being litigated for US university patents is 2.620 times that of non-US university patents.

Discussion and conclusions

Over the past 40 years, there has been a strong growth in university patent filings at the USPTO, due mainly to US institutions increasing their activity in response to the Bayh Dole Act, as well as to the explosion of the software and biotechnology sector and, since the 2000s, to the sharp rise in foreign universities. University patents granted by the USPTO accounted for about 1% of the total number of issued patents before the 1990s and now stand almost at 4%. At the same time, the role of TTOs evolved from ensuring patent protection and simple managing of licensing activities to a more "patent-centric" vision (Kesan, 2008; Pilz, 2020; Frye and Ryan Jr, 2020), in the attempt of achieving sometimes competing objectives (Sherer and Vertinsky, 2020). The extreme consequences of that vision include a tendency to patent as much as possible to relieve the economic pressure to cover their costs, as well as TTOs participating in patent litigation as "buffer" organizations between the asserter university and the defendants (Rooksby, 2011).

Despite the increasing attention devoted to the modern surge in patent filings and to the participation among patent trolls in the patent market, an equal attention has not been devoted to the characteristics and consequences of the increasing interest of universities for litigation activities - except a few cases (Rooksby, 2011; Firpo and Mirales, 2018, 2020).

Our paper goes further in depth on the topic, by collecting data on patents filed by universities at the USPTO and infringement lawsuits involving universities in the years 1990-2019. Our findings can be summarized as follows. First, we show an increasing participation of universities in litigation activities, despite litigating only a share (less than 0.4%) of their patent portfolio. Second, we observe an increasing participation of universities in court in the ICT industry, which is traditionally the sector in which patent trolls litigate the most. Third, universities litigate valuable patents but that are not broader than the non-litigated patents in their portfolios.

Our first evidence seems to corroborate the idea that universities, although sharing some characteristics with trolls, are not trolls. However, this study also presents some important limitations, which constitute avenues for further research. First, the quality of patents litigated by universities should be considered as a factor which could change over time, in order to take a closer look at possible universities' strategy changes. In addition, the same is true for the fields involved in litigation: despite the current prevalence of the *Chemistry* sector, changes over time should be taken into consideration. Second, other litigation strategies (such as the time in which universities start to litigate, the venue and the number of defendants per litigated patent) should also be taken into account.

Abstract

To explore the characteristics of highly cited data records, and exploring the relationship between data sharing/reuse of data records and the socio-economic burden of diseases / funding, the basic information of clinical data records were sorted. We extracted the subject words and exploring the diseases involved in the data records, so as to achieve the matching between the data records and diseases. We found that the data storage type of the DCI platform is data sets mainly, but the most cited data type is repositories. And the number of highly cited papers in data records is much lower than that of highly cited papers in the same field. The highly cited data records can reflect diseases of high concern to a certain extent. The disease related data records' sharing/reuse is positively correlated with its DALYs / foundation counts. Results shows that the data storage format should be further unified, the citation format should be further standardized. The data records on Chronic diseases and lifelong acquired diseases, such as Lower Respiratory Infections, Diabetes Mellitus and HIV/AIDS should be paid more attention.

Background

With the coming of the era of big data, more and more data records are measured and stored. The generation of massive data has brought unprecedented "data explosion". Almost every research field is eager for open access and use of data. Data citation is very necessary in order to protect the rights and interests of data providers and ensure the scientific and traceability of data. The practice of formal data citation includes data references and bibliographic references in the reference section of a publication. But the study showed that "the informal data citation in the main text of articles is far more common than formal data citations in the references of articles" (H. Park, You, & Wolfram, 2018). Management measures for data sharing and reuse are gradually implemented with more and more platforms for open data.

The current situation of data reference needs to study the data reference in specific data records. Informal reference data is difficult to track, but it is still an important way for researchers to share and reuse data, especially in the fields of life science and biomedicine field (H. Park & Wolfram, 2017). At the beginning of the 21st century, the genome science committee of Japan's Council for Science and Technology call for that "To assure scientific progress, all data and results from human genome research should be made public. (Triendl, 2000)" In August, 2013, there were some posters began appearing in doctor's practices in England to establish a unified management database of patients' electronic health records and use them for scientific research. The practice of sharing health records data is conducive to establish the National Health Service(NHS) system in England (Callaway, 2013). The Swiss National Science Foundation (SNSF) strongly supports the sharing of data and open access to data. They hope to achieve the findability, accessibility, interoperability and reusability of data through depositing the scientific data in any recognized digital archive (Egger & Kalt, 2017). In recent years, the application of open data records in the medical science field has helped the containment of infectious diseases, the research of cell and molecular biology, and the application of clinical drugs to solve medical problems. Data sharing is very important for all medical science research, especially for the outbreak of new and unexplored diseases. The publication of scientific paper cannot disclose relevant information at the first time, while the opening of original data can not only improve the value of shared data, but also help save valuable public health resources. Data sharing in medical science accelerates the process of disease research. For example, WHO shared data about Zika virus, and COVID-19 data set shared by Shanghai Public Health Clinical Center in January 2020 (Kieny, Moorthy, & Bagozzi, 2016; Zastrow, 2020).

The spirit of openness is becoming more and more popular in the scientific community, and many researchers and institutions call for making research data, software code and experimental methods publicly available and transparent (Gewin, 2016). Data reference is becoming more and more important in data sharing. However, the existing data are scattered in various industries and platforms, and have not been effectively integrated. There is a lack of unified management and reference format. It is very difficult to realize data sharing and unified use format. However, some data are related to data sets, data repositories or published research (H. Park & Wolfram, 2017). In order to explore the current situation of data sharing and reusing, we took the output and citations of clinical related data records in the Data Citation Index (DCI) platform as an observation. Focusing on clinical related data, we try to figure out 1) the distribution of data records types and related types of diseases in DCI, 2) the most highly cited data records, and 3) the relationship between data sharing/reuse and diseases-disability adjusted life years (DALYs) (WHO, 2018) for diseases, to compare global health needs and data sharing/reuse efforts. 4) the relationship between data sharing/reuse and diseases funding count, to demonstrate if there is an association between funding, and data sharing/reuse.

Methods

Data sources

Open access data records came from DCI database: DCI is a database intend to facilitate the discovery of data, link data to paper, and encourage citation of data. DCI on the Web of Science was selected because DCI provides a single access to over 500 data repositories worldwide and to over two million data studies and datasets across multiple disciplines and monitors quality research data through a peer review process (H. Park & Wolfram, 2017). A study showed that "Thomson Reuters developed this database in response to a stated desire among members of the research community for increased attribution of non-traditional scholarly output such as data records." DCI was launched in October of 2012 on the Web of science research platform. Cross-disciplinary search capabilities in the Index enable new possibilities for data discovery and synthesis. Evaluation of data records can be realized through DCI, and data records' relevance to scientific and scholarly research can be explored (Force & Robinson, 2014). While the reference of informal data records is not recorded in it, the platform can be used to explore the formal citations by scientific publications of data records (H. Park et al., 2018). As this study focuses on exploring the usage of clinical related data records, "Life Sciences & Biomedicine", one of the five research domains of WOS, is selected for retrieval in DCI platform. Among them, 57 subject categories have been obtained in this domain on August 7th, 2020, and 39 discipline categories related to Life Sciences & Biomedicine were obtained after 18 discipline categories without data were removed. In total, 13153 clinical data records were included in our study after removing the records related to molecular biology/pharmacy/animal. The workflow is shown in Figure 1.

Figure 1. Data Records Filtering Flowchart

Data processing:

The Medical Text Indexer (MTI) produced by the National Library of Medicine (NLM) was adopted to extract standardized medical subject headings (MeSH) terms from the title and abstract of data records in DCI. We focused on the diseases related MeSH terms.

A correspondence table (Yegros-Yegros, van de Klippe, Abad-Garcia, & Rafols, 2020a) was used to map World Health Organization (WHO) International Classification of Diseases (ICD-10) with MeSH terms. The WHO Global Burden of Disease (GBD) survey provides useful information, including the corresponding codes of the ICD-10 and the global DALYs. The diseases distribution of DCI data records as well as their burdens was then explored.

In order to evaluate the relationship between the data sharing, data reuse and health demand at the disease level, the quantity of data records related to diseases (indicating the level of data sharing), the citations by scientific publications (indicating the level of data reuse, that is, using them to generate new research) and the social burden of diseases were analyzed respectively. DALYs, one of the Global Burden of Disease, GBD) indicators provided by WHO, is adopted as the index for disease burden assessment.

Concerning the funding for diseases, we noticed a data source in Global Observatory on Health R&D, which collected data on diseases/conditions in the number of grants for biomedical research by funder, type of grant, duration and recipients (WHO, 2019). This report provided statistics related to funding from 10 organizations. We collected data on the classification of disease/condition in the report as funding counts. SPSS 20.0 was used for statistical analysis of all the data. After single sample K-S test, the data of publications, citations and DALYs/funds of various diseases were in accordance with normal distribution, and Pearson Correlation Analysis was conducted to analyze the correlation among variables. Two-sided probability is taken as inspection level. P < 0.05 is statistically significant.

Results

Overall distribution of the data records

A total of 13153 clinical related data records were retrieved, which first appeared in 1900. Data records are mainly concentrated in the recent five years. According to the classifications in DCI, the data records are divided into three types: 10713 (81.45%) data sets, 1939 (14.74%) data studies and 60 (0.46%) repositories. Another 441 (3.35%) records are software. Among all the data records included in our study, 982 data records were cited, that is, new studies were produced through the reuse of these data records (Figure 2). But the most cited data record type is repositories.

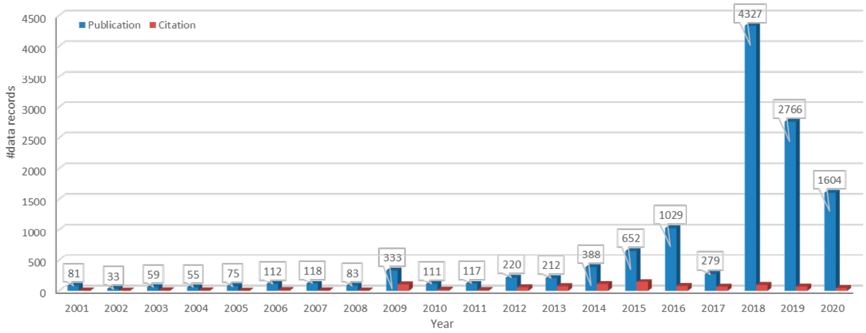

Figure 2. Number of diseases related data records in DCI

We could find the distribution of citations in clinical related data records according to table 1. Although the repositories related to clinical has the lowest proportion of data records, and their cited data records account has the lowest proportion. However, its citations by publications have the most frequency. To a certain extent, it shows that the sharing level of data sets and data studies is higher in clinical, and their scope of influence is wider. Meanwhile, the reuse level of data repositories is higher, which has a greater impact on new research.

Table 1. Distribution of citations in clinical related data records

Data records type	*Number of records (%)*	*Number of cited records*	*Cited times by scientific publications (%)*
data sets	10,713 (81.45%)	425	610 (5.37%)
data studies	1,939 (14.74%)	469	3,973 (34.96%)
repositories	60 (0.46%)	51	6,744 (59.35%)

Among them, 37 of the cited records are software, and the specific situation of this part is not statistically analyzed.

Top 20 related diseases by the number of data records and their citations

There are some differences for the top 20 related diseases by the number of data records and their citations respectively. Such diseases as chronic obstructive pulmonary disease, lower respiratory infections and Infectious bowel disease ranked in the top 10 output of data records, yet out of the top20 reuse of data records. To some extent, the data records related to the above three diseases are broadly shared, but their reuse is relatively poor. The number of shared data records of bipolar disorder and inflammatory bowel disease, which list within the top 10 reuse, but is not in top 20 number of sharing. In addition, the rate of cited data records for such diseases as alcohol use disorders (14, 51.85%), acute hepatitis C (10, 30.30%), brain and nervous system cancers (8, 21.05%) and breast cancer (6, 25.00%), are over 20%, whereas they are not in the top 20 output diseases.

Table 2. Top 20 related diseases by the number of data records and their citations

Rank	*All Records*		*High Cited Records*	
	Disease	*N*	*Disease*	*N (%)*
1	Diabetes mellitus	429	Schizophrenia	32 (18.82)
2	Trachea, bronchus, lung cancers	368	Trachea, bronchus, lung cancers	24 (6.52)
3	Asthma	342	Skin diseases	22 (7.91)
4	Chronic obstructive pulmonary disease	295	Melanoma and other skin cancers	21 (14.89)
5	Skin diseases	278	HIV/AIDS	20 (11.36)
6	Lower respiratory infections	236	Diabetes mellitus	20 (4.66)
7	Inflammatory bowel disease	210	Rheumatoid arthritis	19 (9.55)
8	Rheumatoid arthritis	199	Bipolar disorder	17 (19.77)
9	HIV/AIDS	176	Inflammatory bowel disease	16 (7.62)
10	Schizophrenia	170	Alzheimer's disease and other dementias	15 (14.29)
11	Epilepsy	159	Alcohol use disorders	14 (51.85)
12	Hypertensive heart disease	153	Epilepsy	13 (8.18)
13	Major depressive disorder	147	Acute hepatitis C	10 (30.30)
14	Melanoma and other skin cancers	141	Migraine	10 (10.87)
15	Colon and rectum cancers	141	Brain and nervous system cancers	8 (21.05)
16	Multiple sclerosis	136	Attention deficit/hyperactivity syndrome	8 (13.79)
17	Kidney diseases	120	Asthma	8 (2.34)
18	Alzheimer's disease and other dementias	105	Leukaemia	7 (7.22)
19	Acute hepatitis B	99	Gynecological diseases	7 (13.73)
20	Leukaemia	97	Breast cancer	6 (25.00)

The top 10 highly cited data records

8	Health Improvement Network	Repository	Cegedim Strategic Data Medical Research UK Health Improvement Network	http://www.thin-uk.com/	286
9	Kids' Inpatient Database (KID)	Data study	Agency for Healthcare Research & Quality (AHRQ) Healthcare Cost and Utilization Project (HCUP)	http://hcup-us.ahrq.gov/kidoverview.jsp	271
10	Nord-Trondelag Health Study	Repository	HUNT Research Centre Nord-Trondelag Health Study	http://www.ntnu.edu/hunt	269

Most of the top 10 cited data records are longitudinal cohort studies, which are often carried out for specific groups or regions. Among the top 10 highly cited data records, 8 data records are repositories, and the other 2 are data studies. The most cited data record among them is Longitudinal Aging Study Amsterdam, and it has been officially cited by 765 scientific publications at present (Table 3). Van Noorden, R et al. published a study about the top 100 papers in the world in 2014, which showed that "the number of cited papers ranked first in bioinformatics was 305,148", and the number of cited papers ranked tenth was 40,289" (Van, Maher, & Nuzzo, 2014). It is observed that the cited frequency of data sets is generally lower than that of scientific papers.

The relationship between data sharing/reuse and DALYs

According to our statistics, the published data records (data sharing) were related to 114 diseases and directly linked to 6032 data records. The citations of data records involved 51 diseases and included 369 data records. Pearson correlation analysis was made between the values of Publications and Citations and DALYs in SPSS20.0. The results showed that there was a significant correlation between the two groups of data, and the correlation coefficients were 0.341 P<0.001) and 0.985 (0.003), respectively (Table 4). To some extent, there is a positive correlation between the sharing/reuse of data sets and the disease related DALYs.

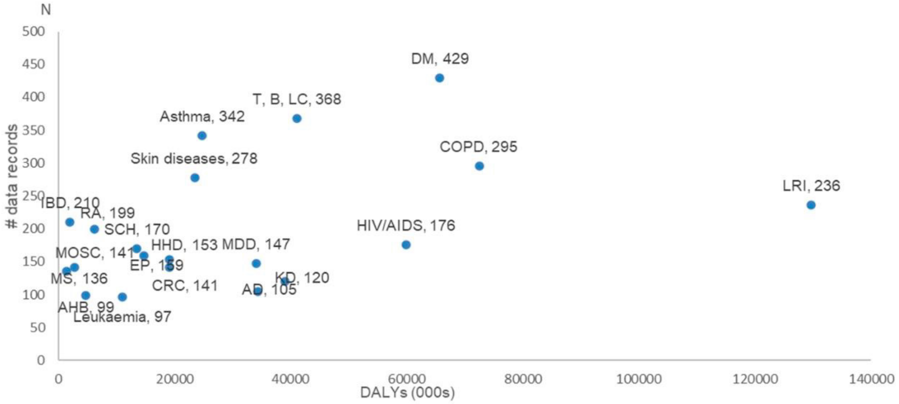
Table4. The relationship between data sharing/reuse counts and DALYs/Funding counts

	r	*P*
# Data sharing vs. DALYs	0.341	<0.001
# Data reuse vs. DALYs	0.985	0.003
# Data sharing vs. Funding counts	0.428	<0.001
# Data reuse vs. Funding counts	0.375	0.020

The published and cited data records involved 77 and 38 diseases respectively, which also have the data of funding count in the World report. We made Pearson correlation analysis between the number of publications, citations and diseases' funding counts. The results showed that there was also a significant correlation between the two groups of data, and the correlation coefficients were 0.428 (<0.001) and 0.375 (0.020), as is shown in Table 4. We tend to conclude that the level of data sharing/reuse for various diseases might be promoted by their funding counts.

The relationship between top 20 shared/reused data records and DALYs

We have found that the total number of disease-related data records and that has been cited by publications were positively correlated with their DALYs overall. In the top 20 number of disease related data sets, lower respiratory infections have the highest DALYs (129689.84), and then is followed by chronic obstructive pulmonary disease (72512.38), diabetes mellitus (65666.15) and HIV/AIDS (59951.10).

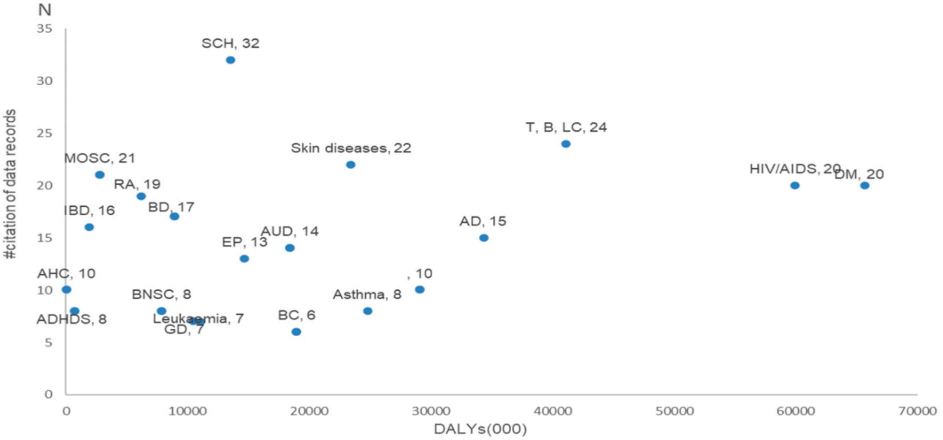


DM: Diabetes mellitus; T, B, LC: Trachea, bronchus, lung cancers; COPD: Chronic obstructive pulmonary disease; LRI: Lower respiratory infections; IBD: Inflammatory bowel disease; RA: Rheumatoid arthritis; SCH: Schizophrenia; EP: Epilepsy; HHD: Hypertensive heart disease; MDD: Major depressive disorder; MOSC: Melanoma and other skin cancers; CRC: Colon and rectum cancers; MS: Multiple sclerosis; KD: Kidney diseases; AD: Alzheimer's disease and other dementias; AHB: Acute hepatitis B

Figure 3. The relationship between the top 20 number of disease related data records and its DALYs

Diabetes mellitus has the highest number of data records among them. The number of lower respiratory infections related data records is relatively fewer compared with their DALYs (Figure 3).

In the top 20 number disease related data sets cited by publications, diabetes mellitus (65666.15) has the highest DALYs, and then is HIV/AIDS (59951.10) and trachea, bronchus, lung cancers (41121.34). Schizophrenia has the greatest number of cited data records, while its DALYs is not relatively high (13541.00) (Figure 4).

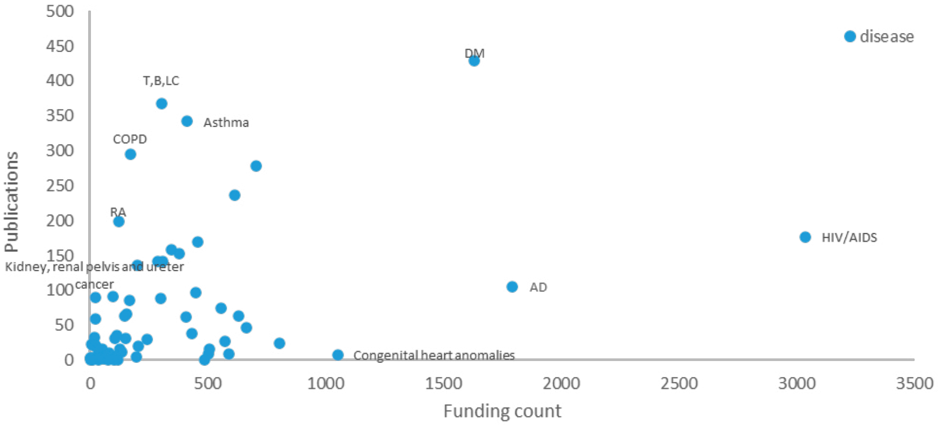


SCH: Schizophrenia; T, B, LC: Trachea, bronchus, lung cancers; MOSC: Melanoma and other skin cancers; DM: Diabetes mellitus; RA: Rheumatoid arthritis; BD: Bipolar disorder; IBD: Inflammatory bowel disease; AD: Alzheimer's disease and other dementias; AUD: Alcohol use disorders; EP: Epilepsy; AHC: Acute hepatitis C; BNSC: Brain and nervous system cancers; ADHDS: Attention deficit/hyperactivity syndrome; GD: Gynecological diseases; BC: Breast cancer

Figure 4. The relationship between the top 20 number of cited disease related data records and its DALYs

The relationship between the number of shared/reused data records and funding counts

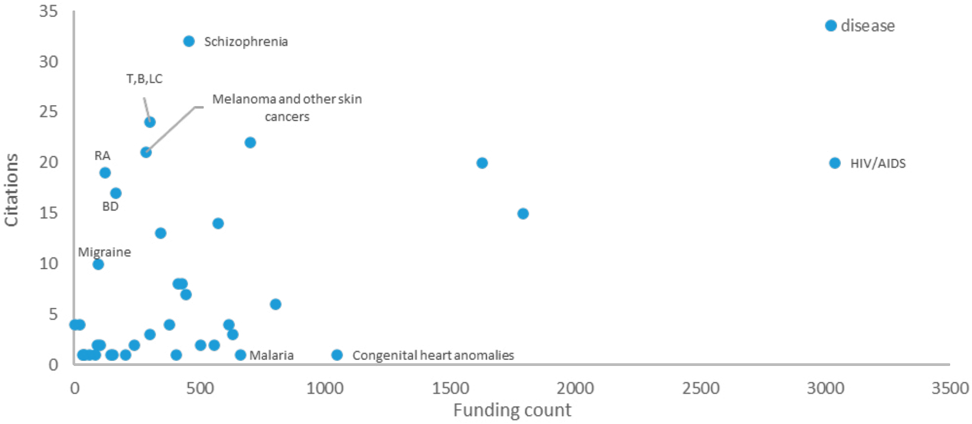
We have found that the total number of disease-related data records and that has been cited were positively correlated with their funding counts overall (Figure 5).



DM: Diabetes mellitus; T, B, LC: Trachea, bronchus, lung cancers; COPD: Chronic obstructive pulmonary disease; AD: Alzheimer's disease and other dementias

Figure 5. The relationship between the output of disease-related data records and its funding counts

For example, the diabetes mellitus ranked first by the number of shared data records and raked third by funding counts. But we also could see some diseases have fewer funding counts, but have a high level of data sharing, such as COPD, RA, asthma, kidney renal pelvis and ureter cancer and T, B, LC. The sharing of these data records may come from the interest of researchers, or it may be demand driven. But there are some diseases has a larger ratio of funding counts to data records sharing, such as HIV/AIDS, AD and congenital heart anomalies. The total number of disease-related data records and that has been reused were also positively correlated with their funding counts overall (Figure 6). But some diseases have a larger ratio of reused number to its funding counts, such as schizophrenia, melanoma and other skin cancers, RA, BD, migraine and T, B, LC. Some diseases have a larger ratio of funding counts to data records sharing, such as HIV/AIDS, AD and congenital heart anomalies.



T, B, LC: Trachea, bronchus, lung cancers; RA: Rheumatoid arthritis; BD: Bipolar disorder

Figure 6. The relationship between the citations of disease-related data records and its funding counts

Conclusions

Our study revealed that data sets are the main type of disease-related data records on DCI platform, followed by data studies and repositories. The overwhelming majority of data records are published in the recent five years, and show a trend of rapid growth year by year. However, the citations of data records are less than that of scientific publications, which may be related to the diversity of data records formats and the inconsistency of reference standards or norms, indicating that the standardized use of data (such as formal citation) needs to be further strengthened.

The mantra of the nascent open-data movement is that “scientists should share online all data underlying their findings”. It sounds simple, but it can be tough to achieve in practice. Many authoritative academic institutions in many countries have successively introduced and implemented various measures and policies to promote data openness and sharing. In 2014, the Gates Foundation announced that it would "require its funded researchers to disclose data", while some publications only encourage scientists to open their data (Van Noorden, 2014). The right to force researchers to abide by the rules of data use lies in the hands of editors and reviewers of journals, and magazines can formulate data citation policies to ensure that the used data is used in a standardized way (Roche, 2016). For example, *Science* and *Nature* have announced the policy of citing research data records in their journals (Hyoungjoo Park &

Wolfram, 2019). It shows that formulating data citation rules through scientific research funds and publications may have the effect of standardizing data formal citation to a certain extent.

According to the analytic data of data records sharing and reuse, the number of data records sharing for the following diseases can be appropriately increased in future research: Bipolar disorder, Inflammatory bowel disease, Alcohol use disorders, Acute hepatitis C, Brain and nervous system cancers and Breast cancer.

Highly cited data records may indicate diseases of high concern to a certain extent. Through correlation analysis of the number of data records corresponding to diseases, it can be found that the total number of disease-related data records and their citations by publications is positively correlated with DALYs as a whole. And more attention should be paid to Lower Respiratory Infections, Diabetes Mellitus and HIV/AIDS, which have a high disease burden.

Previous studies have shown that the burden of disease is not always strongly correlated with the amount of funds and scientific publications related to disease, for example, some underfunded or overfunded diseases can be found. And underactive or overactive disease areas can be also found (Yegros-Yegros, van de Klippe, Abad-Garcia, & Rafols, 2020b; Zhang, Zhao, Liu, Sivertsen, & Huang, 2020). We believe that the reason is that scientific research is driven by both interest and demand. Compared with the amount of funds and scientific publications, the sharing and reuse of data records should be more demand-driven, which mainly comes from disease burden or unmet clinical needs. We will verify it in future research for this hypothesis.

We analyzed the relationship between the data records sharing/reuse of diseases and the its funding counts. They have a significant positive correlation on the whole. However, some diseases deviate from this trend. Such diseases have many funding support but only can search a few data records in DCI, like HIV/AIDS, congenital heart anomalies, malaria and so on. This may because these diseases have a better prevention or control measure. The main purpose of funding is to promote some prevention or control activities, such as AIDS publicity and self-inspection materials distribution. Not scientific research. But some diseases have many data records but only a little funding support, such as diabetes mellitus, COPD, AD, asthma, and migraine. Most of this kind of diseases are chronic diseases. They do not have a good standard of care at present, and this may be why they have more data records than other diseases. And they may need more funding to have in-depth research. We need to explore the research field of highly cited data records in future research, so as to explore how these data records are used many times in subsequent research, such as whether important medical evidence is formed or even written into clinical practice guidelines, so as to evaluate the value of medical data.

Considering the limitations of DALYs, more indicators of disease burden should be included in future research to explore the research focus and development trend of health data records.

At present, the data on funding counts considered in our study only include 10 funding organizations. We will consider including the funding support data for more countries and international organizations to our study in the future research.

Acknowledgments

This work was funded by the National Natural Science Foundation of China (71603280, 72074006), and the Young Elite Scientists Sponsorship Program by China Association for Science and Technology (2017QNRC001).

Abstract

Power laws are a characteristic distribution found in both natural as well as in man-made systems. Previous studies have shown that citations to scientific articles follow a power law, i.e., the number of papers having a certain level of citation x are proportional to x raised to some negative power. However, the distributional character of altmetrics (such as reads, likes, mentions, etc.) has not been studied in much detail, particularly with respect to existence of power law behaviours. This article, therefore, attempts to do an empirical analysis of altmetric mention data of a large set of scholarly articles to see if they exhibit power law. The individual and the composite data series of ‘mentions’ on the various platforms are fit to a power law distribution, and the parameters and goodness of fit determined using least squares regression. We also explore fit to other distributions like the log-normal and Hooked Power Law. Results obtained confirm the existence of power law behaviour in social media mentions to scholarly articles and we conclude that altmetric distributions also follow power law with a fairly good fit over a wide range of values.

Introduction

A power law is simply expressed by the fact that if the probability distribution of measuring a quantity x varies as the inverse power of the same variable raised to a value k, $p(x) \sim x^{-\alpha}$, then x is said to follow a power law with exponent $-\alpha$ (Newman, 2007). Power laws were first noticed a century ago by Pareto in the context of income distribution (Pareto, 1896). They abound in nature as well as in the artificially created technology systems, most recently the Internet (Adamic, 2000; Faloutsos et al., 1999). Basically, any heavily tailed distribution could follow or model into the power law. This specific feature was observed in different disciplinary areas at different periods of time, over the last century by different people, and early power laws go by different names like the Bradford law (Bradford, 1934), Zipf's law (Zipf, 1949), Pareto’s law (Chen & Leimkuhler, 1986; Pareto, 1896). All these types of distribution models are said to imitate the Lotka’s Law (Lotka, 1926). Power law distributions involve various signature characteristics such as - if the full range is represented on the axes, the shape of the curve would be a perfect L. Also, if same distribution is plotted on log-log scale, then the curve is always linear in nature (Adamic, 2000). Also, the power law distribution is the only distribution that holds the scale–free property, i.e., the shape of distribution remains unchanged whatever be the scale at which it is observed (Newman, 2007). Egghe (2005) & Egghe (2009) explored power laws in information production processes (IPPs) and derived various properties associated with the power law in general IPPs and Lotkaian IPPs (where power law exponent $\alpha > 2$). Rousseau (1997) presented a webometric analysis perspective, wherein Lotka’s law was discussed with an indication of Power Law behaviours.

In the domain of scholarly articles, citations have been considered as a widely known parameter of impact assessment for a long time. Several previous studies have shown that Power laws are observed in the distribution of citations to scientific papers (Brzezinski, 2015; Redner, 1998, 2005; Thelwall & Sud, 2016). With the evolution of social media platforms and their increased use in scholarly publishing domain in the recent times, a new and quick event based impact measure has emerged, known as alternative metrics or 'altmetrics' (Priem et al., 2010; Priem & Hemminger, 2010). Many recent studies on altmetrics have pointed that they correlate with citations in different degrees (Banshal et al., 2021; Costas et al., 2015; Eysenbach, 2011; Haustein et al., 2014; Peoples et al., 2016; Shema et al., 2014; Thelwall, 2018; Thelwall & Nevill, 2018). Costas et al. (2016) applied the Characteristic scores and scales (CSS) method devised by Schubert et al. (1987) for selected altmetric platforms. That method classified articles into three classes and studied how those articles were distributed in three classes in different altmetric platforms. They also studied the implications of specific distribution in each platform for development of field-normalized indicators. Some studies, that analysed altmetric data of large sample of scholarly articles, have indicated that they are skewed in nature (Thelwall & Nevill, 2018; Thelwall & Wilson, 2016). However, the altmetric data distributions are not analysed in detail with respect to existence of power laws.

This article analysed the social media mention data drawn from four different platforms (Twitter, Facebook, News and Blog) for a large set of scholarly articles obtained from Web of Science database. Our objective was to test if altmetric indicators also follow power laws – as seen in the case of citations, the Internet, and numerous natural and man-made systems. The altmetric mention data for articles was visualized in log-log space. The individual and the composite data series of 'mentions' on the various platforms are fit to a power law distribution, and the parameters and goodness of fit determined using least squares regression. We also explore fit to other distributions like the log-normal and Hooked Power Law. The article attempts to answer following key research questions:

1. Do altmetrics indicators (mentions) follow Power Laws?
2. Will other distributions like hooked power law and discretised lognormal distribution be plausible for this data?

Related Work

Power law properties are ubiquitous in various natural and behavioural phenomena. Power laws are seen to appear in large, interconnected and self-organising systems. It has scale free nature and has applications in various domains like physics (e.g. sandpile avalanches), economics, linguistics, biology (e.g. species extinction), finance, information and computer science, geology, social science, astronomy etc. (Clauset et al., 2009; Newman, 2007). A lot of studies have been done regarding the emergence of power laws in diverse fields. Power Laws help in explaining various phenomena of Science (Mitzenmacher, 2004), Economics (Gabaix, 2009, 2016), Financial Time series (Bouchaud, 2001), and also network topologies (Faloutsos et al., 1999). The statistics for number of visitors to sites of the World Wide Web and distribution of visitors per site observed, and it approximated a power law (Adamic, 2000; Adamic & Huberman, 2001). There is a long list available as a proof of occurrence of power laws in various disciplines. Some of them mentioned in Newman (2007) are- word frequency count in texts, citations of scientific papers, web hits, copies of books sold, telephone calls, magnitude of earthquakes, diameter of moon craters, intensity of solar flares, intensity of wars, wealth of the richest people, frequencies of family names, population of cities and so on.

The first mention about the existence of power laws in the scholarly articles was made by Solla Price (Price, 1965) for the highly cited articles. Later on, he recommended 'cummulative advantage' mechanism which also can cause power law distribution (Price, 1976). Redner (1998) analyzed the citation distribution of scientific publications and found that the asymptotic tail of the citation distribution appears to be described by a power law, with exponent equal to 3. In another work, Redner analysed articles published over a century in the journal of physical review and found the tailed characteristics of citations (Redner, 2005). The exponent factor of highly cited papers and relatively lesser cited papers found to vary as studied by (Peterson et al., 2010). They analysed two types of mechanisms in citations namely 'direct' and 'indirect' mechanism. In this approach, three different set of scientific articles were examined. The existence of power laws in citations are relatively universally found in the context of research discipline (Radicchi et al., 2008). In a more comprehensive and elaborate empircal approach, Brzezinski (2015) detected power-law behaviour in the citation distribution. In this work, scientific papers published between 1998 and 2002 were drawn from Scopus and analysed. They found that the power-law hypothesis is not satisfied for around half of the Scopus fields of science.

A more robust and quantitative analysis of statistical distributions was performed by Thelwall (2016c) by considering data from 26 Scopus subject areas and seven years including 911,971 journal articles. The study considered three different models-the Hooked Power law model, the Truncated Power Law model, and the Discretised log normal model. He tested whether the discretised lognormal and hooked power law distributions were plausible for citation data. It was also tested if there were too many uncited articles, and zero inflated variants of the discretised lognormal and hooked power law distributions (Thelwall, 2016b). He examined best options for modelling and regression, and tried to detect which distribution best fit citation data by including and excluding uncited articles (Thelwall, 2016a). He concluded that the hooked power law and discretised lognormal distribution were the best options for complete citation data. Though, several studies (Costas et al., 2015a; Haustein et al., 2014; Eysenbach, 2011; Mohammadi et al., 2016; Thelwall, 2018; Thelwall & Nevill, 2018) have found positive correlations between citations and altmetrics, but there are just few studies on distribution patterns of altmetric data.

The only major studies on distribution analysis of altmetric data include analysis of online events- web usage counts (Wang et al., 2016), readership (Thelwall & Wilson, 2016) and download patterns (Duan & Xiong, 2017). Wang et al. (2016) investigated the Web of Science usage count to understand the distribution and the relation with citation counts. They analysed data for about 12,000 articles from five journals of information science domain. The 'usage count' for each article was analysed for fit with power law distribution and positive evidence of power law behaviours was observed for usage counts. The study by Thelwall & Wilson (2016) analysed about 332,000 scientific publications in 45 subfields of medical sciences domain drawn from Scopus database. The study observed the relationship between Mendeley reads and citations and also examined the distribution patterns of reads by exploring fitsto either lognormal or hooked power law. They concluded that, hooked power law is a better fit in case of citation data, but for Mendeley reads, it varied across 45 sub-fields. Duan & Xiong(2017) analysed the download patterns from the Chinese Library & Information Sciences using two-step cluster analysis, outlining the distribution for the same. The authors collected data from eleven chinese journals and grouped them into clusters based on the type of downloads. They concluded that the majority of sets followed power function in the case of absolute downloads. Costas et al. (2016) studied distribution patterns of citations and altmetrics (Mendeley reads, tweets, blogs) and found that twitter and blog mentions are extremely skewed distributions. They observed that it was largely caused by a large share of publications without any mentions on these platforms. There are, however, no previous studies on examining the distribution patterns of mentions in many popular social media platforms like Twitter, Facebook, Blogs etc., particularly with respect to Power Law behaviours.

Data

The article obtained the data for analysis from two sources: Web of Science and Altmetric.com. The scholarly article data was obtained from Web of Science (WoS) and the altmetric mention data for these articles was obtained from Altmetric.com.

The scholarly article data downloaded comprised for the whole Web of Science publication records for the year 2016. There was a total of 2,528,868 publication records for which the metadata was downloaded. The data was download in the month of Sep. 2019 and comprised of all document types. Out of the 2,528,868 records, only 1,785,149 publication records were found to have a DOI (Digital Object Identifier). We have, therefore, used the data for these 1,785,149 publication records for further analysis. This was done due to the fact that DOI was the link between Web of Science and Altmetric.com data. The altmetric data for these publication records was collected from the Altmetric.com aggregator through an automated DOI-based lookup process. The Altmetric.com aggregator accumulates social and online mentions of research output for more than 18 different social and online platforms (such as Twitter, Facebook, Blog, News, Mendeley etc.). Out of the 1,785,149 publication records, altmetric mention data for a total of 902,990 publication records was found and downloaded. **Table 1** provides the details of data. The data obtained from Altmetric.com had 46 fields, including DOI, title, Twitter mentions, Facebook mentions, News mentions, altmetric attention score, OA Status, Subjects (FoR), publication date, URI, etc. We have used the altmetric attention score and mention data for Twitter, Facebook, News and Blog for the analysis.

Table 1. Data collected from Web of Science and Altmetrics.com

Total WoS records (2016)	*WoS records with DOI*	*Publication records with Altmetric.com data*
2,528, 868	1,785,149	902,990

Methodology

For answering the first research question posed, the standard strategy for revealing a power law is to draw a size-frequency plot, i.e., to plot the number of papers N(k) with a given level of mentions k. In other words, we use the fact that a histogram of a quantity with a power law distribution appears as a straight line when plotted on a logarithmic scale (Newman, 2005). Therefore, the mentions were plotted using log-log plot and the parameters of fit calculated to ascertain the plausibility of a power-law. The plots were made for altmetric attention score and mention data for Twitter, Facebook, News and Blog platforms.

In order to answer the second research question, we have tried the following three models, which may all be characterised as empirical models: the truncated power law, the lognormal, and the hooked power law (Thelwall, 2016c, 2016a). Since the altmetrics data is discrete, while the lognormal is for continuous data we have used the Discretized lognormal distribution and tested them for goodness of fit against data taken from Altmetric.com.

Lognormal Distribution: It is a continuous probability distribution that fits data when the natural logarithm of the data follows a normal distribution. Since natural logarithm cannot be calculated for zero or negative numbers, hence only positive values are allowed for such distributions. The lognormal distribution is described as,

$$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-(\frac{\ln(x-\mu)^2}{2\sigma^2})} . \qquad (1)$$

It has two standard parameters, the mean (μ) and standard deviation (σ). Modifications are required in order to convert it into discrete form for discrete data. An offset 1 is added to the mentions for such calculation giving the ***discretized lognormal distribution***.

Hooked power law distribution: There are several other methods of conversion from continuous to discrete distribution (Thelwall, 2016c). The *hooked power law* is defined as,

$$f(x) = A * \frac{1}{(B+x)^{\alpha}} \qquad (2)$$

where an *ad hoc* parameter B is added to the variable x. Here the two parameters that affect the process are "A" and "B". Setting the offset parameter "B" to zero will lead to the pure form of the power law.

Truncated Power Law: A better fit to data can be obtained by simply truncating the data series at the tail end. Again the process is ad hoc. Since the tail of the distribution is sparsely populated, the data loss may not be high. However since the fluctuations are high in the tail region, by truncation we effectively reduce fluctuations and obtain a better model fit to data. Various multiplicative models are also used to generate such distributions. Only a small change from the generative process of one, leads to the other distribution. The power law gives a good visual fit but when logarithms are used the relationship between the raw variables may not be as accurate.

Results

In order to understand the distribution of the data, the four prominent platforms in Altmetric.com data along with the composite score have been explored, namely, Facebook, Twitter, Blogs, News and Alt-score (a combined index created out of all the other indicators). The mentions were plotted using log-log plot and the parameters of fit calculated to ascertain the plausibility of a power-law. We find that the altmetrics data when plotted show reasonably good linear fit (Figure 1). The figure shows plot for the full as well as truncated data. In each case, supplement '1' corresponds to full data and supplement '2' corresponds to truncated data. The power ranges between -1.661 to -2.614, and the variance squared explained by the model ranges between $0.8769 < R^2 < 0.9683$.

Truncated Power Law

It is easy to see from the plots (Figure 1) that the fit may look good, but the parameters are not too high ($R^2 <\sim 1$). $R^2 = 0.9682$ for Blogs, which gives the best fit to a power law. The least value of R^2 is 0.8769 for Twitter with poorest fit (Table 2).

Can the degree of fit of the Power Law be improved? By truncating the distribution in the tail, it is possible to obtain a better fit. It can be seen from the plots that the fit becomes poor at high values of accumulated mentions. In other words, there are only a few papers that merit a high rate of mention, and therefore there are statistical fluctuations at this end. By truncating the distribution at the high frequency end, we get an improvement in the degree of fit, without losing too many data points. Truncation was tried only with the Alt-score, Twitter and Facebook variables, as the data series for News and Blogs were short and therefore not suitable for truncation. The increase in the parameter of fit, R^2 was 1.2%, 9.6% and 6.3 %, respectively, for the Alt-score, Twitter and Facebook (Table 2). The truncated graphs are labelled with the subscript ‘2’ for each of the variables. (Figure 1, Table 2).

Note: In each case, supplement '1' corresponds to full data and supplement '2' corresponds to truncated data.

Altmetric data fit to other distributions: Hooked Power Law and Discretized Lognormal

As we have seen truncation of the data series can improve the goodness-of fit of the Power law model to altmetrics data. However, it can be argued that we are essentially throwing away data in order to get a good fit. Neither can it be theoretically specified which range of data to discard. There could be other distributions, other than the Power law, which give an equally good fit, or even a better fit. These distributions need to be tested against the data. We try two alternative distributions discussed by Thelwall (2016c).

An alternative to assuming that the distribution of the altmetric variables is a power law, or close to a power law, would be to look for other distributions that give a close fit to the data, this is the second research question we have noted. For addressing the second research question, the plausibility of hooked and discretised lognormal power law in altmetric data is tested. The hooked power law concept is based upon the impression that citation can occur in two processes. One of them is that citations can be accrued randomly and in the other concept, one article is getting cited due to its' earlier citations. Merging these two phenomena then the probability that an article attracts *k* citations is proportional to $1/ (B + k)^{\alpha}$. When the offset parameter, B converges to zero than it shows the distribution of pure power law (Thelwall, 2016c).

Two bootstrapped samples were drawn from all four altmetric sources (Twitter, Facebook, Blog and News) to examine the same. As mentioned by Clauset et al. (2009) if data is compatible with power law distribution, then the data is also prone to be comparable with other empirical distributions like Discretised Lognormal, Hooked and Stretched Exponential distributions. Therefore, we checked the plausibility of Hooked and discretised lognormal distributions using standard statistical techniques. The statistical approach that is followed for such calculations is stated. First, we have to consider a hypothesis based on data and then check the plausibility of the hypothesis. Given a hypothesized power law distribution from which our observed data is drawn, we are interested in finding that our hypothesis is a plausible one, given the data. We apply Kolmogorov-Smirnov (KS) statistic for estimating the *goodness of fit* for given data and calculate p-values based on KS statistic. If the p-values are larger than the level of significance, then we do not have sufficient proof to reject the hypothesis i.e., accept the null hypothesis otherwise, we reject the null hypothesis. Note that in this paper, we consider the level of significance as 0.05. To check this plausibility a code implemented earlier by Thelwall(2016c) for citation data has been used.

Table 3. Statistical values of Hooked Power law and lognormal distribution for altmetric data

	Hooked Power law				***Lognormal Distribution***			
	A	*B*	*ks*	*p value*	*μ*	*σ*	*ks*	*p value*
Twitter	2.235	6.709	0.032	0.481	1.701	1.525	0.040	0.266
Facebook	80.566	208.29	0.316	0.000	0.990	0.494	0.151	0.000
Blog	99.990	240.95	0.335	0.000	0.942	0.468	0.176	0.000

Discussion

The existence of power law characteristics have been widely explored for diverse data from many disciplinary domains, including citations, which are the most prevalent and useful impact indicator of the scholarly articles (Brzezinski, 2015; Peterson et al., 2010; Radicchi, Fortunato, & Castellano, 2008; Thelwall, 2016c, 2016a). Given that the altmetric mentions are found to correlate with citations (Thelwall & Nevill, 2018; Banshal et al., 2021; Shema et al., 2014; Thelwall, 2018) and that they are skewed in nature (Thelwall & Nevill, 2018; Thelwall & Wilson, 2016; Costas et al., 2016), it would be an interesting exercise to explore if altmetric mentions follow power laws. Yet, this property had not been put to the test so far. Our approach has been to investigate the plausibility of the existence of power law behaviours in altmetric mentions. The plots in the log-log space indicate existence of power laws in different kinds of altmetric mentions. It is also found that truncation of the data series can improve the closeness of fit. We obtained an increase in the R^2 parameter from about 1 to 9% by truncation of different altmetric data series such as Twitter, Facebook and the aggregate score Alt-score (Table 2). Subsequently, hooked power law and discretised lognormal behaviour have also been explored on bootstrapped samples (Table 3).

Power Law in Altmetrics

The first step in scrutinizing the existence of power laws in altmetric data is the log-log plot for mentions across several social media platforms- Facebook, Twitter, etc. and the composite score built from all individual scores. Altmetric.com also collects data from other platforms not mentioned here, which we have not included in the study due to the sparseness of data. The plot is shown in Figure 1, from which, it is observed that an approximate straight line can be fit to the data plotted on a log-log plot. This is the first characteristic of power laws and verifies the presence of power laws in altmetric mentions. These plots also specify the parameters of fit. These values help in analysing the nature of the plots and also determine where the majority of the distribution of data lies. The low (<=2) value of the power-law scaling exponent reflects an infinite (or divergent) mean, whereas mean is finite/converges for exponent>2. If $\alpha<2$, it means that most of the mentions lies in tail of the distribution. Further, the median exists for exponent (B) >1 and also, variance exists if exponent >3. The parameters of fit have been listed in Table 2.

In the table 2, value of R^2 indicates the variance explained by the model, high value of R^2 is necessary for acceptance of the power law distribution (Clauset et al., 2009). It is also a positive evidence for our first research question. Hence, we can draw the conclusion that altmetrics mentions do follow a power law. These parameters of fit provide evidence of existence and degree of fit, but do not prove that the power law is the sole model for the observed data.

Discretised lognormal and Hooked Power law in Altmetrics

After having conclusive evidence of power law in altmetric mentions, our second investigative point was to check the plausibility of discretised lognormal and hooked power law in altmetrics. To do so, we have drawn samples of 500 random observations from each category of data and then tried to estimate the population parameters for the same. Next, we applied KS statistic for estimating the *goodness of fit* for given data and calculated p-values based on KS statistic for each individual category. The results are summarized in Table 3.

Since the p-values of Twitter for both distributions is greater than the level of significance, it indicates that we don't have enough evidence to reject the hypothesis. Hence for twitter mentions, discretised lognormal and hooked power laws are also a plausible form of power law. Whereas in the case of Facebook, blog and news mentions, the p-values are less than the level of significance, which means these mentions do not provide a good fit for hooked and discretised lognormal distributions. Note that in this paper, we consider the level of significance as 0.05. There could be several factors for such low p-values. One could be that, these distributions are better observed only above a certain minimum value. Next could be that there are always some deviations because of the random nature of sampling.

In this approach also, altmetric mentions show similar trends like citations to some extent as both discretised lognormal and hooked power law are found to be plausible for the citation data (Thelwall, 2016c, 2016a). Though, the online mediums like blogs, news and Facebook do not show enough proof of the existence of discretised lognormal and hooked power law, Twitter is showing some indication towards the plausibility of these modified forms.

This discussion shows that altmetric data do follow power law distribution (Table 2). Truncation of some data in the tail of the distribution improves the degree of fit. Furthermore, discretised lognormal and hooked power law provide a good fit for Twitter (tweets). Other social media platforms like Facebook, blog and news mentions do not have a good fit for the same distributions. For these the power law provides the best fit. One could further explore other forms of power laws or exponential distributions, but it appears unnecessary as the degree of fit to power law is reasonably good as seen from Table 2 and data truncation.

Conclusion

We report here on the occurrence of power laws in altmetrics, where our data on altmetrics constitute counts of mentions and reads about scientific articles. While not entirely surprising, it is nevertheless interesting to see more and newer systems getting subsumed under the same law. Not only do the above categories follow power laws, but we find that the composite altmetrics index, created by combining individual altmetric indices, also follows a power law. Finally, we test some models, used by authors earlier in similar contexts, with the observed data we have gathered from Altmetric.com.

The study draws useful information on the nature of social media data of scholarly articles, chiefly whether they follow power law distributions which have been found to be ubiquitous in many natural and man-made systems. We find that the distribution of altmetric data does follow a power law, but with variable goodness of fit for the various social media data. For a closer fit, we tried using the discretised lognormal and hooked power laws. We find that to a fair degree of approximation ($R^2 > 0.9$) data from the four social media platforms and the composite data follow power laws. The degree of fit can be further improved by some data truncation in the tail. As future endeavours, one can address and discuss the implications of existence of the power law in Altmetrics.

Acknowledgments

The authors would like to acknowledge the support of Stacy Konkiel, Director of Research Relations at Digital Science, for providing access to Altmetric.com data.

Abstract

With the amount of open access (OA) mandates at the funder and institution level growing, the accurate measurement of OA publishing is an important policy question. Existing studies have provided estimates of the prevalence of OA publications ranging from 27.9% to 53.7%, depending on the data source and period of investigation. This paper aims at providing a comparison of the proportion of OA publishing as represented in two bibliometric databases, Web of Science (WoS) and Dimensions, and assess how it affects the measurement of OA across different countries. Results show that publications indexed in Dimensions have a higher percentage of OA than those indexed by the WoS, especially for publications from outside North America and Europe. The paper concludes with a discussion of the cause and consequences of these differences, motivating for the use of more inclusive databases when examining OA, especially for publications beyond North America and Europe.

Introduction

Over the past 30 years, the democratization of the internet has allowed researchers to make their publications freely available on a worldwide scale. This practice, also known as open access (OA), allows anyone with an Internet connection to access, read, distribute, and download scientific publication for free with no legal or technical barriers. OA publishing is no longer a marginal phenomenon: for the most recent years, nearly half of all scholarly publications are estimated to be freely available online (Piwowar et al., 2018). This is due to a massive rise in OA mandates (Larivière & Sugimoto, 2018), the introduction of several new OA publishers and of OA options from legacy publishers, the creation of software that facilitate the production of publications (such as the Public Knowledge Project), and the rise of OA mega-journals such as PLOS ONE. The advantages of OA have been highlighted in the scientific literature such as a higher global visibility (Evans and Reimer, 2009), higher citation rates (Archambault et al., 2014; Piwowar et al.,2018), and a better use of taxpayers' money (Suber, 2003). Several studies have attempted to assess the overall share of OA publications in the scientific literature, with results ranging from 27.9% to 53.7%, depending on the data source and period of investigation (Piwowar et al., 2018; Archambault et al., 2014; European Commission, 2019). This study aims at providing a comparison of the proportion of OA as represented in two bibliometric databases, Web of Science (WoS) and Dimensions, and assess how the different coverage of these two databases may affect the measurement of OA across different countries.

Data sources

The Science Citation Index (SCI) was originally developed by Eugene Garfield (1955) to help librarians and researchers to find articles and journals relevant for their work through their references. Since it was impossible to manually cover the entire range of journals (~50 000 at the time; Garfield, 1955), only the most cited publications were indexed in the SCI and eventually in WoS. WoS was the main source of data used by researchers in the bibliometrics community for decades. However, over the past 15 years, there have been a multiplication of new bibliometric sources of data such as Scopus (2004), Google Scholar (2004), Microsoft Academic (2016), and more recently, Dimensions (2018), which all offer different coverage of the scientific literature. Given their different coverage and indexation practices, the use of a given bibliometric data source may affect the results obtained. Mongeon and Paul-Hus (2016) have shown that WoS' and Scopus' coverage differed considerably: WoS has a significantly lower coverage of research in social sciences and humanities from non-English-speaking countries compared to Scopus. Similarly, Dimensions has much broader coverage than both WoS and Scopus (Herzog, Hook, & Konkiel, 2020; Visser, van Eck, & Waltman, 2020), given that indexing is not based on selective criteria (e.g., citations) but rather on a technical component: the presence of a Digital Object Identifier (DOI). However, the effect of this larger inclusion on the measurement of uptake of OA remains largely unknown.

Open access and developing countries

Developing and developed countries have historically differed in terms of preferred approaches to OA. Developed countries tended to make use of repositories, with self-archiving mandates in place at many institutions (Jingfeng et al., 2012) and by funders (Sugimoto & Larivière, 2018). These mandates are supported by corresponding infrastructure, such as the government-funded PubMed repository or institutional repositories. These types of infrastructure are less prevalent in developing countries as reported by the Registry of Open Access Repositories (https:// http://roar.eprints.org/). On the other hand, authors from developing countries tend to make use of OA journals when rendering their publications OA (Sotudeh & Horri, 2008: 71). Several factors can explain the difference in self-archiving facilities and practices. For instance, developing countries do not necessarily have access to the same technological infrastructure (i.e., computer servers, computers, access to internet) as developed countries (Evans and Reimer, 2009). OA is built on the assumption that Internet access is a basic public utility that is available to everyone. This flawed assumption places developing countries at a significant disadvantage when discussing OA (Ouangré, 2020). For example, in 2018, nearly 75% of the African population did not have access to the internet (Broadband Commission, 2019). Various platforms have emerged aiming to increase online visibility of research publications from developing countries and to combat the effect of the serials crisis (Das, 2015), with the focus on supporting and launching OA journals. Such platforms include AJOL (Africa), AmeliCA (Latin America), and SciELO (Brazil).

Methods

We investigated all the journal-based publications indexed in WoS and Dimensions for the publication years 2015 to 2019 for which first author country affiliation data is available. We used Unpaywall's five-categories classification system (Piwowar et al., 2018) to identify the OA status of publications.

- **Gold:** Published in an OA journal that is indexed by the Directory of Open Access Journals (DOAJ).
- **Green only:** Toll-access on the publisher page but is free in an OA repository.
- **Hybrid:** Free under an OA license in a toll-access journal.
- **Bronze:** Free to read on the publisher page, but without a clearly identifiable license.
- **Closed:** All other publications, including those shared only on an Academic Social Network (ASN) or in Sci-Hub.

More generally, OA publications are defined in this paper as all publications that are not in the "closed" category. We also investigated publications by region. Each publication is assigned to a single country based on the country affiliation that appeared on the publications for the first author. Countries are then categorized by region. The classification system we used is the World Bank Country Classification by Region for 2020 (World Bank 2020).

Results

For the years 2015 to 2019 WoS indexes a total of 8,053,050 publications for which affiliation data is available, whereas Dimensions indexes 10,743,016 publications. Of these publications, 43.4% of WoS publications and 46.6% of the Dimensions publications are available as OA publications, as shown in Figure 1. The largest differences observed between the two datasets are for the "green only", and "bronze" categories, with a larger percentage of OA publications in WoS for the former, and a larger percentage in Dimensions for the latter. These global results are not surprising: as shown by Visser et al. (2020), most of WoS papers are actually indexed in Dimensions — although their metadata is often incomplete.

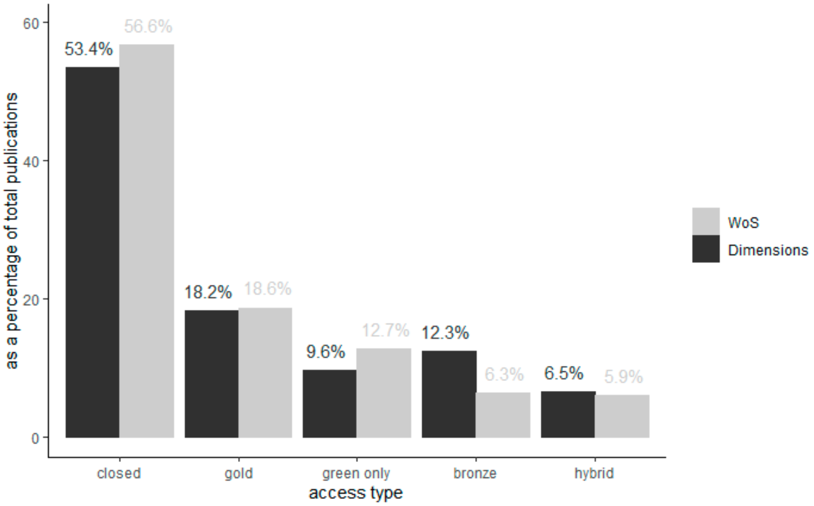

Figure 1 Percentage of open access publications, by access type and database, 2015-2019.

When we investigate publications by region (Figure 2) for the two databases we observe that the percentage of publications that are OA are similar to each other for North America, Europe and Central Asia. For the other regions, the percentage of OA publications in Dimensions are significantly higher than in WoS, especially for South Asia (+57.9%), Latin Americas and the Caribbean (+36.6%), the Middle East and North Africa (+33.5%) and, to a lesser extent, Sub-Saharan Africa (+12.4%).

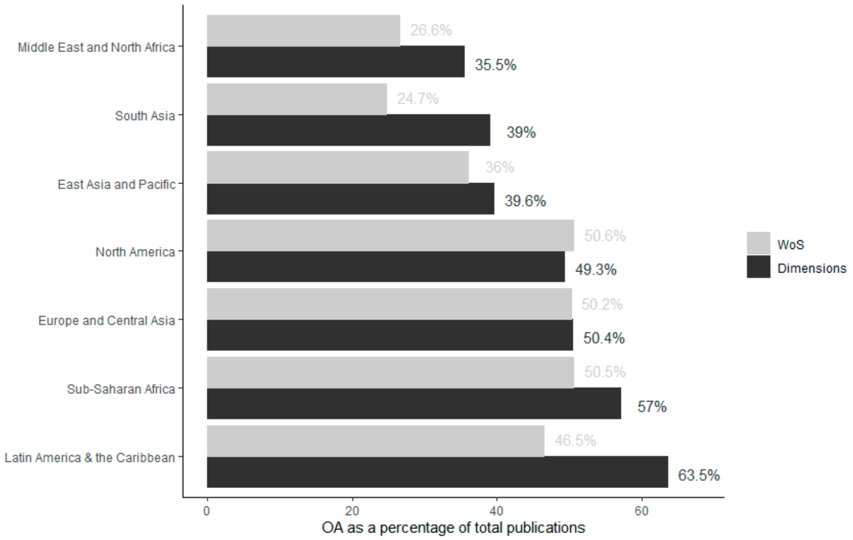

Figure 2 Percentage of open access publications, by region and database, 2015-2019.

To further examine these differences, we investigated the percentage of OA publications for the individual countries, with a specific focus on those countries for which a substantially higher percentage of publications are OA than in the other dataset. We only considered those countries for which more than 100 publications are indexed in both datasets for the period of investigation. In Figure 3 we present the results for the top 10 countries with the largest difference between the two datasets. When examining the top 10 countries with the largest difference in favour of Dimensions we can observe substantial differences in percentage of OA publications, ranging from 24.4% to 46.0%. For WoS, we see a smaller range, from 2.4% to 9.5%.

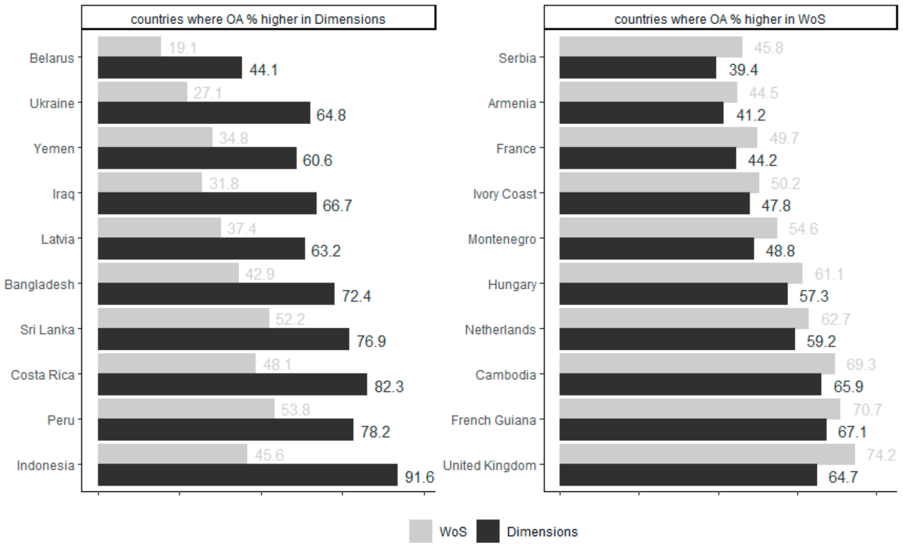

Figure 3 Percentage of open access publications, for selected countries and database, 2015-2019.

Discussion

Our results show that the measurement of OA differs when using WoS or Dimensions, and that the difference is more striking for authors from outside North America, and Europe and Central Asia. Given the Western bias of journals indexed in WoS (Mongeon and Paul-Hus, 2016)—which are also indexed in Dimensions (Visser et al., 2020)—the measurement of OA in these regions does not vary much in the two databases. However, for the other regions, which generally have their scientific production underestimated in WoS, the additional publications that are indexed in Dimensions are much more likely to be OA. More specifically, as Dimensions has much broader indexing, this higher percentage of OA publications is potentially due to the inclusion of smaller national journals. Further research is required to investigate the characteristics of the additional publications included in Dimensions.

This has further implications for the distribution of the different types of OA, as the literature suggests that the countries generally represented in WoS are also those that tend to more often make use of self-archiving (green OA). This potentially explains the larger percentage of green OA publications in WoS, as various mandates are applicable, and many repositories are available, to these authors. The higher percentage of bronze OA in Dimensions could reflect the inclusion of many non-DOAJ listed journal publications in Dimensions. It is likely that these bronze OA publications are in journals not published by the major publishers and lack the same level of standardization in metadata, resulting in difficulty classifying the publications and their inability to be indexed in DOAJ.

Lastly, this difference in measurement is most clearly illustrated at the level of countries. If WoS is used to measure OA for countries, it can significantly underestimate the percentage of OA publications for some countries in comparison to a more inclusive database such as Dimensions. Just as OA aims to provide visibility and access to research publications beyond toll-access journals, Dimensions provides a lens to investigate a broader number of publications, as opposed to only those that are considered to be the most relevant or core by WoS. What our analysis has shown is that the measurement of OA may differ significantly when one looks beyond this scientific core. Ultimately, Dimensions has the potential to be a more suitable platform for a more inclusive measurement of OA uptake, especially of publications by authors from outside North America, Europe and Central Asia, where mandates, repositories or infrastructures are not as prevalent.

Abstract

There is a growing interest in determining the factors that influence a journal's flipping to Open Access (OA). Using semi-structured interviews combined with bibliometric indicators, this paper uncovers the perception of Spanish managers related to Open Access and the decision to flip. The key research questions are twofold: How well do bibliometric measures reflect the changes in the status of the journal? How do journal managers perceive the flipping process? In order to answer these, twelve semi-structured interviews were conducted with journal managers of Spanish Journals. The findings suggest the great majority of managers are aware of the indicators, but only two mentioned they reflect their reality. An increase in the number of submissions, visibility, or internationalization since the transition is perceived as a benefit while the loss of interchanges with other institutions is seen as the major drawback. Although flipping to OA is perceived by the managers to have many advantages, it raises some challenges too, especially the need for funding, lack of resources capacity for technical support, and the creation of alliances.

Introduction

Several studies have analyzed the motivations to publish in Open Access (OA) journals at different levels. At the author level, in a survey comparing OA-authors and no-OA authors, Swan and Brown (2004) found that the main motivations for publishing in OA, as opposed to publishing in subscription-based journals, were free access, faster publication times, and larger readerships. In a large-scale international survey of authors' perceptions, Rowlands, Nicholas, and Huntingdon (2004) found that reputation, impact factor, or speed of refereeing are essential in authors' choosing OA. Based on surveys and interviews, Kim (2010) investigated the factors that motivate or impede faculty participation in self-archiving practices, ranging from web pages to OA repositories. He identified seven factors (in descending order of importance): (a) altruism (the idea to provide OA benefits to users); (b) perceived self-archiving culture; (c) copyright concerns; (d) technical skills; (e) age; (f) perception of a non-harmful impact of self-archiving on tenure and promotion; and (g) concerns about additional time and effort. A longitudinal analysis by Xia (2010) analyzed the changing pattern of scholars' attitudes OA journal publishing from 1991 to 2018. This author observed an increase in the publication and awareness rates for OA journals despite the concern related to the prestige of the journal. In a similar study, Togia and Korobili (2014) explored the attitudes and perceptions toward OA presented in different studies and found differences across countries and disciplines. Free access which facilitates wider dissemination is a strong incentive, while the author-pays model, the quality of peer-review, and the impact of the journals are perceived as major concerns. Later, Nelson and Eggett (2017) surveyed chemistry authors from OA journals to determine why they chose hybrid journals. Among the main reasons, funding mandates and receiving higher numbers of citations are highlighted. Furthermore, altruistic reasons, such as providing scientific results to the wider public and to other researchers who might not have the financial means to obtain the articles otherwise, were found to play an important role. Rowley et al.

(2017) revealed a high level of uncertainty about future intentions in scholars' attitudes and behaviors toward publishing their research in OA journals, with small differences between disciplines'. In a recent study, Heaton, Burns, and Thoms (2019) surveyed 250 authors at Utah State University about their motivation of publishing OA articles. In this study, the ability to pay publication charges, disciplinary colleagues' positive attitudes toward OA, and personal feelings such as altruism and desire to reach a wide audience were mentioned as main factors.

Following up on a similar 2013 survey, a study published in 2021 tracked the changes in attitude towards OA publishing among faculty in Information Studies schools (Peekhaus, 2021). In agreement with recent research, this study revealed that engagement with OA has increased significantly between 2013 and 2018, but it observed a high level of uncertainty about future perception of OA. At the same time, the work outlined that some of the historical concerns of OA publishing are dissipating, such as those regarding the perception of quality, and underlined that even the willingness to pay for articles processing charges (APC) has increased significantly.

While there are many studies that explore OA perceptions at the *author* level, few studies addressed the perception of journal *managers*. From the perspective of the senior managers, Wakeling et al. (2019) examined the motivations for launching an OA mega journal (OAMJ). Two motivations were in line with OA: a) supporting the OA movement, which can be seen as a societal benefit; and b) the 'effect change' which is perceived as an opportunity for experimentation (e.g. open peer review) or a change at the systemic level (e.g. transform scholarly communication). In the Spanish context, Segado-Boj, Martín Quevedo and Prieto-Gutiérrez (2018) conducted 15 interviews with managers of Spanish journals to study their perception towards open access, open peer review, and altmetrics. Open access is perceived as a positive factor as managers highlighted many advantages (e.g., improving scientific dialogue, availability of the content, achieving higher visibility). However, this model also generated concerns: the difficulty of making the magazine profitable or the creation of an economic barrier for authors that could not afford the payment. Robinson and Scherlen (2009) surveyed managers of dozens of journals in criminology and criminal justice. These authors found that the managers were highly supportive of the OA principles, however, they had a more favorable view of traditional journals rather than of OA journals.

At the Spanish level, a few studies analyzed the perceptions of OA authors in Spain. Hernández-Borges et al. (2006) surveyed medical authors to determine their awareness and attitude towards OA publishing and the ''author pays'' model. These authors were found to have a low level of awareness of this model as well as a low acceptance of journals charging author fees. Ruiz-Pérez & Delgado-López-Cózar (2017) surveyed 554 researchers from different fields and concluded that 76% consider OA beneficial for their discipline. Serrano-Vicente, Melero, & Abadal (2016) analyzed the awareness of open access among the academic staff of a Spanish university and found that many respondents supported OA. In addition, the decision to publish in OA is directly related to academic reward and professional recognition. However, to the best of our knowledge, no previous study has conducted an analysis at the manager level in the Spanish context.

Methods

The use of qualitative interviews has the potential to detect issues not covered in the literature. Interviewing journals can provide answers to the following questions: How well do bibliometric measures reflect the changes in the status of the journal? How do journal managers perceive the flipping process?

Twelve semi-structured interviews (see interview guide at Bautista-Puig et al., 2021) were conducted with managers from Spanish journals collected in the first study by the current authors (Bautista-Puig et al., 2020). For more information the reader is referred to this article.

This technique provides a flexible tool for small-scale research as questions can be adapted, allowing for unexpected answers whilst also clarifying the interviewee's response. It also allows for a deeper insight into the respondent's views. The sampling procedure identified the participants through contact information with the journal websites. Out of 24 journals identified in the first round, twelve responded positively to the request to participate, two declined and ten did not respond after sending two reminders. All the interviews were conducted online, digitally recorded, and transcribed for analysis. The length of the interviews ranged from 40 to 90 minutes. The answers were coded subjected to a thematic analysis (Braun and Clarke, 2006) in the process to facilitate further analysis. These codes represent themes which emerged by combining insights from existing literature with the data. A data matrix was created with variables identifying the questions and values identifying specific answers to a question. Secondary data analysis of bibliometric indicators of each journal from SCImago Journal Rank (SJR), a database with journal indicators based on data from Elsevier's Scopus, complemented the primary data, highlighting the importance of adopting a mixed-method approach. Adoption of these methods enabled the current authors to observe how open access is conceptualized and operationalized across different journals from different fields, and to discuss the motivations underpinning Open Access. Table 1 lists the participants by subject category associated with the journal, the age of the journal, and the validated transition year. The sample represents different disciplines from philosophy to engineering. In total, 12 journals were interviewed, between June 2020 and October 2020.

Table 1. Participants characteristics

Journals	*Branch of science (based on the LCC Subject Category)*	*Starting year and age of the journal*	*OA year validated*
Participant 1	History (General) and history of Europe: History (General)	1964 (53 years)	2006
Participant 2	Geography. Anthropology. Recreation: Anthropology: Ethnology	1944 (73 years)	2006
Participant 3	Medicine: Surgery	1975 (42 years)	2006
Participant 4	Geography. Anthropology. Recreation: Geography (General)	1940 (77 years)	2006
Participant 5	Science: Geology	1966 (51 years)	2003
Participant 6	Technology: Home economics: Nutrition. Foods and food supply	1960 (57 years)	2006
Participant 7	Science: Botany	1879 (38 years)	2006
Participant 8	Technology: Electrical engineering. Electronics.	1949 (68 years)	2006
Participant 9	Science: Biology (General): Ecology	1945 (72 years)	2006
Participant 10	Technology: Home economics: Nutrition. Foods and food supply |	2012 (5 years)	2013
Participant 11	Language and Literature: Philology. Linguistics | Philosophy	1941 (76 years)	2006
Participant 12	Philosophy. Psychology. Religion: Philosophy (General)	1952 (65 years)	2009

The objective of the interviews is a) to gain a better understanding of the journal flipping process by journal managers' view, and b) to determine the contextual factors that influence the (un)success of OA flipping journals.

Results

Performance of bibliometric indicators

Half of the journal representatives (Nos. 3, 5, 6, 7, 9, 10, 12) were familiar with bibliometric information while the indicator showing the countries citing a journal surprised them the most. Even though many managers see the use of journal-level indicators as part of their editorial duty to try to improve the indicators (Krell, 2010), the lack of indicators awareness was associated with a lack of time or staff for monitoring this information (Nos. 1, 2, 3). In terms of how well bibliometric measures reflect the development of the journal, only two managers agreed they 'reflect the reality' (but some have concerns in only attributing this change to OA).

Benefits and cons of the transition and barriers identified

Table 2 summarizes the benefits and disadvantages related to the transition towards OA identified by the journal's interviewee ranked by descending order of frequency. The number of benefits outstands the number of cons, denoting a positive attitude towards the benefits perceived by the journals since the flipping. Within the main benefits, the increase in visibility is highlighted. This is in line with findings from several previous studies at the author level (Warlick and Vaughan, 2007; Williams et al., 2019) and at the journal level (Segado-Boj, Martín Quevedo, and Prieto-Gutiérrez, 2018). Almost half of respondents observed an increase in the number of submissions and publications. However, as pointed out by Participant 10, this increase in number of submissions does not imply an increase in the 'quality', and the selection of papers even becomes more difficult. In contrast, many participants did not identify any drawbacks (e.g. nrs. 1, 2, 3, 5 or 6). The loss of interchanges was pointed out by five of the interviewees (1, 2, 3, 8, 9). The lack of resource capacity was also mentioned by some participants (1, 8, 10, 12), meaning that an increase in the number of received manuscripts also leads to an increase in work. Such an increase could become unmanageable, and it could become especially difficult for journals managed by few people (1, 8, 10, 12). Participant 8 even considered the increase in the number of submissions as negative for them, stating 'we didn't have the capacity to manage this large number, we need to find enough reviewers to follow the publication standards'.

Table 2. Benefits and drawbacks identified by the interviewees (participant number between brackets)

Benefits	***Cons***
Increase in visibility (1, 2, 3, 6, 7, 9, 10, 11)	Loss of interchanges between institutions (1, 2, 3, 8, 9)
Increase in the submissions and publications (1, 2, 3, 6, 9, 10)	Lack of resource capacity: increase of workload (1, 8, 10, 12) or lack of knowledge about the processes (e.g. request a DOI, obtain data in xml…) (10)
Increase of the internationalization (2, 3, 9)	Competence with big publishers (4, 5,10, 11)
Chance to publish in other languages (1, 2, 9)	Loss of national languages i.e. more papers on English-speaking languages (12) and loss of readers (2)
Better accessibility (1, 3)	No increase in the submissions (12)
Reductions of costs e.g. images in a paper (5, 9)	
Acceptance and happiness with the decision within the editorial board (7) or the authors (12)	
The prestige of the host institution and the journal (4)	
Increase of the citations/JIF (6)	
An increase of the acceptance of peer review requests (as the journal is more widely recognized) (10)	
Adoption of a platform for the management of the journal (12) i.e. Open Journal System (OJS)	
Better quality of the papers (9)	
Having the capacity to take decisions about the management of the journal (10)	

Finally, it is also important to observe that some interviewees attributed the evolution of the journal not to OA, but rather to other factors. As an example, the integration of the journal into Journal Citation Reports (JCR) and the change of the journal's publication language to English were highlighted as the main drivers of change (nrs. 7, 8). This perception was also shared by Participant 10, who pointed out that other changes took place in his journal at the same time (namely its entry into SCIELO, a large Brazilian literature database) and, therefore, concluded it was not possible to draw a firm conclusion about the benefits directly related to OA. However, the decision to enter into Scielo was partly driven by OA. Another reason is the interdisciplinarity of the journal (1, 2). For Participant 5, the change was described in terms of the transition from paper-based to electronic publishing, not as a flip to OA itself.

Challenges for OA in Spain

Regarding the question of the main challenges towards OA in general and particularly in Spain, different views were expressed (Table 3). The need for funding for OA is a widely shared challenge. Despite the fact that the majority of journals receive funding from the host institution, the problem is the scarceness of resources which allow only for subsistence. Participant 10 believed there must be an institutional initiative to maintain open access without charging authors and readers. In addition to money, the lack of recognition was also pointed out by the journal managers. They feel they do not have any additional recognition with incentives or rewards for being OA (7). Another widely accepted challenge mentioned by the interviewees is the lack of resources capacity or technical support in general. Participant 2 commented that it was difficult to differentiate the roles within the journals between the management, the authors, and the technical staff because they are all sharing tasks. For instance, technical staff is not only dedicated to one single journal but to five more journals, and the managers are performing management tasks of the journal. In social sciences and humanities, technical staff is even scarcer.

Table 3. Challenges identified by the interviewees

Challenges identified
Lack of resources capacity or technical support (1, 2, 8, 10, 12)
The need for funding (1, 7, 10, 11)
Get institutional help or agreements to maintain OA without charging authors and readers (5, 6, 10)
Competence with the big publishers, especially when you are a 'small journal' (7, 10, 12)
'Appreciation of OA' and change of mind of researchers (3).
Maintain and value national publication languages (4)
Resistance to flip to OA, especially in Humanities (2)

Conclusions

Although some studies analyzed the motivations behind journal flipping, limited research has been conducted on how this transition is perceived by journal managers. The current paper provides insights into the elements, benefits, and challenges of OA flipping from a manager perspective. This research adds to the growing body of literature on Open Access, accentuating the complexity involved in incorporating OA in journals in the Spanish context. As regards the question how bibliometric measures reflect the changes in the status of the journal, findings suggest that the great majority of journals are aware of the indicators, but only two mentioned they reflect their reality since the transition. The results also show that the flipping process was largely perceived as beneficial. The number of benefits outstands the number of cons, denoting a positive attitude towards the journal's performance since the flipping. Among the main benefits, the increase in visibility or number of submissions is highlighted, while the loss of interchanges and the resource capacity are seen as major drawbacks.

This study has several limitations. First, this study is based on a small sample. As such, results cannot be generalized for the whole population and only subjective conclusions can be generated. Second, the great majority of journals that accepted to make the interview, belong to the same host institution and were subjected to the same set of requirements. This can affect the independence of the responses provided and can limit the ability of the findings to be generalized to other contexts. Third, the extent to which the perceptions on OA flipping of managers of flipping journals differ from those of non-OA journals has not been addressed in the current study and could be examined in a follow-up study. In addition, this research has highlighted a number of issues that require further investigation. The related literature has shown that the positive attitude toward OA among journal managers is increasing. We envision further study in this area through surveys and interviews with more journal managers in various fields which can analyze both the short and long-term effects on the journal. Contributions from other countries would complement this study and increase its generalizability.

Abstract

The role of preprints in the scientific production and their part in citations have been growing over the past 10 years. In this paper we propose to study the citations of preprints in several different aspects: the progression of these citations over time, the sections of the articles in which they are most likely to appear and the percentage of such citations with respect to all citations in articles. We have processed the PLOS dataset that covers 7 journals and a total of about 240000 articles up to January 2021. The results show that preprint citations are found with the highest frequency in the Method section of articles, though small variations exist with respect to journals. The PLOS Computational Biology journal stand out as it contains more than three times more preprint citations than any other PLOS journal. The relative parts of the different preprint databases are also examined. While ArXiv and bioRxiv are the most frequent citation sources, bioRxiv's disciplinary nature can be observed as it is the source of more than 70% of preprint citations in PLOS Biology, PLOS Genetics and PLOS Pathogens.

Introduction

In recent years, the growing role of preprints in the publication process and the creation of a large number of publicly available preprint databases has led to an increasing interest by the research community in scientometrics (see (Berg 2017; Kaiser 2017; da Silva 2017a,b,c)). Indeed, a growing number of online repositories provide access to new research that is still in production and not yet validated by peers. This contributes to the acceleration of the dissemination of science (Larivière et al., 2014), (Abdill & Blekhman, 2019). The arrival of bioRxiv on the ArXiv model and its operation (see the work of Pinfield (2001) who is interested in the use of this type of service by physicists) is presented by (Berg et al., 2016). (Fu & Hughey, 2019) show that having a paper in bioArxiv is correlated with a high altmetric value.
Beyond dissemination of recent results, preprints are also present in publications as cited references. (Frasr et al., 2020) show that papers submitted to bioRxiv receive more attention from the scientific communitythan other pubications. This implies that in the publication process, the citation of work from preprint databases is becoming now a part of the publication cycle (Hoy, 2020; Penfold & Polka, 2020). (Desjardins-Proulx et al., 2013) question the relationship between the preprint databases and the publishers with regard to the quality, but also the relevance of this type of production. Other ethical considerations arise such as plagiarism (Giles, 2003).
Direct citations to preprint databases such as arXiv, RePEc, SSRN and PMC all increased steadily from 2000 to 2013 according to the Scopus study by (Li,Thelwall & Kousha, 2015). Subsequent health crises mobilize research efforts and the role of preprints as an under-utilized mechanism for accelerating the dissemination of scientific findings is discussed by (Johansson et al., 2018) and (Majumder & Mandl, 2020). More broadly, this phenomenon has invited community researchers to produce datasets to include the production of arXiv in a recommendation system (Saier & Färber, 2019).

Traditionally, the knowledge built through scientific articles relies on originality and refers to previous and peer-reviewed work, thus participating in the cumulative structure of scientific knowledge through the act of citations. In fact, (Fry, Marshall & Mellins-Cohen, 2019) that the purposes of preprints are diverse: from increased dissemination speeds for authors to an invitation to critical reading for work that has not been peer-reviewed by the reader. The question that arises today is the place of preprints alongside scientific articles and their citations: how do preprints contribute to the construction of new scientific knowledge while their validity, as sources, is not established by peer review. Will the use of preprint citations reinforce the critical attitude expressed in articles or will it weaken the edifice of knowledge? To answer this question, one of the necessary steps is to study the nature and place of preprints in scientific journals.

In this paper we propose to study the citations of preprints with respect to their position in the different journals and the IMRaD (Introduction, Method, Result and Discussion) structure of articles. By processing the PLOS dataset that contains 7 journals mainly in the bio-medical domain, our study aims to provide evidence to answer the following questions:

- What is the part of the progression of preprint citations in articles over the last 10 years?
- In which sections of the rhetorical structure of articles are preprint citations most likely to appear?
- How do preprint citations relate to the overall number of citations in articles and in the different sections of the IMRaD structure.

As preprints contain recent results and methods that have not yet been validated by peers, one important question is whether these methods and results are actually cited and used in peer-reviewed journals. Knowing whether the preprints belong to one section rather than another is an indicator of the role of preprints in the construction of knowledge.

Method

In this study, we investigate the place of preprint citations within the IMRaD (Introduction, Method, Result and Discussion) structure of articles.

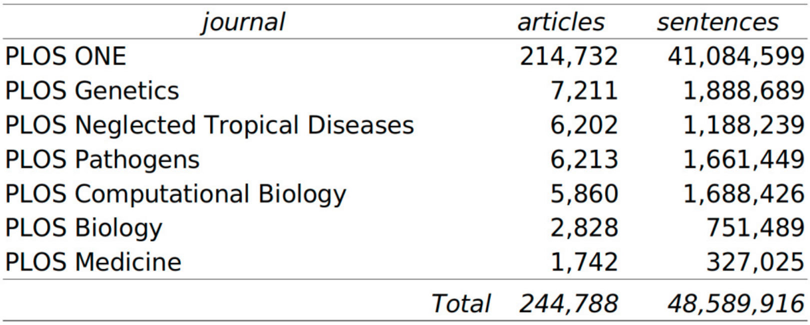
Dataset

We have used as a dataset all research articles published by PLOS up to January 2021. This dataset contains seven different journals and the majority of the articles is in the biomedical domain. The largest journal, PLOS ONE, is multidisciplinary and contains a large number of articles in various other domains. Table 1 gives the overall size of the dataset and the number of articles and sentences per journal.

The editorial requirements of PLOS journals impose using the IMRaD structure for research articles and the vast majority of the articles follow this pattern. This means that the four main section types (Introduction, Method, Result, Discussion) are present in all articles, while the order of these sections can vary according to the discipline and the journal.

In our experiment, we have considered only research articles that follow considered only research articles that follow this IMRaD pattern.

Table 1. PLOS dataset (up to January 2021)



journal	*articles*	*sentences*
PLOS ONE	214,732	41,084,599
PLOS Genetics	7,211	1,888,689
PLOS Neglected Tropical Diseases	6,202	1,188,239
PLOS Pathogens	6,213	1,661,449
PLOS Computational Biology	5,860	1,688,426
PLOS Biology	2,828	751,489
PLOS Medicine	1,742	327,025
Total	*244,788*	*48,589,916*

Processing pipeline

The dataset in available in XML format following the JATS (Journal Article Tag Suite) that is specifically designed to facilitate the processing of scientific papers. Our processing pipeline contains the following main steps:

1. Extraction of article metadata and bibliography items
2. Extraction of section titles and section classification
3. Processing of section content: paragraph and sentence segmentation
4. Processing of citations and linking them to bibliography items
5. Identification of preprint citations, their positions in the sections and all metadata related to the cited items.

Section classification

The first non-trivial processing step is the classification of section into the four section types ("Introduction", "Method", "Result" and "Discussion").

About 57% of the sections in the dataset are labelled as "intro", "method", "results" etc. in the "sec-type" attribute of the XML section element. We used these labels where possible. The remaining sections were classified using their section titles. Sets of regular expressions were manually designed to account for the possible variations in the titles. For example, the Discussion section was found under 488 different titles such as: 'Discussions', 'Discussion on practical implementation of proposed handover strategy', 'Summary and Discussion', 'Discussion and implications', 'General Discussion', 'Strengths and Limitations of the Study', 'Discussion/Conclusion', etc.

Some of the articles contain sections with titles that are subject-specific and could not be classified in this way. Such articles were left out. Among the total of 263,542 articles in the dataset, 234,592 (89%) articles contain the four section types and were used for our study.

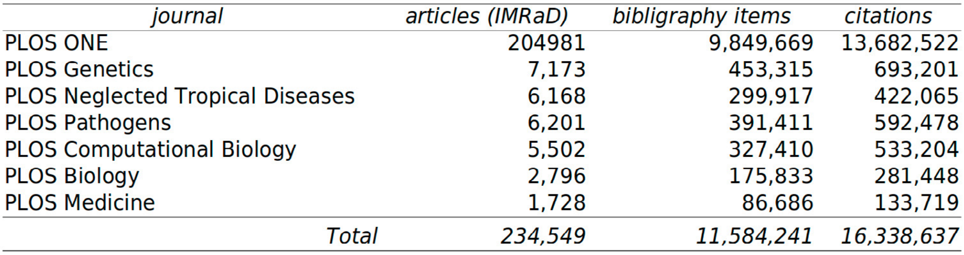
Processing of Citations

Article content was segmented into paragraphs and sentences. Citations were identified and linked to bibliography items using the existing annotations in the XML source files (i.e. xref elements that point to bibliography items).

The presence of citation ranges (e.g. [7]-[11]) requires supplementary processing as each range in represented in the XML structure of the document by only two xref elements that are linked to bibliography items. The remaining citations (e.g. [8], [9] and [10] in the range [7]-[11]) do not have xref elements in the XML. The creation of these new links accounts for about 9.5% of all citations in the dataset.

Table 2 presents the number of bibliography items and citations per journal.

Table 2. PLOS dataset: IMRaD articles, bibliography items and citations per journal



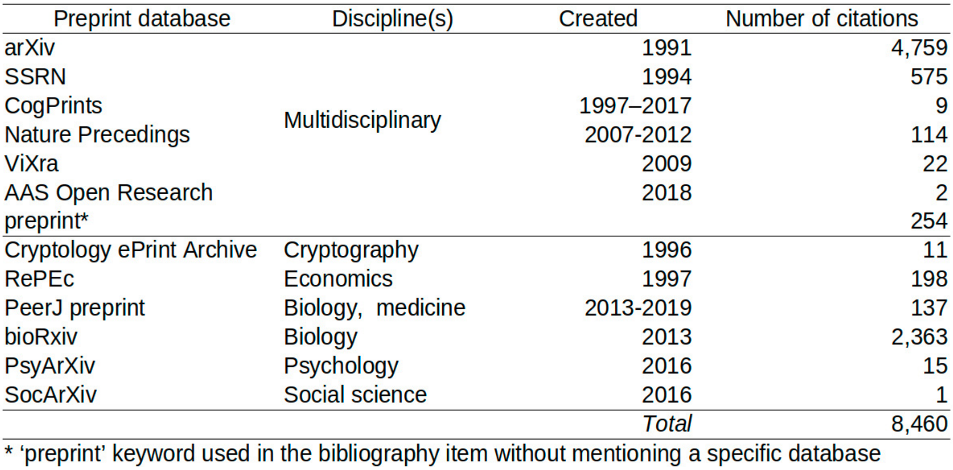
journal	*articles (IMRaD)*	*bibligraphy items*	*citations*
PLOS ONE	204981	9,849,669	13,682,522
PLOS Genetics	7,173	453,315	693,201
PLOS Neglected Tropical Diseases	6,168	299,917	422,065
PLOS Pathogens	6,201	391,411	592,478
PLOS Computational Biology	5,502	327,410	533,204
PLOS Biology	2,796	175,833	281,448
PLOS Medicine	1,728	86,686	133,719
Total	*234,549*	*11,584,241*	*16,338,637*

Identification of Preprint Citations

In order to account for all possible preprint databases, we have made a list of repositories from several sources[1]. Preprint citations were identified by regular expressions that were matched against bibliography items metadata. From the entire list of preprint databases, we identified 12 sources that are cited in our dataset.

Preprint servers can be multidisciplinary, thematic, linguistics, linked to a publisher, etc. We account for this diversity in Table 3 that lists the preprint databases and the number of citations found in the dataset for each database. A total of 8460 preprint citations were extracted and used to produce the following results.

Table 3. Preprint databases



Preprint database	Discipline(s)	Created	Number of citations
arXiv	Multidisciplinary	1991	4,759
SSRN		1994	575
CogPrints		1997–2017	9
Nature Precedings		2007-2012	114
ViXra		2009	22

SocArXiv	Social science	2016	1
		Total	8,460

* ‘preprint’ keyword used in the bibliography item without mentioning a specific database

[1] https://asapbio.org/preprint-servers, https://zenodo.org/record/4321522, https://en.wikipedia.org/wiki/List_of_academic_preprint_repositories, https://libguides.lib.hku.hk/preprint

Result

Progression of Citations over the Past 10 years

We have plotted the number of preprint citations that were received by the different preprint databases by year. Figure 1 shows that the overall number of preprint citations grows very rapidly since 2011 and this growth is consistent with the creation and development of new preprint repositories. For example, the bioRxiv database was created in 2013 and its presence in the citations is visible from 2014 and has been growing ever since.

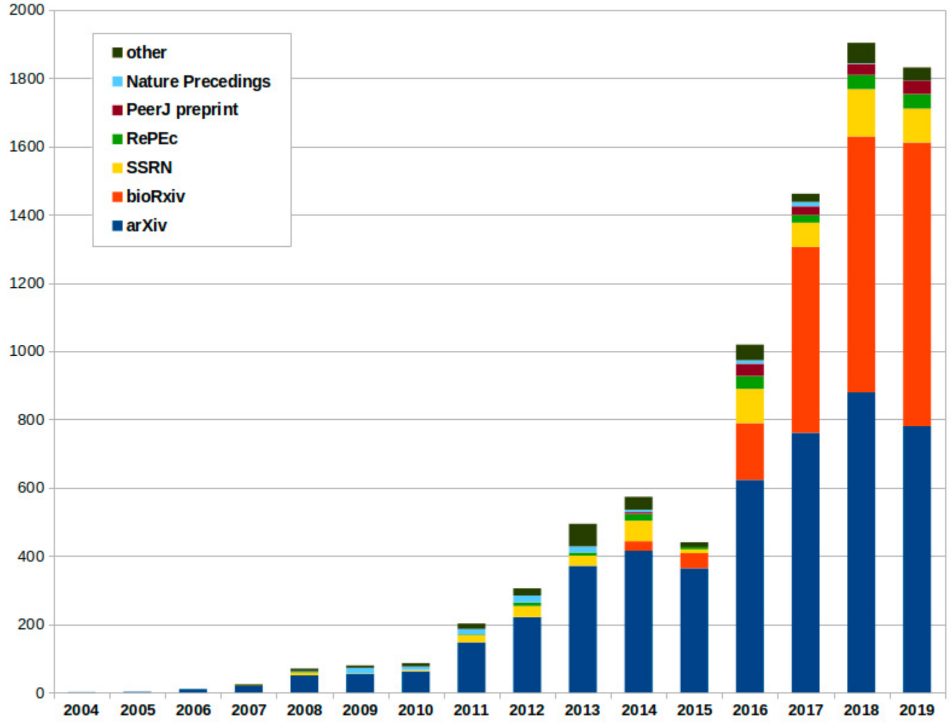

Figure 1. Progression of the number of preprint citations by year.

Frequency of Preprint Citations in the Different Sections of Articles

We have examined the positions of preprint citations with respect to the IMRaD structure in the different PLOS journals. Figure 2 presents the relative parts of preprint citations in the different sections.

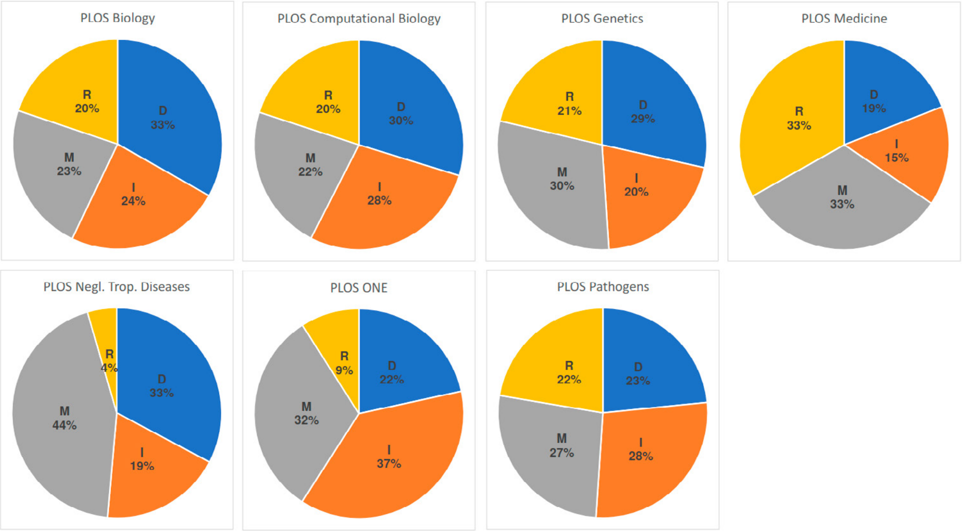

Figure 2. Preprint citations in the different sections.

One important observation is the part of preprint citations in the Method section. In fact, other studies on the distribution of citations in the IMRaD structure (Bertin et al., 2016) have shown that the Method section contains the smallest number of citations in the articles, the biggest number of citations being, naturally, in the Introduction. The fact that between 22% and 44% of preprint citations are found in the Method section is particularly interesting and means that preprint citations have distributions that are very different from the rest of the citations.

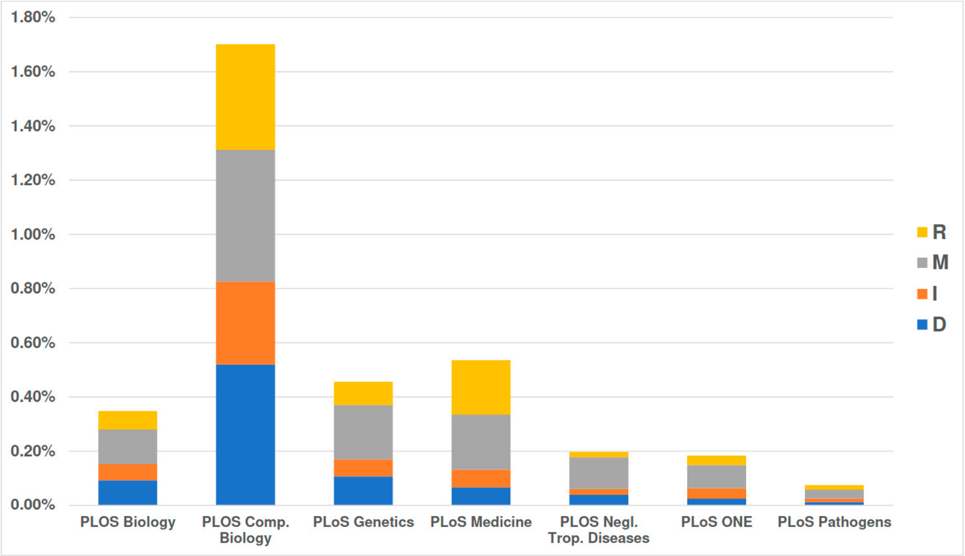

Figure 3. Preprint citations as a percentage of all citations in IMRaD.

Figure 3 shows the relative part of preprint citations as a percentage of all citations in each section and journal. Preprint citations are particularly frequent in the Method section, and somewhat less frequent in the Result and Discussion sections, except for PLOS Computational Biology. The journal PLOS Computational Biology stands out on this graph as having a very high relative number of preprint citations. Also, in this journal the parts of citations in the Method and Discussion sections are almost the same.

Distribution of Preprint Databases per Journal

The disciplinary nature of the different preprint databases is one of the factors that result in different number of citations. Figure 4 shows the distribution of the major preprint databases that were observed in the PLOS journals.

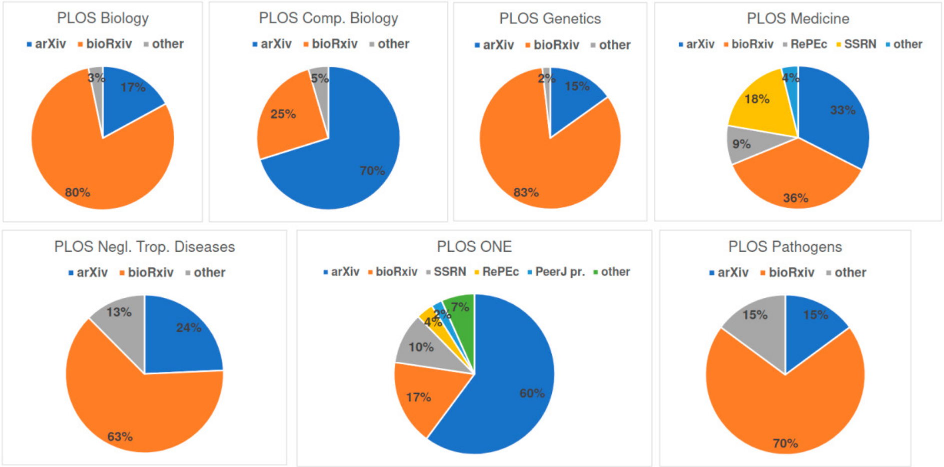

Figure 4. Distribution of preprint sources present in PLOS citations

BioRxiv is present in all PLOS journals, but it is most frequently cited in PLOS Biology, PLOS Genetics, PLOS Negl. Trop. Diseases and PLOS Pathogens. This shows clearly that the disciplinary speciality in the biomedical field leads to the wide use of this preprint database by researchers in a given field. This corroborates the results obtained by (Li,Thelwall & Kousha, 2015) who identified the point at which repositories are cited in their own domain.

Discussion and Perspectives

This paper presents an approach to study the distribution of preprint citations in scientific literature by considering their relation to the IMRaD structure of articles. We have observed the part of preprint citations in the four section types of the PLOS journals, and also the presence of the different preprint databases in the dataset.

We have shown that preprint citations gain more and more importance over the last years and this means that preprints are actively used by the community. The growth in the number of preprint citations corresponds to the creation and growth of repositories.

The position of preprint citations in the IMRaD structure shows that these citations do not follow the same distribution as the rest of the citations in the articles. In fact, an intuitive hypothesis could be that non-validated knowledge should be placed in the introduction or background of an article. Also, we could expect to find preprint citations, naturally, in the discussion section where authors could confront their results with other ongoing experiments or give new perspectives and comment on emerging approaches. However, our results show clearly that the largest part of preprint citations is to be found in the methodology section. This means that we can observe the construction of scientific knowledge that is based on research that has not been validated by the peers.

We have shown that preprint citations differ from classical citations in the sense that they do not follow the same distributions that were already established in the literature around PLOS (Bertin et al., 2016). Preprints are a new citation object to be taken into consideration and studied with the utmost attention as they represent a new paradigmatic shift. This for the following two reasons:

a) a preprint might have the quality to become article, or might simply not be intended for this purpose.
b) a preprint must be quoted with reference to the version. Indeed, a preprint can be modified over time, with no restrictions to the depth and significance of such modifications.

The next stage of this work will be to study of the contexts of citations to preprints in order to understand qualitatively the citation mechanisms behind citing preprints. Understanding citation contexts is an essential element in determining the role of preprints in terms of scientific argumentation and their contribution to the construction of new knowledge.

Augmenting context-aware citation recommendations with citation and co-authorship history

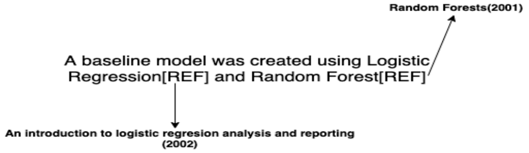
Abstract

With the increasing number of research papers being published, it has become a challenge to search for the most suitable articles for accurate referencing. Many local citation recommendation systems have begun to locate the suitable candidates by using the texts accompanying the citation suffix, along with the metadata of the target documents. Previous research has shown the positive effects from the citation relationships on such recommendations, however, the influence from the co-authorship history has not been fully investigated. In this paper, we extend the model proposed by Jeong, Jang & Park (2020) by combining the context, citation history with co-authorship information into the recommendation system. We also propose to use more domain-specific embeddings to better capture the semantics in the context. Our experiments show the positive effect of co-authorship information on citation recommendations, and that our model based on the combination of domain-specifically embedded context, the citation and the co-authorship history significantly outperforms the basic context-based recommendation model.

Introduction

Citation Recommendation is defined as the task of recommending citations from a textual content. Due to the increasing number of scientific works in recent years, and the need of citing appropriate publications when writing scientific papers, citation recommendation has become one of the most important research topics. Depending on the length of the citation context that are used for recommendation, there are two categories of methods: 1) global citation recommendation where the entire text has been used to recommend citations or abstract can be used to understand the context, and 2) local or context-aware citation recommendation where a short-length window of words surrounding the citation, as shown in Figure 1, are used as context for recommending citations.



Random Forests(2001)
A baseline model was created using Logistic Regression[REF] and Random Forest[REF]
An introduction to logistic regresion analysis and reporting (2002)

Figure 1. Example of paper with citation mentions with [REF] placeholders.

There arises a vocabulary gap between the context and the corresponding cited publication which results in recommending not so high-quality publications. A publication's quality can be estimated by its previous citation relations and its authors' previous collaborations. A field breakthrough paper citing another publication speaks volumes about the cited paper quality. Similarly, a paper quality can also be determined individually by its authors, and with whom they have shared and gained knowledge by collaborating in the past. Currently existing state-of-the-art models have explored citation relations and metrics to recommend appropriate citations such as the BERT-GCN model proposed by Jeong, Jang & Park (2020). Very few have explored co-authorship relations due to the mixed views about the influence of co-authorship in this task. Ebesu & Fang (2017) employed co-author networks and found promising results and new direction for context-aware citation recommendation. In our paper, we extend the existing model of Jeong, Jang & Park (2020) with co-authorship network and domain-specific embeddings to understand if these may help in improving the performance of the existing model. By devising a way to use citation relations and co-authorship relations along with the domain-specific context embeddings, we observe a significant improvement over the existing model. Evidently, we managed to improve the Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) by 5% and Recall@k by almost 10%.

Related Work

Citation recommendation is about recommending citations given a piece of text. These systems are divided into global and local citation recommendation where global recommendation recommends the citations considering the whole publication text while local recommendation recommends citations based on local context of input text. There is a recommendation system which employs both local and global context together as described in (Muhsina & Naseer, 2019). Yang (2018) used forward and backward positions of the quotation marks of the citation in an LSTM based model to customize the context-aware citation recommendation by splitting the left and right sentences when encoding the citation context. It suggested a procedure for learning and combining LSTM cells with MLP to learn. The investigators have used the papers' author(s) and location details to encode the research model. There are other works such as Ebesu & Fang (2017) which used citation context along with authors network convolution to develop the Neural Citation Network for context-aware citation recommendation systems. This paper combined the cited and citing author network features in the citation context encoders. It becomes important to focus on co-authorship in scientific field as this dictates the quality of the research output. As per Kumar (2015), co-authorship networks generated from co-authorship meta information from various publications gives rise to a social network among the researchers which describes who is more willing to collaborate with whom influencing the publication quality. He also found that there is high correlation between co-authorships and citation behavior. It is found that co-authored papers are cited more than papers with single authors and Ding (2011) found in their study that more cited authors usually do not co-author with each other but cite each other. Lis, Yang & Ding (2009) in their study found that centrality measures from co-authorship network are highly correlated with citation counts. Biscaro & Giupponi (2014) in their study concluded that co-authorship networks' structure matters in scientific collaboration. Publications' bibliography information not only identifies the publication uniquely but also gives information about the quality of the publication. The bibliographic information such as citation count of publication, venue, year, author determines the quality of the work. These information are employed by the graph techniques which not only considers the citation count in the form edges in the graphs but also considers other bibliometric information as the nodes' features. Kipf & Welling (2016) proposed semi supervised classification with graph convolution networks to classify graph nodes by using the graph edges and nodes' features. They also introduced variational graph autoencoders to learn the latent representation of the graph.

Data Overview

For our work, we use the FullTextPeerRead dataset[1] proposed in Jeong, Jang & Park (2020). This dataset consists of peer reviews of submitted papers in top-tier venues of the ML/AI field, along with their bibliometric information. This dataset contains left and right context sentences

[1] https://bert-gcn-for-paper-citation.s3.ap-northeast-2.amazonaws.com/PeerRead/full_context_PeerRead.csv.

surrounding a citation[2] as well as the cited and the citing papers' meta information such as title, author, abstract, etc.

Table 1: Dataset description

Dataset Name	***FullTextPeerRead***[1]
Total number of papers	4,898
Total number of base papers	3,761
Total number of cited papers	2,478
Total number of citation context	17,247
Total number of unique authors	9,529
Years of papers published	2007-2017

This dataset has been split into the training and the test datasets based on the cut-off year of 2017. The training dataset consists of 3,411 papers and the test data consists of 2,559 papers. The left and right context sentences length has been trimmed to 50 words, such that sufficient information is taken from both sides of the citation.

Methodology

In order to check the effects of better context-embedding and co-authorship information, we extend the BERT-GCN model proposed in Jeong, Jang & Perk (2020) by incorporating the co-authorship network, as illustrated in Figure 2. The model consists of three components that gives embeddings for context sentences, co-authorship network and citation network. Here, the BERT transformer is used to learn the feature representation of context sentences surrounding the citations and individual Graph Convolution Networks (GCNs) are used to learn the network representations of citation network and co-authorship network. The code can be found here.[3]

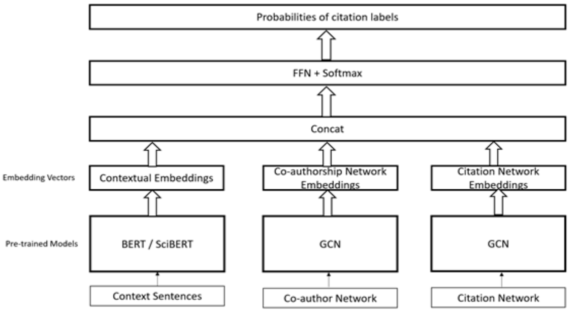


Figure 2: The BERT-GCN[2] model architecture

Context embedding

The context of a citation consists of the left and right text surrounding the cited references. We use the pre-trained BERT (Devlin, et. al., 2019) and SciBERT (Beltagy, et. al., 2019) to generate the embedding of such context. BERT in pretrained on Wikipedia articles and is capable to understand the meaning of its input due to its ability to read in both directions at once. SciBERT, an extension to original BERT is pretrained on multi-domain scientific publications and has the vocabulary which helps better understand scientific texts. As our main goal is to find suitable reference papers in computer science domain, SciBERT could be highly relevant in processing the input data from the dataset.

[2] This dataset does not consider multiple citation data where multiple papers are cited in a single sentence.
[3] https://github.com/anubratabhowmick/tf-BERT-GCN

Citation and co-authorship embedding

We generate the co-authorship network and citation network from the dataset. Two separate Graph Convolutional Network (Zhang, Hanghang & Jiejun, 2019) models are trained on these two different networks, generating two sets of embeddings for each author and each citation respectively. More specifically, for each network, we train a Variational Auto-encoder Graph Convolutional Network (VGAE) as proposed by Kipf & Welling (2017). Variational Graph Autoencoders works similarly as variational neural network auto encoders that generates stochastic based representation embeddings. We use VGAE GCN to generate the co-authorship and citation network embeddings.

Concatenation and training

The context around citations is the input to the BERT/SciBERT which on training learns these context feature representations and generates the contextual embedding. For each context sentence passed to BERT/SciBERT, the corresponding paper's citation embedding and the embedding of the last author, who is often the supervisor in the computer science domain, is concatenated with the BERT/SciBERT contextual embeddings output and passed to the feedforward network (FFN) layer. The output from this layer is then passed to the softmax activation function which then generates the probabilities of each publication being the citation for the context sentence passed as input. The BERT/SciBERT along with the feedforward layer is trained on the cross-entropy loss calculated by trying to predict the actual cited publication given the surrounding context, the corresponding citation and author embeddings as the input to the model.

Experiment Setting

The experiment has been done in eight variations, with the first four variants being trained with BERT and the last four with SciBERT, to understand how much better context embedding helps in the performance, and how much information does the respective citation and co-authorship network add to the models, in respect to the existing Jeong, Jang & Park, 2020 model. In the initial four variants, we have made a comparison of the BERT model exclusively and then, by adding the networks separately to BERT, and ending with the combined citation and co-authorship embedding added to BERT together. We repeated the same process in the next four variations by replacing the BERT with the SciBERT model.

BERT/SciBERT and GCN Setting

The context sentences are passed to BertTokenizer/SciBertTokenizer to tokenize the context sentences, respectively. The initial experiments, which only includes BERT and SciBERT separately have been trained by using these tokenized context sentences. BERT (and SciBERT) generates the contextual embeddings of the input at the [CLS] which is passed to the feedforward layer, followed by the SoftMax activation, giving the final output. The feedforward layer's input size is 768 which is equal to the output size of BERT's [CLS] token. The feedforward layer, followed by the SoftMax activation, generates the citation probabilities output of the size of 489 that is the total number of citation candidates, i.e. those that have been cited for at least 5 times in the training set. The BERT/SciBERT is being trained for 30 epochs with batch size set to 16. For training purposes, Adam optimizer (Kingma, & Ba, 2015) is used with the default parameters and the learning rate set to 2e-5.

For other settings where co-authorship networks' and citation networks' embeddings are being used, GCN has been trained for 200 epochs. The first hidden dimension in GCN for citation network training is 4837 which is total number of documents in the dataset and for co-authorship network it is 9529. The second hidden dimension in GCN is the same for both networks which is 768. The batch size for training for both networks is the total number of documents and the total number of authors in the dataset (full-batch gradient descent). For training, Adam optimizer is used with the learning rate of 0.01.

Results

We use similar metrics including Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and Recall at k as mentioned in (Jeong, Jang & Park, 2020). MAP measures the average precision which reflects upon the rank position regarding the retrieval list. MRR reflects on the position of the actual result in the recommendation list. A higher MRR score indicates the higher ranks of the target citations in the recommendation list. Recall at k (R@k), where k is in [5,10,30,50,80], is used to measure the actual hit ratio in the top k recommendation results.

Table 2: MRR, MAP and R@k scores of experiments

Model Name	*MRR*	*MAP*	*R@5*	*R@10*	*R@30*	*R@50*	*R@80*
BERT Base*	0.415	0.415	0.480	0.520	0.593	0.637	0.689
BERT-GCN*(Citation)	0.418	0.418	0.486	0.529	0.604	0.649	0.699
BERT Base	0.432	0.432	0.504	0.548	0.621	0.668	0.717
BERT-GCN (Citation)	0.412	0.412	0.481	0.523	0.606	0.649	0.701
BERT-GCN (Co-Authorship)	0.439	0.439	0.505	0.556	0.632	0.677	0.728
BERT-GCN^2	0.443	0.443	0.516	0.561	0.643	0.689	0.735
SciBERT Base	0.467	0.467	0.542	0.593	0.675	0.722	0.766
SciBERT GCN (Citation)	0.467	0.467	0.547	0.592	0.677	0.722	0.772
SciBERT GCN (Co-authorship)	0.466	0.466	0.545	0.594	0.680	0.719	0.773
SciBERT-GCN^2	**0.468**	**0.468**	**0.548**	**0.598**	**0.685**	**0.733**	**0.781**

Table 2 shows our results and those (marked with *) reported by Jeong, Jang & Park (2020). Our self-implemented BERT base model outperforms the previously reported results, while the combined BERT and GCN with the citation network has slightly poor results than previously reported. This might be due to our parameter settings are not optimal. However, we can easily see the BERT-GCN with the co-authorship network performs better than both BERT-base and BERT-GCN with the citation network. A combination of both networks further improves the performance. Replacing BERT with SciBERT improves the performance significantly, even without the citation and the co-authorship network. The citation and co-authorship networks, when added to SciBERT show negligible increase in performance, but when both networks combined, the performance is again improved substantially. This suggests that co-authorship information has positive influence on context-aware citation recommendation. A combination of both the citation and co-authorship network to a base BERT/SciBERT model can certainly improve the recommendation performance.

Conclusion

Our proposed addition of the co-authorship network to the existing citation network, delivers a significant improvement in MAP, MRR and Recall@k over the existing model. This clearly shows that the co-authorship network manages to add meaningful information to the base model, and a combination with the citation network results in better citation recommendations. We can conclude that, in addition to the co-authorship network, better context embedding plays a significant role when it comes to model performance, and using proper context embeddings, along with the appropriate networks can go a long way in effective citation recommendation

There are also room for improvements in the model proposed in this paper. We have selected the last author's network embedding to be added to our model, but another viable way of using the co-author embeddings is separating the authors, increasing the dataset, and using all their embeddings separately. Although this would be computationally more expensive, there is a chance of improvement in performance over our proposed model. Another improvement could be using node features in the Graph Convolution Network, as encoding both the graph structure and the node features might improve the performance by a significant margin, while being computationally efficient, and could be worthwhile to investigate further.

A systematic method for identifying references to academic research in grey literature

Abstract

Grey literature is research that has not been written with the intent to publish in a traditional journal or book. From this, and due to its unstandardised nature, its impact in academia can be difficult to identify. Research impact can be assessed in multiple ways, with citation analysis a usual method. Impact can include the citing of an output, but in some situations, cited references may be useful in assessing *'academic impact'*. Cited references in grey literature, however, may reflect *'non-academic impact'* of research such as in policy making, clinical practice or legislation. This study introduces and tests a semi-automatic method to measure cited references in grey literature with unknown standardisation of references. Metadata (lead author surname, title, year) of 2.45 million Russell Group university outputs were collected, added to known citation metadata from a 100-document sample of UK government grey literature, and then searched within each document, assessing the accuracy of 21 proposed variations of matching terms. A 'best method' is proposed (lead author surname and title in either order, maximum of 200 characters apart) to show cited references present, enabling the ability to analyse impact differences impact across subject areas and years within grey literature in future studies.

Introduction

Grey literature is a term which describes text-based documents not published in a standard academic format (e.g., books or journal articles, IGLWG, 1995). These documents are usually produced by organisations that do not focus on publishing (Schöpfel, 2010, p.11). Grey literature includes, but is not limited to, unpublished research, governmental reports, policies, conference proceedings, theses and dissertations (GreyNet International, 2019; UNE, 2019). The use of standardised reference lists in grey literature has not been widespread (Benzies et al., 2006), complicating their automated extraction and assessment.

Academic research impact has been mainly based upon counting citations from formal academic publications (e.g., journal articles) with traditional citation indexes such as Scopus or Web of Science. Nevertheless, other types of non-standard publications may be needed for monitoring the wider benefits of academic research. For instance, in the context of the UK Research Excellence Framework, impacts on "economy, society, culture, public policy or services, health, the environment or quality of life, beyond academia" must be demonstrated (REF, 2019, p.68). Cited references in grey literature can form part of this evidence by showing specific non-academic uses of research. For instance, World Health Organization (2020) guidance on water, sanitation, hygiene and waste management for COVID-19 has cited several scientific journal articles for healthcare policy making. The historical roots of research can also be found by analysing cited references (Marx & Bornmann, 2016), which can potentially show differences in impact across various literature.

Although Altmetric (n.d.) counts references to academic research from grey literature and some previous studies have analysed documents citing grey literature in narrow contexts dating back varying years (Alberani, Pietrangeli & Mazza, 1990; Pelzer & Wiese, 2003; Cordes, 2004; Woods, Phillips & Dudash, 2020), no practical method has developed to systematically identify academic research citations in grey literature. In response, this article demonstrates a method to semi-automatically identify citations mentioned in grey literature. This would help researchers or research groups show the contribution of grey literature output within the scientific community, by showing how grey literature is both cited by other research (Bickley, Kousha & Thelwall, 2019, pp.1801-1812; Bickley, Kousha & Thelwall, 2020) and the types of studies cited. The latter of these is potentially one of the "additional possibilities for [cited reference analysis] application in scientometrics," (Marx & Bornmann, 2016) and is the focus of this study.

Research questions

The goal of this study is to assess if a predictive method can be established that reliably and robustly captures citation mentions within documents, where reference sections are not indexed or known (grey literature). UK government publications are the focus, because of the large number of freely available online documents and the authors are familiar with the locale. The research questions are:

1. Can references in non-standard grey literature be automatically identified accurately?
2. Can a comparison of newly established methods be compared to determine a best approach within the context of grey literature repository impact assessment?

Methodology

The new data extraction method uses *Publish or Perish* and *Webometric Analyst* software to gather and analyse data. It was tested on a sample of grey literature. Twenty-one heuristics to extract citations were compared using Bland-Altman analysis and plots (Bland & Altman, 1986).

To imitate a dataset held by an institution or company wishing to assess impact of their studies in a wider context, a grey literature database was needed to extract documents. The UK government website was chosen because it contains high value and varied documents that provide useful impact evidence when citing academic research. It has previously been studied to investigate the impact of these documents (Bickley, Kousha & Thelwall, 2019, pp.1801-1812; Bickley, Kousha & Thelwall, 2020), but not the references in them.

Step 1: Google Scholar search (via Publish or Perish)

Publish or Perish (Harzing, 2010) was used to identify digitised UK government reports indexed by Google Scholar during 2010-2018. Other programs such as Dimensions (Hook, Porter & Herzog, 2018) could also have been used. To generate effective searches, the '*site:*' command was used together with the '*filetype:*' command to limit the results to UK Government website documents in PDF format:

site:gov.uk filetype:pdf

The query was also amended and submitted to search for Microsoft Word documents (.doc and .docx), which are also present in the repository. Publish or Perish allows searching by year which was used to allow for discrepancies between years to be isolated so subject area differences can be analysed in a future study. From this, each query term above was searched 9 times, one for each of 2010-2018, leading to a total of 27 different search queries (9 years, 3 filetypes). This method found the URLs of about 65% (4,280 of 6,591) search results indexed in Google Scholar (4,206 PDF files, 74 Word documents; Table 1).

Step 2: Downloading UK government reports

Webometric Analyst (*Services -> Download binary or text URLs*) was used to download each document found by Publish or Perish. About 80% of the documents were successfully downloaded by Webometric Analyst (3,435 of 4,280; Table 1). The documents missed were likely due to some unstandardised PDF settings or document protection causing the automatic download of the file to fail.

Step 3: Converting PDF files to text files

The Xpdf command line tool (Glyph & Cog, 2019) through Webometric Analyst (*Text -> Convert PDF files in folder to text*) was used to automatically convert the PDF and Word documents to text, of which over 98% (3,374 of 3,425; Table 1) were successfully converted. Manual conversion of a PDF or Word document is possible, but the methods presented here are intended to form a basis for potentially larger scale studies where manual conversion is infeasible.

Table 1. Documents found using Google Scholar, extracted using Publish or Perish, downloaded using Webometric Analyst and converted using PowerShell, with totals and success ratios for each step compared to the previous step (number of documents found using Publish or Perish out of number of documents shown in Google Scholar, for example), split by year/filetype.

Year	*Filetype*	*Google Scholar*	*Publish or Perish*	*Webometric Analyst*	*Converted*

Total		6591	4280	3425	3374
Success ratio		N/A	64.9%	80.0%	98.5%

Step 4: Identification and extraction of references

The above steps produced 3,374 plain text UK government grey literature documents. Two random samples of 50 documents were selected for initial testing. One sample had reference lists and the other did not, produced using manual checking.

The metadata and references for the 50 documents with references were manually extracted from the original PDF/Word documents to bypass automatic document processing errors (e.g., incorrect line breaks). The following metadata was also manually extracted: lead author surname, title and publication year. Reference titles with fewer than 5 words were removed (short titles may contribute to inaccurate results as the title is inherently more generic), and those with more than 10 words in the title were included but shortened to the first 10 words only to avoid matching problems (e.g., line wrapping). Table 2 shows the number of references in each document used, which only includes those with titles of 5 or more words (i.e., each document may contain more references that are not be included in the matching process).

The metadata extracted as above from the documents formed a set of potential references that a computer program could try to match with the same (or another) set of documents. This would test the ability of the program to recognise the pre-selected reference list. This would be an unrealistically small set of references to match, however. Scopus references were therefore used to expand the set, as follows. Scopus Advanced Searches were used to download the metadata (authors, title and year) for all UK Russell Group university outputs, giving 2.45 million records.

Step 5: Matching search terms using Webometric Analyst

Webometric Analyst (*Text -> Find two/three strings close together in a set of files*) was used to match the references in the expanded list with the original documents. A bespoke routine was added to allow a batch of text files to be imported and then a matching file be added to search each document in the batch for matching terms. Two versions were created (one to match 2 terms, another to match 3), and each version allowed for adjustable options; to allow for the pair (or triple) of terms to appear in any order or with a specific one first, and for the maximum distance in characters between the terms found to be classed as a match.

The different methods changed which indicators to include. Four combinations of matching terms were chosen: 1) lead author surname, title and year, 2) lead author surname and title, 3) lead author surname and year, and 4) title and year. Because many reference formats start with author names (Pears & Shields, 2019), each option was repeated with the author forced to appear before the other terms (when included). Options of 50-, 100- and 200-character maximum distances between each term were chosen by inspection of references seen in many documents. A total of 21 different methods were created using combinations of these options and used in the results, and each is numbered in Tables 2 and 3 for identification purposes.

Results

For 18 of the 21 methods (1-12 and 19-21), 49 of the 50 documents without references are always correctly predicted to have no references (Table 2, combined into one row to avoid repetition). The remaining methods (13-18) are relatively large overpredictions for these 49 documents, so although cited reference counts for each document is different, the fact that they are much larger than zero when zero is predicted by methods 1-12 and 19-21, means the exact value is unimportant. The remaining document without references is shown on its own row (Table 2) for clarity as all methods predict at least 1 cited reference when the true value is zero. For the 50 documents with known reference counts of at least 1, each document is shown on a separate row (Table 2) to illustrate the difference between the number of cited references known to exist in the document and each of the 21 methods' predicted measure.

Once calculated, Bland-Altman analysis (Bland & Altman, 1986) was used to compare the methods to the known number of manually counted references. Bland-Altman analysis is used traditionally in clinical contexts to compare two methods for estimation across multiple observations and is a simple way to estimate an agreement interval (limits of agreement), within which 95% of the differences of one method compared to the other, fall (Giavarina, 2015). However, it should be noted that these limits of agreement should be defined in advance for what the 95% central limit should be in terms of the variable being measured – it could be that the method proposed is still unacceptable if the limits are too large.

For this study, as 21 varying methods are being proposed via different combinations of indicator-pairs/triples and distances, Bland-Altman analysis can be used to show which of the 21 methods is best by finding the smallest (absolute) bias along with acceptably small limits of agreement compared to the known reference count in each document. For the best method, it is also necessary to state if the limits of agreement are acceptably small. This is because it is possible that the bias is for a method is close to zero but if the limits of agreement are too large, the method would be deemed unreliable.

In general, if a measurement is to be taken of a specific variable, but this measurement is difficult or costly, it may be of interest to know the level of another variable which can be taken easily or relatively inexpensively. Bland-Altman analysis is appropriate here as large-scale manual counting of cited references in grey literature would be time consuming if not expensive. A paired Student's t-test for the total number of references found by each method would be insufficient because it only compares group means rather than differences observation-by-observation, leading to ignoring false matches in this context.

Table 3 shows the biases and standard deviation calculated using Bland-Altman analysis for each method and ranks them within both statistics (smaller absolute bias and standard deviation is better). The most accurate method in terms of the smallest absolute bias (-0.21) and standard deviation (1.76) uses the lead author surname and title (author not necessarily first), with a maximum of 200 characters between the two (method 12). The limits of agreement are calculated similarly to a confidence interval, meaning that 95% of the predictions would be within 3.4496 cited references (3.4496=1.96*1.76, 3 or 4 rounded to the nearest integer number of references) of the true value. It is deemed that this is acceptable for a 'best-method' proposed, but further research into the distance parameter may yield improvements, reducing this uncertainty.

The same indicators used in the best method above, but with the author surname required to be first (method 9) was the second-best method for both statistics (bias=-0.28, standard deviation=1.78). All other methods have comparatively worse bias and/or standard deviation (e.g., method 21, using title and year with distance of 200, is ranked third in both statistics but the bias is more than double the best method).

Negative bias implies that the method underpredicts the number of references in each document, whereas positive bias indicates overprediction. For the 15 methods with biases and standard deviations much closer to zero (methods 1-12 and 19-21), they show underpredictions, so these methods are missing matches (false negatives) rather than including (m)any false positives. The remaining 6 methods (13-18, using author and year) are wildly overpredicting the number of references (also large standard deviations), likely due to the generic nature of a single author surname and a 4-digit integer, both of which could commonly be contained within other strings of text (e.g., "Ng 2018" is a common surname and potential year combination, but would show as a match in the string "predicting 2018 as a more fruitful year"). A space in front of the lead author surname could remove this type of false positive, but if the author surname were preceded by other characters, text markup language (such a new line delimiters), or by nothing at all (if the author surname were the first text in the document), then there would be many false negatives.

Table 2. All methods showing predicted number of references in each document against known number of references.

Bland-Altman plots of the methods can illustrate the difference between the known and predicted number of references against mean of the two. A ‘good’ prediction method (Figure 1) shows a scatter plot which has similar spread across all parts of the x-axis (mean of known and method-reported number of references), ideally with points being close to zero on the y-axis (difference between known and method-reported number of references), meaning narrow limits of agreement. It follows that this method would then have low bias and standard deviation (limits of agreement), meaning the method presented is a good predictor of the true measure.

An unsuitable method (Figure 3) would show ‘fanning-out’ along the axis from left to right. Here, as all measures are positive integers and the worst of the prediction methods presented wildly overpredict rather than underpredict, ‘one-sided fanning-out’ is shown but leads to the same conclusion; larger bias and limits of agreement are visible.

Figures 1-3 show Bland-Altman plots from the best ranked method (12), the worst ranked of those with relatively close-to-zero bias/standard deviation (method 1) and the worst ranked overall (method 18). Bland-Altman plots for the other methods (Figures 4-21) are shown in the online Appendices (Appendices 1-18, Bickley, Kousha & Thelwall, 2021).

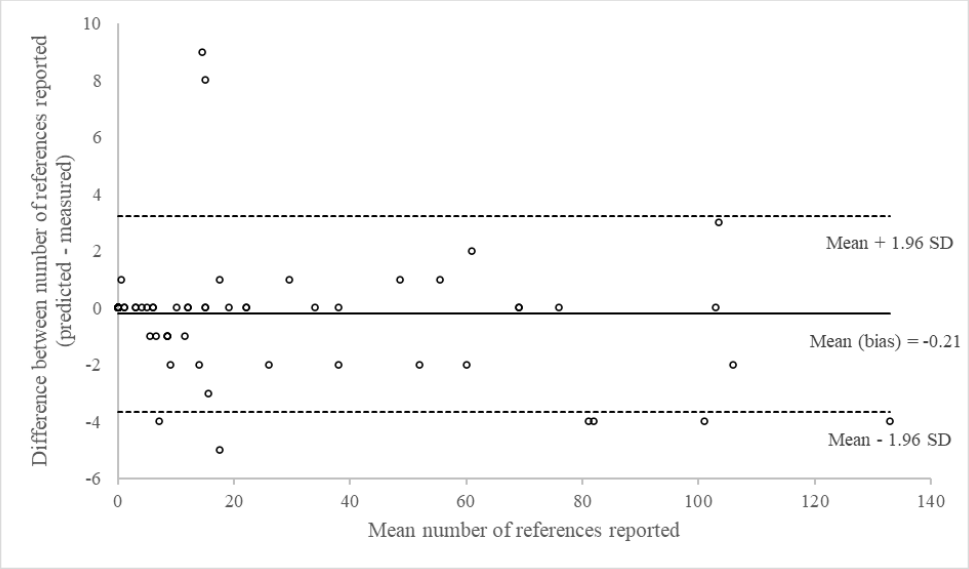

Figure 1. Bland-Altman plot of agreement between method 12 (lead author surname and title, author not necessarily first, distance 200) and known reference count of 100-document sample, the best method proposed.

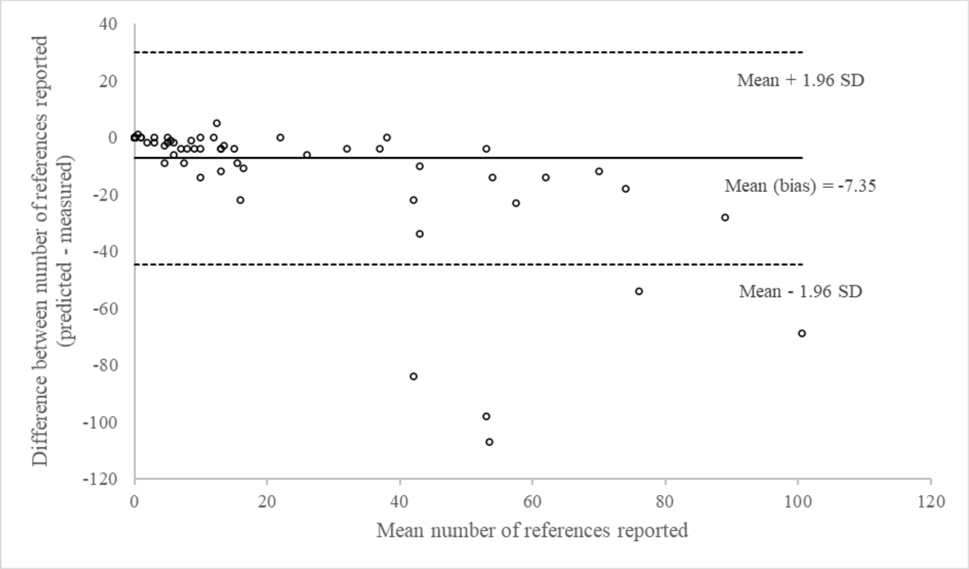

Figure 2. Bland-Altman plot of agreement between method 1 (lead author surname, title and year, author first, distance 50) and known reference count of 100-document sample, showing larger bias/limits of agreement (bias ± 1.96 SD) to Figure 1.

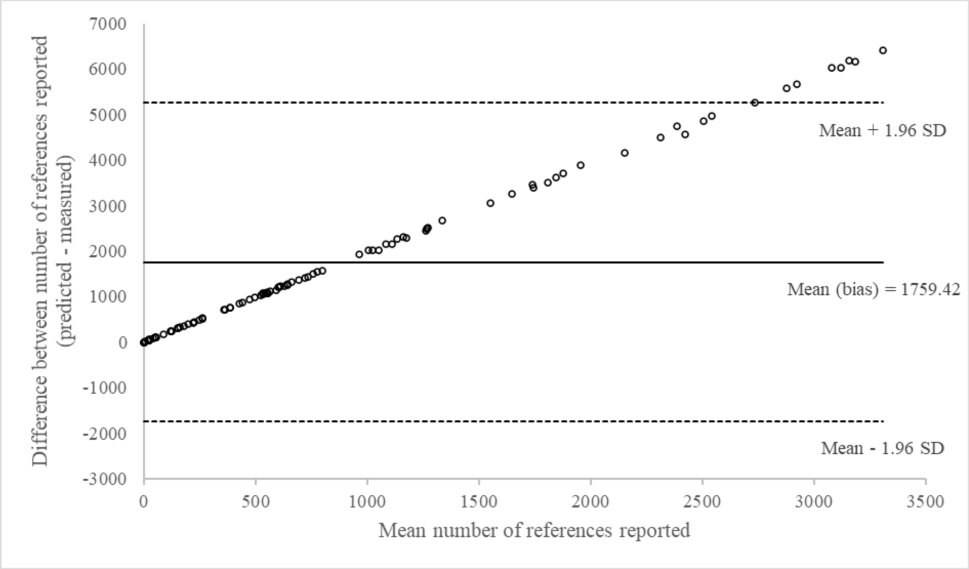

Figure 3. Bland-Altman plot of agreement between method 18 (lead author surname and year, author not necessarily first, distance 200) and known reference count of 100-document sample, demonstrating a poor method with 'one-sided fanning-out'.

Discussion and limitations

The best method found here does not necessarily represent the new 'gold-standard' to measure impact of grey literature upon standard academic output but is an accurate and reliable approach for use in further research. In this way, the combination of options above that lead to the smallest difference (bias) and variation across all records is the aim, allowing the conclusion that the best method proposed has both high recall and precision. The best method was deemed to having an acceptably low standard deviation/limits of agreement, but further research into the methodologies here may present a way at reducing this variability while keeping the bias small.

The distances between indicators chosen were arbitrary. A pattern in the result shows that of the more feasible approaches (methods 1-12 and 19-21), the larger the distance between matching terms, the smaller the absolute value of the bias and the standard deviation, hence more accurate and precise. It is plausible that a larger distance may obtain a more accurate method, although this was not tested in this research.

It is possible that due to the short nature of some lead author surnames and years, they could be contained within other strings, leading to false positives. The best method proposed here does not make use of the year of a reference but does include lead author surnames. An extended method could include looking for a preceding line break (in the case of most reference lists where each reference starts with the lead author surname) and/or a following comma (a common format in references, Pears & Shield, 2019). However, this brings extra complexity to the method and may cause missed matches if the grey literature uses a non-standard format.

The results are limited to using a single case study (UK government grey literature publications matched with Russell Group university academic output). It is possible that other grey literature repositories may have more standardised ways of reporting references within documents or recording these within metadata (e.g., Scopus), but this method has been designed to be applicable to any text documents, regardless of definition or knowledge of content.

Although this study has been limited to a sample of documents taken from a single grey literature repository, the inclusion of tools such as Publish or Perish and Webometric Analyst allow for much larger scale studies to use the methodology presented here. This process has been undertaken in a later study, with promising results assessing impact of an entire repository and allowing for subject areas differences to be seen.

Conclusions

In answer to the research questions, it is possible to count the number of references in a batch of files in a semi-automated way by using the combinations of indicators above, hence identifying reference sections. This was possible here as a large list of metadata was collected from Scopus – the hardest part of this method due to the manual collection. If these tests were to be repeated by other users, it may be useful to find an automated way of collecting data like this, and to make sure the origin of potential matches is suitable (i.e., US-based journals/books if undertaken on US-based repositories).

The exact number of citations here may be trusted as the lead author surname, title and year of the known matches were deliberately included in the matching process to check if the method is reliable for both false positives and negatives. In addition, 21 different combinations of options were tested extensively to determine a best approach. The ultimate method proposed (lead author surname and title in either order, a maximum of 200 characters apart) has low underestimation of reference count and can be treated as effective. However, when performing on a dataset with potentially any number of references, any method is likely to present many missed matches due to the unknown nature of potential citations – all academic output from all recorded years would have to be included in the list of matching terms to remove this problem. It may be more appropriate to use the method proposed here to assess impact in terms of proportion between different subject areas rather than pure numbers or if the scope of academic references used is small and known. A future project using this method on a wide scale within different subjects is underway by the authors of this paper.

Researchers wishing to assess impact of their own grey literature should endeavour to create DOIs where appropriate so persistent identifiers already used to assess impact by other mediums (Altmetric, n.d.) can be extended into the grey literature realm.

Appendices

Appendices 1-18, as mentioned in this study, can be found in the online Appendices (Bickley, Kousha & Thelwall, 2021).

Abstract

This paper presents an impact evaluation of São Paulo Research Foundation (FAPESP)'s Doctoral Scholarship Program. The objective is to assess whether the program impacts the scientific production of its beneficiaries. The study population included all the individuals who applied for PhD scholarships from FAPESP between 2003 and 2017 and were either granted or rejected. The evaluation employed a quasi-experimental design. The treatment group comprehended individuals whom FAPESP awarded and completed their PhD degree. The control groups comprehended individuals who were rejected in their FAPESP application but completed their PhD with scholarships from other funding agencies or those without funding support. Data collection was carried out on secondary bases from different sources (including Scopus and Google Scholar for citations and H-index). For the analysis, we used exact matching with the Propensity Score (PS) as matching distance. As a result, we find that the number of publications, number of citations, and H-index is higher for former FAPESP scholarship holders than for those rejected. The effect is even more significant compared to those who did not have the financial support of research agencies during their PhD studies. Therefore, findings demonstrate that scholarships for doctoral students drive the production of qualified scientific knowledge.

Introduction

The importance of scientific research for creating new knowledge, the generation of innovation, and promoting the competitiveness of regions and countries are recognized by academics and policymakers (Benavente et al., 2012; Lin et al., 2014). In this context, the existence of qualified researchers is seen as a way to expand the scientific, technological, and innovation skills of a region and to promote economic and social development (Leitch, 2006; Halse & Mowbray, 2011; Salter & Martin, 2001; Tremblay, 2005; Neumann & Tan, 2011). In Stephan's words (1996, p. 1199), "science is a source of growth."

The historical governmental interest illustrates this understanding materialized in public policies aimed at funding research (Benavente et al., 2012; Lin et al., 2014; Langfeldt; Bloch; Sivertsen, 2015) and training qualified human resources, particularly in master and PhD levels (Stephan, 1996; Ali; Bhattacharyya & Olejniczak, 2010).

There is no doubt that graduate students are considered an essential part of the academic workforce. OECD. Stat data points out about 278 thousand doctoral graduates in 2018 in OECD countries. Some of the non-OECD economies, such as Brazil, also have expressive numbers –

23 thousand doctoral graduates in the same year. Considering that doctoral studies take some years, the number of students enrolled in PhD programs worldwide is quite expressive.

Larivière (2012) reinforces the importance of this workforce with evidence of the significant contribution of PhD students to the advancement of knowledge through their participation in the publication process. The expression "on the shoulders of students" used by the author brings the real meaning of this contribution and raises a complimentary issue regarding the guarantee of adequate conditions through research funding for those students to dedicate themselves to their doctoral research.

The association of these two factors – research funding and scientific productivity and impact – has been investigated by previous studies regarding doctoral and post-doctoral programs in different countries and particular knowledge fields and time intervals. In general, findings show a positive relationship between funding and performance of those that has been supported (Goldsmith et al., 2002; Bornmann et al., 2010; Jastrob, Bukstein y Güimil, 2012; Larivière, 2013; Meyer and Bührer, 2014; Horta et al., 2018; Belavy et al., 2020).

This positive performance of alumni in scientific production is mainly explained because scholarships allow their beneficiaries to focus entirely on their doctoral research during the program. On the other hand, other studies (Böhmer & Von Ins, 2009 and Langfeldt et al., 2015) did not find the same positive relationship between funding and scientific performance.

Although a doctoral student's whole experience cannot be diminished to scientific publications, this is undoubtedly a critical output and a fundamental element in young researchers' training and attaining research excellence, as explored by Lindahl et al. (2020). Thus, further investigation about the association of funding and scientific performance must be conducted, particularly in developing countries such as Brazil, where this kind of studies are scarce and, conversely, threats regarding governmental funding to science, technology, and innovation, and particularly doctoral scholarships, are abundant (Angelo, 2017; Escobar, 2019; Andrade, 2019). This article fills this gap by providing insights on the impact of research funding on PhD holders' scientific performance in the Brazilian context.

Our purpose was to evaluate the impact of São Paulo Research Foundation's (FAPESP)'s Doctoral Scholarship Program. FAPESP is the largest state research funding agency in Brazil, accounting for almost 40% of the total financial support given annually to research activities in the state. Established in 1962, the FAPESP Scholarship Program's main objective is to develop scientific or technological research and new staff training for the research system of the state of São Paulo.

The research question that guides this article is whether the program impacts the scientific performance of its beneficiaries. A previous study on this same program (Bin et al., 2015 and Bin et al., 2016) brings forth some conclusions in convergence with the presented literature. However, it is limited for not including in the comparison individuals who have completed their PhD degree without any scholarship, using self-reported primary data and employing impact factor (IF) and not citations as a proxy of scientific impact.

The present research advances on these three fronts, expanding the control group in the evaluation and employing secondary data from the integration of different sources of information, seeking to test the hypothesis that the impact of the scientific production of the former FAPESP awardees is more significant than those who did not have a FAPESP scholarship. Secondary data also enabled analyze of circa 21 thousand individuals from all knowledge fields and compare scientific impact within two different databases (Google Scholar and Scopus).

Our paper is organized as follows. Section 2 outlines the Brazilian background regarding the research-funding system for PhD students. Section 3 outlines data and methods. Section 4 presents our findings and discussion. Finally, we bring some conclusions and implications of the study.

Background

Brazil's research funding system for PhD students is organized at both federal and state levels. At the federal level, scholarships are awarded by the Coordination for the Improvement of the Higher Education Personnel (CAPES) and the National Council for Scientific and Technological Development (CNPq). State research funding agencies award these scholarships at the state level, among which FAPESP is by far the largest.

The federal agencies CAPES and CNPq historically used a decentralized institution-based system to award scholarships. These agencies allocate quotas to universities and other research organizations based on established criteria of their institutional performance in a national ranking of graduate programs: institutions with better-ranked programs receive more scholarships than the others. The institutions themselves then follow non-standardized internal awardee- selection processes.

In its turn, FAPESP uses peer review, not the institutional system, to award scholarships based on proposals presented by applicants regularly enrolled at institutions in São Paulo State. The criteria employed in the peer review are the student's academic excellence, the supervisor's experience and expertise, and the quality of the project (objectives, theoretical base, methodology, and feasibility).

PhD students from São Paulo State can apply for a scholarship under the institutional quota or directly to FAPESP. This decision is often taken with their supervisors and considers the availability of institutional quota and the chances to be awarded. FAPESP scholarships mainly differ from CAPES/CNPq's in terms of resource amount - although, with variations in the period, the former's value is about 50% higher than that of the others. There is also a frequent follow-up of the awardees from the peers based on regular reports.

Data and Methodology

The study population was composed of all the individuals who applied for FAPESP's doctoral scholarships between 2003 and 2017 and had their requests either granted or rejected, but with the added condition that they had concluded their PhD degree.

The central database containing the data of individuals who applied for FAPESP in the evaluated period was made available by the Foundation. In addition to this base, two others were used: CAPES, which allowed identifying all students linked to Postgraduate programs in the evaluated period and who completed their PhD degree, and CV Lattes, with information from the academic curricula registered on the Lattes Platform, making it possible to identify whether or not these individuals had a scholarship from another funding agency during their doctorate.

A quasi-experimental evaluation design was employed to test our hypothesis. The treatment and the two control groups, described in the sequence, were made using exact matching with the Propensity Score (PS) as matching distance. The PS is the probability that a given individual belongs to the treatment group.

- Treatment group: individuals who have been awarded with a doctoral scholarship from FAPESP and who have completed their PhD (from now on identified as "FAPESP awardees");
- Control group 1: individuals who had their scholarships request rejected from FAPESP and who completed PhD with scholarships from other agencies – CAPES/CNPq (from now on referred to as "other awardees");
- Control group 2: individuals who had their scholarships request rejected from FAPESP and completed PhD without any funding support (from now on referred to as "no awardees").

The observable baseline control variables used in the pairing, the support domain for PS estimation, were:

- The starting year of the different academic stages of the individuals (undergraduate, master and PhD);

- The field of knowledge of doctoral research of the individuals;
- The institution and city in which the PhD was carried out (since the quality of institution might play a significant role);
- The occurrence of PhD funding support and, if positive, the type of scholarship (FAPESP or CAPES/CNPq); and
- The former scientific production of the individuals.

Two sets of PS were estimated, one for each control group, providing two different effective samples for treatment impact evaluation. Table 1 shows the size of the eligible population for each quasi-experiment, considering the variables listed above.

Table 2. The eligible population for each quasi-experiment

	FAPESP Awardees	*Other Awardees*	*No Awardees*	*Total*
PhD	12.618 (59,89%)	6.814 (32,34%)	1.635 (7,76%)	21.067 (100%)

Source: Research data.

The comparative analysis of former awardees' and no awardees' scientific production was based on data provided by individuals in their CV Lattes and organized in four categories, namely: (i) complete papers published in journals; (ii) published books; (iii) chapters of published books; and (iv) complete papers in conference proceedings.

Two types of analysis of scientific production were undertaken. The first considered the number of publications in these four categories. For this, we considered the average number of publications by individuals before and after completing their PhD. The option to use all these categories is based on the finding that different areas of knowledge have very different dynamics in terms of the primary vehicles used to communicate the results of research. Thus, the use of the category "complete articles published in journals" - most commonly used in bibliometric studies - could impose a limit to assess the behavior of areas in which articles in events, books, and book chapters are typical.

The second type of analysis was based on the impact of complete articles published in journals, measured by the number of citations and the H-index.[i]. Citation data and H-index were extracted from two different bases for comparison: Google Scholar and Scopus. Means of citations and H-index were calculated before and after the end of the doctoral studies, and the FAPESP scholarship effect indicates the scholarship's influence on these indicators.

Once the matching was done and data collected, the FAPESP scholarship effects were estimated, using the Generalized Linear Models (GLM) approach (Nelder & Wedderburn, 1972), choosing the link function and distribution family appropriate to the type of outcome/output indicator. In this article, since all indicators are based on counting, the model used was the Quasi-Poisson. This one uses Poisson distribution and log link function. The estimated effect is the ratio between the average occurrences in each group, with 1 having no effect. The term "quasi" is since the variance of the data is estimated proportionally to the average and is not exactly the average, as in the usual Poisson. This feature allows for the modeling of data that breaks this assumption of "mean equals variance," both for more (overdispersion) and for less (subdispersion). The data were analyzed using the software R.

For each bibliometric indicator, the model estimated the FAPESP (treatment) effect adjusted for the lagged indicator before the grant to control the regression to the mean bias. For instance, the number of papers after the scholarship was adjusted for the total number of articles before the scholarship.

Results

Figure 1 compares the number of papers in conference proceedings and journals published by former FAPESP scholarship awardees and individuals who received scholarships from another agency and the number of book and book chapters, in different knowledge fields and in general. The dot on the graph indicates the effect, and the lines indicate the confidence interval.

The so-called "FAPESP scholarship effect" indicates the extent to which the scholarship influenced the individuals' number of publications. For interpretation purposes, values equal to one indicate no effect. Values less than one indicate that former FAPESP awardees' performance is lower than that of their peers who had a scholarship from another agency, while values greater than one indicate that the performance of former FAPESP awardees is superior to that control group.

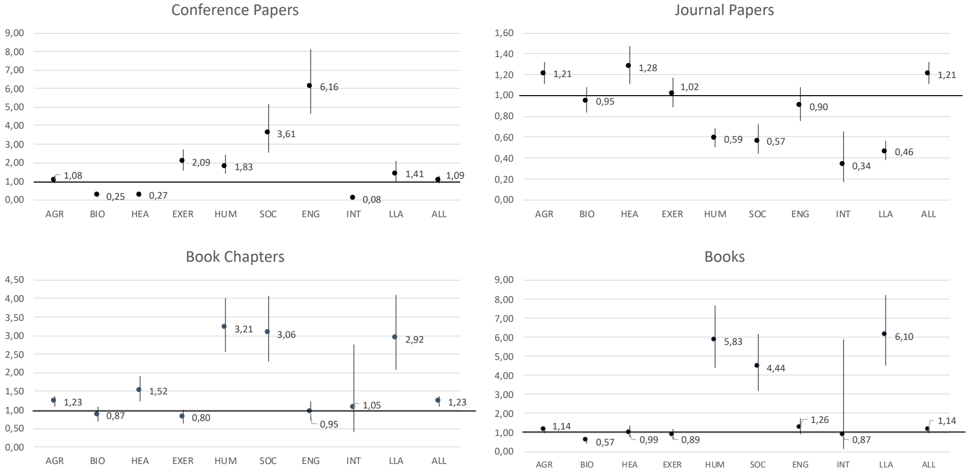

Figure 1. Publication ratio between FAPESP awardees and other awardees (number)

Legend: AGR: Agricultural Sciences; BIO: Biological Sciences; HEA: Health Sciences; EXER: Exact and Earth Sciences; HUM: Human Sciences; SOC: Social Applied Sciences; ENG: Engineering; INT: Interdisciplinary; LLA: Linguistics, Literature, and Arts; ALL: General.

Source: Research data.

It is possible to state that the former PhD FAPESP awardees publish more articles in journals, book chapters, and books than the former PhD awardees from other agencies. The effects are 21%, 23%, and 14%, respectively.

There are significant differences in knowledge fields. The FAPESP scholarship effect is positive for conference papers in all areas of knowledge except for Biological Sciences, Health Sciences, and the Interdisciplinary field. The main highlights are for Engineering and Social Applied Sciences, in which the FAPESP effect is 516% and 261%, respectively.

For papers in journals, the effects are positive for Health Sciences (28%) and Agricultural Sciences (21%) and neutral and negative for all other areas. For book chapters, the effects are very favorable for Human Sciences, Social Applied Sciences and Linguistics, Languages, and Arts and Agriculture and Health. For Biological Sciences, the effects are negative. Finally, for books, the same thing happens as for book chapters: the effects are very favorable for Human Sciences, Social Applied Sciences, Linguistics, Languages and Arts and Agriculture. For Biological Sciences, the effect is negative.

The following figure brings the same information as the others but now comparing former FAPESP scholarship holders with individuals who did not receive a doctoral scholarship.

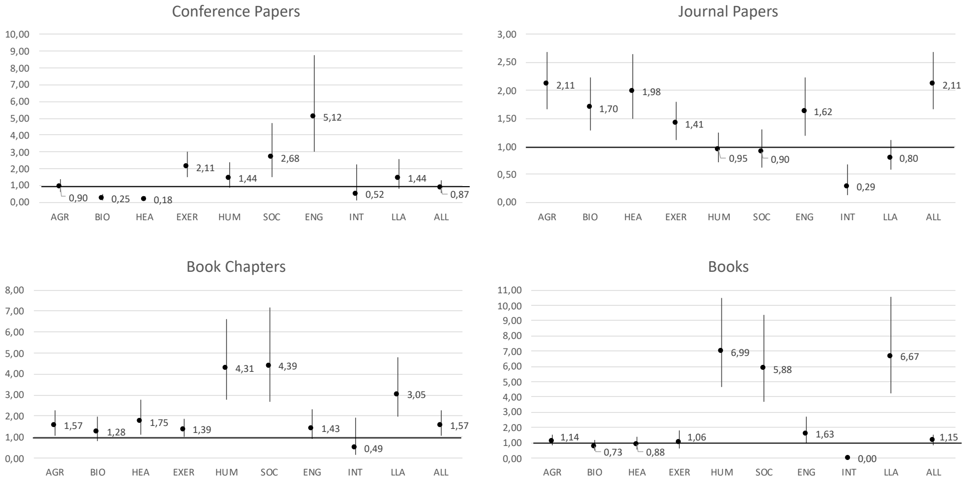

Figure 2. Publication ratio between FAPESP awardees and no awardees (number)

Legend: AGR: Agricultural Sciences; BIO: Biological Sciences; HEA: Health Sciences; EXER: Exact and Earth Sciences; HUM: Human Sciences; SOC: Social Applied Sciences; ENG: Engineering; INT: Interdisciplinary; LLA: Linguistics, Literature, and Arts; ALL: General.

Source: Research data.

Once again, the former FAPESP PhD fellows publish more articles in journals and book chapters than individuals who have done their PhD without a scholarship. These are essential effects: 111% and 57% respectively.

As expected, there are also quite different behaviors between knowledge fields. There are negative effects in only two cases: Biological Sciences and Health Sciences for conference papers and the Interdisciplinary field for papers in journals. In all other categories in which the measures are statistically significant, the effects are positive.

As can be seen, FAPESP PhD scholarship has positive effects in terms of the number of publications in vehicles of great importance for each of the knowledge fields, generally journal papers for Agricultural Sciences, Biological Sciences, Health Sciences, Exact and Earth Sciences and Engineering, and book chapters and books for Human Sciences, Social Applied Sciences and Linguistics, Literature, and Arts. Negative FAPESP PhD scholarship effect in conference papers compared to no awardees show that the latter concentrate their efforts in conferences rather than journals, which could be considered a relatively more straightforward path for disseminating research results.

The following Table (Table 2) presents impact indicators corresponding to the second type of analysis: H-index and citations.

Table 2. Citations and H-index

Source: Research data.

The impact of scientific production measured through citations and the H-index is positive for FAPESP PhD scholarships, especially compared to individuals who had their PhD studies without funding support, using both Google Scholar and Scopus databases.

Considering the overall research performance of Brazilian researchers from 2010 to 2019 in Scopus, one can find 10,9 citations per publication regarding all knowledge fields. As expected, the ratio for students before completing their PhD is similar (1,00 citation per publication) and far below the Brazilian ratio for all groups. This implies that FAPESP scholarship has no effect during the project time, probably because journal publications are more common after research is ended and feedbacks from dissertation defense are incorporated.

However, FAPESP awardees, as well as other awardees, surpass the Brazilian average after this completion, revealing not only the influence of funding in the scientific production of PhD holders after the doctorate period has ended, but also the quality of research results from this group of investigators from São Paulo State, Brazil.

Figure 3 depicts the effect of the Google Scholar quote by knowledge field, comparing former FAPESP awardees with those who obtained funding from another agency and individuals who did not receive funding.

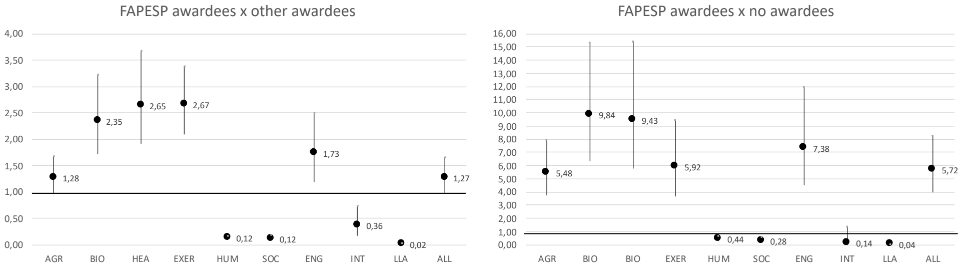

Figure 3. Google Scholar Citation Effect in Knowledge Fields

Source: Research data.

Figure 4, in turn, illustrates the effect of the H index on the knowledge field.

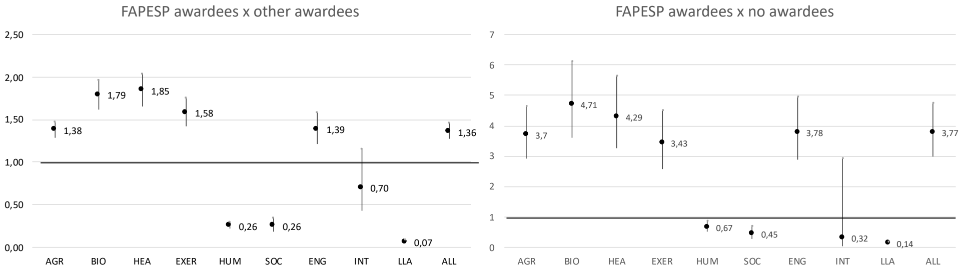

Figure 4. Google Scholar H Index Effect in Knowledge Fields

Source: Research data.

An analysis of the effects of citations and the H index by knowledge field (carried out for this report using only Google Scholar data, as stated above) confirms the generally positive effects of the FAPESP PhD scholarship, except for Humanities, Social Applied Sciences, Interdisciplinary Sciences and Linguistics, Languages and Arts, in which former scholarship holders from other agencies and those who took their PhD courses without a scholarship perform better than those from FAPESP. In other words, the pattern verified for the number of publications in journals previously analyzed is repeated, except for disciplines that have a different publication rationale not based on journal papers.

In short, our initial hypothesis is confirmed since the number of publications, the number of citations, and H index are higher for former FAPESP awardees when compared to individuals rejected by FAPESP. The effect – mainly shown after the PhD project has ended – is even more significant compared to those who did not have scholarships from other agencies, who took their PhD without funding support by a research agency. Through scholarships, the maintenance of these students allows them to focus entirely on their doctoral research and, consequently, to concentrate efforts to disseminate the achieved results.

Conclusions

This study's results allow us to state that the FAPESP PhD scholarship makes a quantitative and qualitative difference in scientific production. These effects are much more significant when comparing between former FAPESP scholarship holders and individuals who have completed a PhD course without a scholarship, revealing that despite the difference that the FAPESP scholarship makes, it is possible to state that PhD scholarships in the long run (either from FAPESP and other agencies) make much difference in the production and quality of scientific knowledge of PhDs, as already stated in other studies. Additionally, effects in scientific production quality (measured by citations and H-index) are detected in non-humanistic and non-social science knowledge areas, where journal papers are the preferred vehicle for disseminating research results. The impact of books and book chapters, although relevant, must be investigated with another kind of metric.

Therefore, it is also possible to state that the scholarships and what they mean in terms of dedication to graduate school represent fundamental conditions for knowledge production. Although it is a valid conclusion for the eligible study population (individuals who applied for FAPESP scholarships in the context of the State of São Paulo), the same likely happens in the broader Brazilian context, since the conditions for maintenance of researchers in other States are even more critical.

In this respect, the data is overwhelming: the quality of scientific production is firmly correlated to scholarships' granting. In this sense, if the goal of programs for supporting postgraduate studies through granting scholarships is to train scientists, it is possible to find much evidence of their success in the evaluation carried out.

A firm conclusion that emerges from the evaluation is that without scholarships (or another similar form of financing), there are essential threats to science in countries with Brazil's political and socioeconomic profile. This is because postgraduate students are one of the foundations of Brazilian (and so other countries') scientific and technological production and a renewing force of the advancement of knowledge made in public and private research centers and universities.

The immediate policy implication is the need to reinforce doctoral scholarship programs, which seems obvious to many developed countries that have reinforced support for education and scientific research in moments of crisis. However, it is controversial in the Brazilian context where governmental budgets decrease, and research funding agencies suffer from constant menaces.

Managerial implications concern the need for funding agencies to examine the behavior patterns related to different knowledge fields more deeply to establish appropriate mechanisms for support PhD students and evaluate the impacts of scholarships.

The main limitations of the study that we hope to address in the future are as follows: i) use information about peer review reports creating more comparable groups, such as best- rejected

applicants, as proposed by Bornmann et al. (2010) and Melin and Danell (2006) and worst-approved; ii) use gender as a new variable in this comparison of scientific production of PhDs; (iii) use coauthorship information to better understand the achievement of academic autonomy of these individuals and patterns of national and international collaboration.
Thus, we understand that there is a strong association between PhD scholarship and the quantity and quality of scientific production and that further investigation on this subject is still needed.

Abstract

We present a large-scale bibliometric analysis of gender differences in science, covering all scientific disciplines and a large number of countries worldwide. We take a longitudinal perspective in which we trace the scientific careers of almost six million male and female researchers in the period 1996–2018. This enables us to analyze when male and female researchers entered the research system and how long they stayed in the system. It also allows us to study gender differences in productivity and seniority. Our analysis indicates that differences in the number of men and women entering the system are the most significant cause of gender imbalances. Differences between male and female researchers leaving the system do not play an important role. We also find that men produce substantially more publications than women and that men are more likely than women to move to more senior positions.

Introduction

Differences between men and women in their participation in scientific research are extensively being discussed. Underrepresentation of women in the research system may indicate that the system does not sufficiently benefit from the contributions that highly-qualified female researchers could make. To the extent that men and women differ in their research interests, it may also be a signal that the system does not provide sufficient room for female perspectives, causing certain topics, ideas, or approaches to be overlooked or marginalized.

In this paper, we present a large-scale bibliometric analysis of gender differences in science. Our analysis covers all scientific disciplines and a large number of countries worldwide. Rather than providing a cross-sectional picture of gender differences in the research system at a specific point in time, we offer a longitudinal perspective in which we trace the scientific careers of almost six million male and female researchers in the period 1996–2018. Such a longitudinal perspective enables us to analyze when male and female researchers entered the research system and how long they stayed in the system. It also allows us to study differences between male and female researchers in productivity (in terms of the number of publications they produce in specific years in their career) and seniority (in terms of the authorship positions they occupy in specific years in their career).

There is an extensive bibliometric literature on gender differences in science (for an overview, see Halevi, 2019). While earlier studies usually provided a cross-sectional picture of gender differences (e.g., Filardo et al., 2016; Holman et al., 2018; Jagsi et al., 2006; Larivière et al., 2013; West et al., 2013), more recent studies have started to offer longitudinal perspectives in which the careers of researchers are traced over time. A recent report by Elsevier (2020) for instance analyzed the development of male and female careers that started in 2009, and a recent study by Huang et al. (2020) presented a historical analysis by tracing male and female careers that ended between 1955 and 2010. Huang et al. concluded that gender differences in publication productivity and citation impact can largely be explained by differences in career length.

The importance of longitudinal analyses that account for factors such as career length and publication productivity is illustrated by research into gender differences in self-citations.

Based on an analysis of 1.5 million publications that appeared between 1779 and 2011, King et al. (2017) found that men self-cite 56% more than women. However, Mishra et al. (2018) showed that gender differences in self-citations largely disappear when accounting for a researcher's prior number of publications (for additional results pointing in the same direction, see Azoulay & Lynn, 2020), suggesting that men do not disproportionally self-cite compared with women.

Like the work by Huang et al. (2020), Mishra et al. (2018), and others, our work in the present paper offers a longitudinal bibliometric perspective on gender differences in science. By analyzing the careers of a very large number of researchers in all scientific disciplines, we aim to provide a solid high-level understanding of the relationship between gender and factors such as career start, career length, productivity, and seniority.

Data and methods

Bibliographic database

Our analysis is based on the Scopus database produced by Elsevier. Scopus bulk data is delivered annually by Elsevier to the Centre for Science and Technology Studies (CWTS) at Leiden University. To facilitate large-scale bibliometric analyses, the data is stored in a relational database at CWTS. Our analysis uses Scopus data received in April 2019. The data covers publications from 1996 to early 2019.

When two publications include the same author name, they may have been produced by the same author. However, they may also have been produced by two different authors that happen to have the same name. The other way around, when two publications do not include the same author name, they probably have not been produced by the same author. However, it may be that the publications have been produced by the same author, but the author may not have reported his or her name in a consistent way. An author name disambiguation algorithm attempts to determine which publications belong to the same author.

Our analysis relies on author identifiers provided by Scopus. These identifiers have been assigned using an author name disambiguation algorithm. In some cases, manual corrections have been made to the identifiers based on feedback from Scopus users. The author name disambiguation algorithm used by Scopus is a black box for which no public documentation is available. Based on an evaluation of 12,000 randomly selected authors, Scopus claims that its author identifiers have a precision of 98.1% and a recall of 94.4% (Baas et al., 2020). In an independent evaluation focused on Japanese authors, a precision and recall of 99.4% and 98.4%, respectively, were obtained (Kawashima & Tomizawa, 2015). For Dutch authors, lower values of 87.3% and 95.9% for precision and recall were found (Reijnhoudt et al., 2014). In a more recent evaluation focused on German authors, a precision and recall of 100.0% and 97.1% were reported (Aman, 2018). In the rest of this paper, we use the terms 'author' and 'researcher' to refer to authors as defined by author identifiers in Scopus.

Gender inference

For each author in Scopus, we attempted to algorithmically infer a gender, either male or female. If no gender could be inferred for an author, the gender was considered unknown. While we believe that algorithmic approaches to gender inference yield valuable insights, we emphasize that these approaches also have major limitations. In particular, algorithms for gender inference reduce gender to a binary concept, they are susceptible to bias, and their transparency is limited. We refer to Mihaljević et al. (2019) for a further discussion of these important issues.

Our algorithmic approach to gender inference uses three tools: Gender API (https://gender-api.com/), Gender Guesser (https://pypi.org/project/gender-guesser/), and Genderize.io (https://genderize.io/). Because of space limitations, we do not discuss our gender inference approach in more detail.

Gender statistics

In the calculation of the gender statistics reported in this paper, we considered only publications of the document types *article*, *chapter*, *conference paper*, *conference review*, and *review* in Scopus. Publications of other document types were disregarded. We considered only authors that have at least three publications. Authors with one or two publications are relatively likely to be the result of mistakes made by Scopus' author name disambiguation algorithm.

For each author, we determined the year of the first publication and the year of the last publication. We used the year of the first publication as a proxy of the year in which someone entered the research system. Likewise, the year of the last publication was used as a proxy of the year in which someone left the system. An important caveat applies. Because publications that appeared before 1996 are not included in our data, the year of someone's first publication could not always be correctly determined. The other way around, because someone may continue to publish in the future, the year of someone's last publication could not always be correctly determined either. For instance, someone's last publication in our data may be from 2017, but this person may have produced another publication in 2020. This person is then incorrectly considered to have left the research system in 2017. As a consequence of these issues, statistics for the first and last years covered by our analysis are less reliable than statistics for the years in between.

We also linked authors to scientific disciplines. We used the disciplinary classification provided by Scopus for this purpose. In this classification, each source (e.g., a journal or a conference proceedings) in Scopus belongs to one or more disciplines. The classification consists of two hierarchically related levels. We considered only the top level, which comprises 26 disciplines. We linked an author to a discipline if at least 80% of the publications of the author have appeared in sources belonging to the discipline. Some authors could not be linked to a discipline. Other authors were linked to multiple disciplines. (This is possible because a source may belong to more than one discipline.)

Finally, we linked authors to countries. An author was linked to a country if the author has an affiliation with an address in the country in at least 80% of his or her publications. Some authors could not be linked to a country. Other authors were linked to multiple countries. (This is possible because an author may have multiple affiliations in the same publication, possibly with addresses in different countries.) Our analysis covers only the 95 countries for which the share of authors for which the gender is unknown does not exceed 33%. For other countries, we do not consider gender statistics to be sufficiently informative. Our general statistics that do not pertain to a specific country cover all authors that have in at least 80% of their publications an affiliation with an address in one of the above-mentioned 95 countries.

Results

We first analyze gender differences for researchers entering and leaving the research system. We then consider gender differences in the productivity and seniority of researchers.

Our analysis includes 6.9 million researchers with at least three publications in the period 1996–2018. The analysis of researchers entering the system is based on 3.9 million male researchers and 2.1 million female researchers. In most of the results, the 0.9 million researchers for whom the gender could not be inferred are not included.

In the remaining analyses, we consider only the 205,779, 251,343, and 267,815 male and female researchers that entered the research system in, respectively, 2000, 2005, and 2010. By focusing on these three cohorts of researchers, we are able to separate gender differences in recent years from those in earlier years.

Entering the system

We first consider gender differences for researchers that enter the research system. Figure 1 shows the time trend in the percentage of men and women that entered the system. The left panel presents the time trend when researchers with an unknown gender are included in the statistics. The right panel presents the time trend when these researchers are excluded from the statistics. Like the statistics in the right panel, all remaining statistics reported in this paper do not include researchers with an unknown gender.

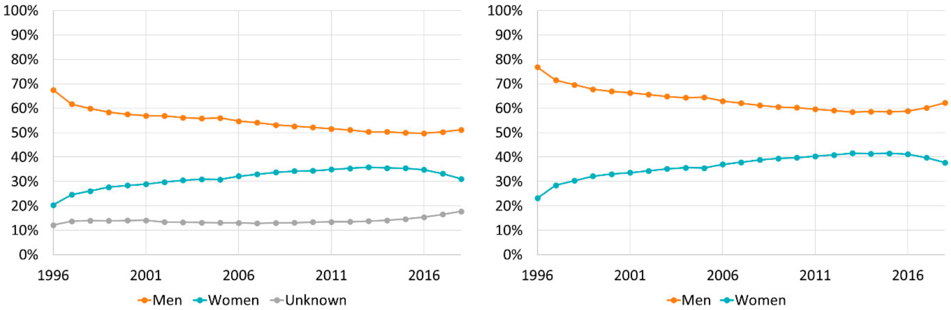

Figure 1. Percentage of men and women that entered the research system. Annual statistics for the period 1996–2018, including (left) and excluding (right) researchers for whom the gender is unknown.

Figure 1 shows a clear increase in the percentage of women that entered the system. Before 2000, for every two women that entered the system, there were four to five men that entered the system. In recent years, there were about three men that entered the system for every two women. We note that the statistics for 1996 and 1997 are not reliable because they also include many researchers that entered the system before 1996. Likewise, the statistics for the most recent years have a low reliability because some researchers that entered the system in these years do not yet have three publications and are therefore not included in the statistics. Most likely, the drop in the percentage of women that entered the system in recent years is an artefact resulting from the requirement of having at least three publications.

We also made a breakdown by discipline of the percentage of men and women that entered the system in 2000 and 2010 (not shown). In all disciplines in the physical sciences, engineering, and mathematics, the number of men that entered the system in 2010 was much larger than the number of women, ranging from 62% men in Chemistry to 85% men in Engineering. The strong underrepresentation of women in these disciplines is discussed extensively in the literature, including also in detailed bibliometric studies of specific disciplines, such as computer science (Cavero et al., 2015), mathematics (Mihaljević & Santamaría, 2020; Mihaljević-Brandt et al., 2016), and physics and astronomy (Mihaljević & Santamaría, 2020).

In most disciplines in the biomedical and health sciences, there were no major differences in the number of men and women that entered the system in 2010. In some disciplines, such as Environmental Science and Dentistry, the number of men that entered the system was somewhat larger than the number of women. In other disciplines, such as Immunology and Microbiology, the situation was the other way around. Nursing was the only exception. In this discipline, women represented 78% of all researchers that entered the system in 2010.

For disciplines in the social sciences and humanities, the picture is more mixed. The two extremes are Economics, Econometrics and Finance on the one hand, where women represented only 28% of all researchers that entered the system in 2010, and Psychology on the other hand, where women represented 66% of all researchers that entered the system. We refer to Lundberg and Stearns (2019) for an in-depth discussion of the underrepresentation of women in economics. In psychology, the overrepresentation of women among new researchers entering the system was also observed in a recent analysis by González-Alvarez and Sos-Peña (2020). When looking at researchers that entered in system in 2010, Arts and Humanities is close to gender parity. However, this may hide significant variation among different Arts and Humanities fields. Women are for instance reported to be strongly underrepresented in philosophy (Wilhelm et al., 2018).

For all disciplines except for Nursing, the percentage of women that entered the system in 2010 was higher than the percentage of women that entered the system in 2000. The difference is largest in Psychology, Environmental Science, and Chemical Engineering. In each of these disciplines, the percentage of women that entered the system increased by 12 percentage points between 2000 and 2010. Most disciplines moved in the direction of gender parity. However, Psychology is a notable exception (see also González-Alvarez & Sos-Peña, 2020). In this discipline, the percentage of women that entered the system increased from 54% in 2000 to 66% in 2010.

Figure 2 shows a breakdown by country of the percentage of women that entered the system in 2010. For countries that are colored gray, no statistics are available. Percentages below 30% can be found in some African countries, a number of countries in the Middle East, and also for Asian countries such as Japan (18%) and South Korea (21%). There are 12 countries where more than half of the researchers that entered the system in 2010 were female. In addition to a number of countries in Eastern and Southern Europe, this was the case for Puerto Rico (51%), Iceland (52%), Tunisia (56%), Philippines (57%), and Argentina (57%). We note that country-level statistics need to be interpreted with some care, because the accuracy of our approach to gender inference differs between countries.

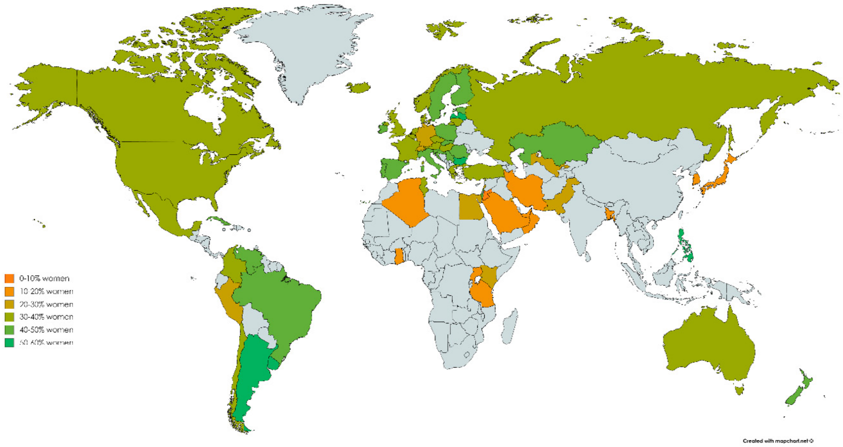

Figure 2. Percentage of women that entered the research system. Country statistics for researchers that entered the system in 2010.

Leaving the system

We now turn to gender differences for researchers that leave the research system. For male and female researchers that entered the system in 2000, 2005, and 2010, Figure 3 shows the annual percentage of researchers leaving the system. This percentage is calculated relative to all male and female researchers still in the system after a certain number of years. For instance, of the 137,715 male researchers that entered the system in 2000, 120,366 were still in the system after

5 years and 114,753 were still in the system after 6 years. Hence, after 5 years, (120,366 − 114,753) / 120,366 = 4.7% of the remaining male researchers left the system. This was the case for 5.2% of the remaining female researchers.

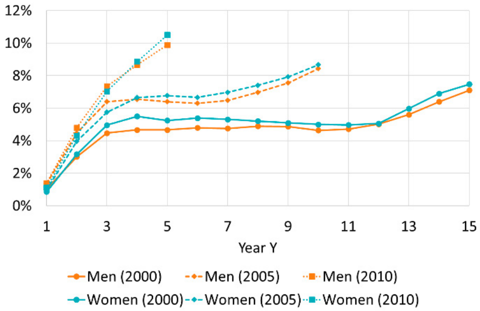

Figure 3. Percentage of men and women that left the research system after Y years relative to all men and women still in the system. Statistics for researchers that entered the system in 2000, 2005, and 2010.

For researchers that entered the system in 2005 or 2010, Figure 3 shows that in the early years of their career men were somewhat more likely to leave the system than women. In later years, women were more likely to leave the system. For researchers that entered the system in 2000, women consistently had a higher probability to leave the system than men (except for Y = 1 in Figure 3), but in later years of their career the difference was very small. We note that at the end of all three time trends in Figure 3 there is a substantial increase in the percentage of men and women leaving the system. This is an artefact resulting from researchers that are incorrectly considered to have left the system in recent years. These researchers have no publications in the most recent years covered by our analysis, but they will have publications in future years not covered by our analysis.

We also made a breakdown by discipline of the percentage of men and women leaving the system within five years after they entered the system (not shown). Statistics were calculated for researchers that entered the system in 2000 and 2010. For researchers entering in 2010, most disciplines show only a small difference between men and women. In some disciplines men were somewhat more likely to leave the system, while in other disciplines women had a somewhat higher probability to leave. The difference between men and women was more substantial in Nursing (44% vs. 35%) and Business, Management and Accounting (27% vs. 21%), with men being significantly more likely to leave the system than women in both disciplines. For researchers that entered the system in 2000, the situation was less balanced. In 19 of the 25 disciplines men were less likely to leave the system than women. The difference was largest in Psychology (13% vs. 20%) and Engineering (26% vs. 32%).

Results similar to ours were reported by Elsevier (2020) for researchers that entered the system in 2009. Huang et al. (2020) also performed a similar analysis, but their findings are different from ours. They found that each year female researchers are almost 20% more likely to leave the system than male researchers. The analysis of Huang et al. covers an older time period, which probably explains why their findings are different. For assistant professors hired since 1990 at US universities, it was found that both in science and engineering (Kaminski & Geisler, 2012) and in the social sciences (Box-Steffensmeier et al., 2015) there are no or almost no gender differences in retention rates. This seems to align with our finding that in later years of their career (i.e., after the PhD and postdoctoral period) female researchers that entered the system in 2000 were only slightly more likely to leave the system than their male colleagues.

Productivity

We next consider gender differences in the productivity of researchers. For male and female researchers that entered the research system in 2000, 2005, and 2010, Figure 4 shows the time trend in their average annual number of publications. The left panel presents statistics based on a full counting approach. In this approach, all co-authors of a publication are considered to have contributed to the publication, irrespective of the total number of co-authors of the publication. For all researchers that were still in the system in a certain year of their career, the left panel shows the average number of publications to which they contributed. The right panel presents statistics based on a fractional counting approach. In this approach, if a publication is co-authored by *n* researchers, each of these researchers is considered to have produced (1 / *n*)th of a publication. For all researchers that were still in the system in a certain year of their career, the right panel shows the average number of fractionally counted publications they produced.

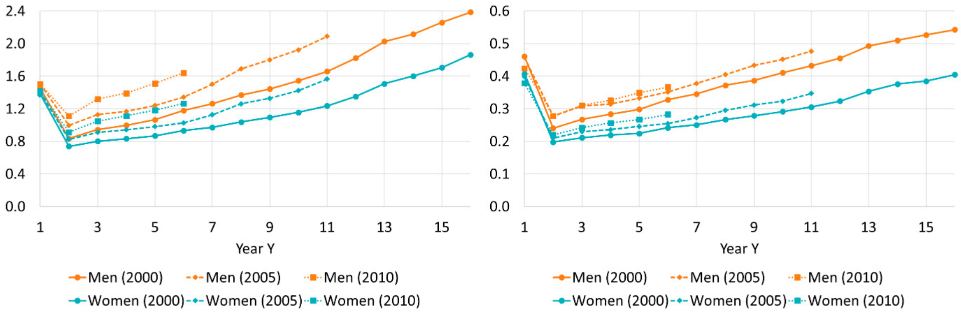

Figure 4. Average number of publications of men and women in year Y of their scientific career. Statistics for researchers that entered the research system in 2000, 2005, and 2010 based on full (left) and fractional (right) counting.

Figure 4 shows that, regardless of the year in which they entered the system and the year of their career, men consistently had a substantially higher productivity than women. Based on the full counting statistics, the productivity of men was between 20% and 35% higher than the productivity of women. The difference is even larger when looking at the fractional counting statistics. Based on these statistics, the productivity of men was between 25% and 40% higher than the productivity of women.

There are well-known differences between disciplines in the average number of publications of a researcher. The gender differences observed in Figure 4 could be due to a relative overrepresentation of men in disciplines with a larger average number of publications per researcher and, conversely, a relative overrepresentation of women in disciplines with a smaller average number of publications per researcher. To explore this possibility, we made a breakdown by discipline of the average number of publications of men and women in year 6 of their career (not shown). Statistics were calculated for researchers that entered the system in 2000 and 2010, based on both a full counting approach and a fractional counting approach.

We first consider the full counting statistics. For researchers that entered the system in 2000, in year 6 of their career male researchers had a higher productivity than their female colleagues in 22 of the 25 disciplines. The same observation can be made for researchers that entered in 2010. On average, the productivity per discipline was 17% higher for male researchers that entered in 2010 than for their female colleagues (calculated by averaging the percentage difference over all disciplines, weighing each discipline by its number of researchers). Hence, the overall gender difference in productivity observed in the left panel of Figure 4 can also be found at the level of individual disciplines. However, at the disciplinary level, the relative differences between men and women were somewhat smaller than at the overall level. This means that the overall gender difference in productivity was partly caused by a relative overrepresentation of men in disciplines with a larger average number of publications per researcher. In particular, the average number of publications per researcher was much larger in Physics and Astronomy than in other disciplines, and Physics and Astronomy was also one of the disciplines with the largest overrepresentation of men among researchers entering the system.

Like the full counting statistics, the fractional counting statistics indicate that in most disciplines men were more productive than women in year 6 of their career. The fractional counting approach yields somewhat larger relative differences between men and women than the full counting approach. For researchers that entered the system in 2010, on average the productivity per discipline was 20% higher for male researchers than for their female colleagues. Based on the fractional counting approach, the average number of publications per researcher was substantially larger in disciplines in the physical sciences, engineering, and mathematics than in disciplines in the biomedical and health sciences. The overrepresentation of men among researchers entering the system was also much larger in the physical sciences, engineering, and mathematics than in the biomedical and health sciences. This means that the overall gender difference in productivity observed in the right panel of Figure 4 was caused partly by gender differences in productivity at the level of individual disciplines and partly by the relative overrepresentation of men in certain disciplines, in particular in the physical sciences, engineering, and mathematics.

Productivity differences between male and female researchers, with male researchers on average producing more publications than their female colleagues, have been found in a large number of studies (for an overview, see Halevi, 2019). These differences, which lead to the so-called productivity puzzle (Cole & Zuckerman, 1984), were also observed in recent large-scale analyses by Elsevier (2020) and Mishra et al. (2018). In line with our results reported above, the literature generally finds that productivity differences cannot be explained by differences in career length or career stage. However, a notable exception is a recent study by Huang et al. (2020). Based on a large-scale longitudinal analysis, Huang et al. found that differences in career length explain differences between male and female researchers in productivity, leading to the conclusion that "men and women publish at a comparable annual rate", referred to as a 'gender invariant' by Huang et al. These findings are in stark contrast with our findings presented above as well as the findings of many other studies. The discrepancy may be due to the older time period covered by the analysis of Huang et al. Moreover, unlike our analysis, the analysis of Huang et al. does not consider the productivity of researchers in a specific period in their career, but only their average productivity during their entire career. This may also explain why the findings of Huang et al. are different.

Seniority

Finally, we look at gender differences in the seniority of researchers. We use a researcher's position in the list of authors of a publication as a crude proxy of seniority. More specifically, we focus on the first and last author of a publication. In most disciplines, being first author of a publication indicates that one has made a major contribution to a research project, either in a more junior or in a more senior role. Being last author of a publication is especially relevant in biomedical disciplines, where the last author typically is a senior researcher that carries the overall responsibility for a research project. Although statistics on first and last authorship provide useful information, we emphasize that there are important differences between disciplines in the way in which the order of the authors of a publication is determined. In some disciplines, in particular in economics, high energy physics, and mathematics, it is quite common to list authors in alphabetical order (Waltman, 2012). First and last authorship have little or no meaning in these disciplines. We refer to Marušić et al. (2011) for an overview of the literature on authorship practices.

For earlier large-scale studies of gender differences in first and last authorship, we refer to Holman et al. (2018) and West et al. (2013). There are also several studies with a specific focus on medical journals (e.g., Filardo et al., 2016; Jagsi et al., 2006). Importantly, unlike our analysis reported below, earlier studies were of a cross-sectional nature. These studies therefore could not account for factors such as the career length of researchers.

For male and female researchers that entered the research system in 2000, 2005, and 2010, Figure 5 shows the time trend in the probability of being first (left panel) or last (right panel) author of a publication. In the early years of their career, researchers were relatively likely to be first author of a publication. In later years, the probability of being first author decreased and researchers were more likely to be last author. However, there are significant gender differences. As can be seen in the left panel of Figure 5, in the early years of their career, men were more likely than women to be first author of a publication. The opposite pattern can be observed for later years. Moreover, as shown in the right panel of Figure 5, both in earlier and in later years of their career, men were substantially more likely to be last author than women. The probability of being last author was between 15% and 30% higher for men than for women. Since last authorship is an indication of seniority, especially in biomedical disciplines, this suggests that on average it took less time for men than for women to reach a more senior position in the research system.

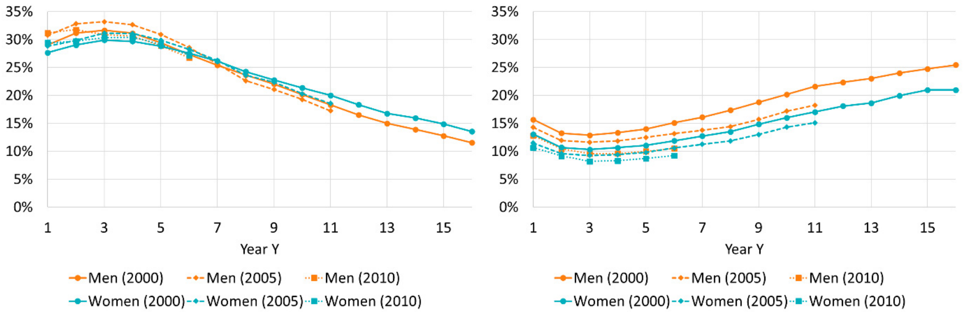

Figure 5. Probability of being first (left) or last (right) author of a publication for men and women in year Y of their scientific career. Statistics for researchers that entered the research system in 2000, 2005, and 2010.

As already mentioned, different disciplines have different norms for determining the order of the authors of a publication. For men and women in year 6 of their career, we made a breakdown by discipline of the probability of being last author of a publication (not shown). The statistics pertain to researchers that entered the system in 2000 and 2010.

From the viewpoint of understanding gender differences in researchers' seniority, the most interesting results are the statistics for last authorship in the biomedical and health sciences. Looking at researchers that entered the system in 2010, we find that in all disciplines in the biomedical and health sciences men had a higher probability than women to be last author of a publication in year 6 of their career. For researchers that entered in 2000, this was the case in 9 of the 11 disciplines in the biomedical and health sciences. In terms of the number of researchers, Medicine is by far the largest discipline in the biomedical and health sciences, followed by Biochemistry, Genetics and Molecular Biology and Agricultural and Biological Sciences. In each of these disciplines, for researchers that entered the system in 2010 and that were in year 6 of their career, the probability to be last author of a publication was about 25%

higher for men than for women, suggesting that on average men moved to more senior roles more quickly than women. Underrepresentation of women among last authors was also observed by Holman et al. (2018) and West et al. (2013), but these cross-sectional studies did not account for differences in career length and other factors.

Discussion and conclusion

The large-scale bibliometric analysis presented in this paper provides detailed insights into differences between men and women in entering and leaving the research system and in their productivity and seniority while they are in the system.

The percentage of women entering the research system shows a clear increasing trend. About 40% of all researchers that entered the system in recent years were female. In 2000 this was the case for only 33% of the researchers, and before 2000 the percentage of women entering the system was even lower. There are large differences between disciplines. In the physical sciences, engineering, and mathematics, only 22% of the researchers that entered the system in 2010 were female. In economics, this was the case for just 28% of the researchers. In contrast, in nursing and psychology, women represented, respectively, 78% and 66% of the researchers that entered the system in 2010. Differences between countries are large as well. In some countries, for instance in Eastern and Southern Europe, more than half of the researchers that entered the system in 2010 were female. In other countries, such as Japan and South Korea, this was the case for only one out of every five researchers.

Women seem to be somewhat more likely to leave the research system than men. This difference is most clearly visible for researchers that entered the system in 2000. For researchers that entered in 2005 and 2010, the difference is less clear. In the first few years of the careers of these researchers, women were actually less likely to leave the system than men. In later years, however, women had a higher probability to leave than men. Even for researchers that entered in 2000, the gender difference in leaving the system was not very large. As mentioned above, 33% of the researchers that entered in 2000 were female. After 15 years, 52% of the male researchers and 54% of the female researchers had left the system, resulting in 32% of the researchers still in the system being female.

There are substantial gender differences in productivity, where we define productivity in terms of the number of publications produced by a researcher in a certain year of his or her career. Depending on the year in which they entered the research system, the year of their career, and the counting approach (i.e., full or fractional counting), men were on average between 20% and 40% more productive than women. This can partly be explained by the strong overrepresentation of men in disciplines with a larger average number of publications per researcher, in particular in the physical sciences, engineering, and mathematics. After correcting for this overrepresentation, we found that in year 6 of their career men were on average between 15% and 20% more productive than women.

Determining researchers' seniority is challenging, but being last author of a publication can be used as crude proxy, especially in biomedical disciplines. Gender differences in last authorship are substantial. Overall, men were between 15% and 30% more likely to be last author of a publication than women. For researchers in biomedical disciplines that entered the research system in 2010 and that were in year 6 of their career, the probability of being last author was about 25% higher for male researchers than for their female colleagues. These statistics suggest that men moved to more senior roles more quickly than women.

Based on the various factors considered in our analysis, the overall picture emerging from our work is that differences in the number of men and women entering the research system are the most significant cause of gender imbalances in the system. In recent years, the number of male researchers entering the system was between 40% and 50% larger than the number of female researchers entering the system. In earlier years, the difference was even larger, and the effect of this is still visible in the current composition of the scientific workforce. It will be interesting to see whether the increasing trend in the proportion of women entering the research system will continue in the coming years. Compared with the gender differences that we found for researchers entering the system, differences between male and female researchers leaving the system are small and do not play an important role in explaining overall gender imbalances in the system. However, our statistics on last authorship do suggest that within the research system men and women follow significantly different career trajectories, with men being more likely than women to move to more senior positions. Finally, publications play an important role in the research system, which leads to an additional gender imbalance, since men produce on average between 15% and 20% more publications than women.

We end this paper by drawing attention to a number of important limitations of our research. First of all, our work is subject to the limitations of the Scopus database. The coverage of the scientific literature provided by the Scopus database is incomplete. Some researchers therefore are not included in our analysis, while for other researchers their publication oeuvre is covered only partly. In addition, the Scopus data to which we have access does not go back before 1996. This means that our analysis does not properly cover researchers with long careers in science. The disciplinary classification provided by Scopus also has weaknesses, such as questionable classifications of some journals and large size differences between disciplines. Furthermore, our analysis relies on algorithmic approaches to author name disambiguation and gender inference. These approaches inevitably make mistakes that affect our analysis. For instance, Scopus' author name disambiguation algorithm may sometimes fail to recognize that two authors in fact represent the same person. Our approach to gender inference has the limitation of relying on a binary notion of gender. Moreover, for many researchers our approach is unable to infer a gender, leading to missing statistics for important countries such as China and India. Another limitation of our research is that all publications are treated in the same way. The citation impact of publications for instance is not taken into account. Finally, while a large-scale bibliometric analysis like the one presented in this paper offers valuable high-level insights into gender differences in science, it does not provide a more in-depth understanding of gender differences in specific disciplines or countries and of the underlying mechanisms causing these differences. To obtain such an understanding, our work needs to be complemented with case studies in which gender differences in individual disciplines or countries are analyzed in more detail.

Abstract

We review some recent works of our research lab that have applied novel text mining techniques to the issue of research impact assessment. The techniques are Semantic Hypergraphs and Lexicon-based Named Entity Recognition. By using these techniques, we address two distinct and open issues in research impact assessment: the epistemological and logical status of impact assessment, and the construction of quantitative indicators.

Introduction

In the latest few months, we have published four papers in various journals that contribute to the debate on research impact (Bonaccorsi et al. 2020; 2021a; 2021b; 2021c). The overall aim of this effort is to call the attention on two dimensions of the research impact that have been somewhat neglected. The first is a theoretical issue: What kind of statement is a statement of the type "research X has produced an impact on Y"? What is the logical nature of this statement? What is the semantic structure of a statement of this type? It turns out that addressing this apparently theoretical question has far reaching implications. The second is a methodological issue: Which methods can we use for research impact assessment? Can we build indicators, as it happens in other areas of S&T? In this paper we deepen the conceptual issues underlying these papers, we describe their findings, and illustrate a research program for future studies and practical applications.

The historical nature of research impact statements

What kind of statement is a statement of the type "research X has produced an impact on Y"? When asked to give account of the impact of their research, researchers make use of a narrative. This is dictated by the nature of the requirement: the impact of research is a process that unfolds over time, involving several actors, with many events, facts, accidents taking place at different points in time. The outcome is a change of state that does not take place abruptly but is prepared by a sequence of events and a plurality of actors. To make sense of the unfolding of the impact process the only type of writing is a narrative one. Researchers must persuade their readers that their research has indeed taken part to a historical process, whose reality can be demonstrated, in which some actors have directly or indirectly benefited from it, leading to some improvement. To persuade the readers the researchers must do two things: first, it must build a narrative that unfolds over time, is plausible and realistic, and ends up with the impact; second, it must demonstrate that within this narrative, researchers have had a role, that is, have produced the impact, or have contributed to the production of the impact.

The narrative style is shared by two fundamentally different types of writing: history and fiction. Historical narrative is expected to reconstruct sequences that represent historical facts, or events that have taken place in historical time, according to the best available documentation. Historical narratives may have a subjective flavour in the way in which the flow of events is reconstructed and the importance is weighted, but they must comply with severe standards of control about the historical truthfulness of their statements. In contrast, fiction has no obligation whatsoever with respect to truth.

In order to build a flow of events that make sense, when writing a narrative text authors place of attention in giving details, offering a rich and contextualized description of what indeed happened. Vividness, detail, and richness of the description are essential component of narratives.

The narrative nature of research impact reports, however, may reasonably lead to the claim that they cannot include causal statements. To have a causal statement one must satisfy some general requirements that cannot be satisfied if the action takes place in the past. According to an influential tradition of research in post-structuralism, if the events narrated are placed in the past, then there is no difference between history and fiction, because the readers can never control the objectivity of the events.

Causality and credibility

In our first paper (Bonaccorsi et al. 2021a) we argue that research impact reports do include propositions that have a causal value. We defend this argument in two ways: making reference to the philosophical debate on the nature of historical knowledge, and by applying to impact statements a new text mining technique that makes it possible to identify the semantic structure of complex text structures, such as entire sentences, called Semantic Hypergraphs. By applying this technique to the collection of REF impact case studies we achieve some interesting results.

If we agree that research impact statements are historical statements, then we can move forward and ask some questions that have been the object of a passionate debate in the ‘50s and ‘60s, which has been renewed in recent times. The questions can be formulated as follows: Do historical narratives include explanatory statements? Can historical explanation be considered a scientific explanation? If the answer is positive, under which formal conditions do historical statements have explanatory value? If the answer is negative, how can historians aim at scientific objectivity?

The debate was sparked by the celebrated article by Carl Hempel. The argument was sharp: for a statement to be explanatory, it must include reference to a law-like proposition and a specific, contextualized event, given some boundary conditions. The explanation is the logical process by which we demonstrate that the specific event (explanandum) is logically entailed by the general law (explanans), given the boundary conditions. We perform this task in a logical way, by subsuming the individual event into a general category, following a nomological-deductive approach.

This formulation had an enormous impact. We might say it is, explicitly or implicitly, at the root of all arguments that sharply separate between hard science and humanities, negating the scientific value of the latter. Interestingly, it has been rejected with a number of strong arguments by philosophers and historians. We summarize these arguments here, before showing why they are relevant to the debate on research impact.

First of all, the nomological-deductive model of explanation is not the only possible model of causality. It is a model of necessary and sufficient conditions, which requires for any explanation the existence of general laws that treat the specific event as a member of a class. In other words, it requires the existence of a class of entities. The class of entities is demonstrated by repetition, that is, by producing experimentally manipulated pieces of evidence that reproduce with regularity the same outcomes.

This is not the only logically valid type of explanation. Another logically valid type is a statement which claims that a given condition X has been partially sufficient for Y. This statement would not treat X as a case in a class of entities that can be reproduced. By reasoning on X historians can build up a collection of partial explanations which together produce a sufficient reason for the manifestation of Y. Each of them has local and circumstantial value.

Second, historians do make use of general laws in their formulations. As stated by Nicholas Rescher, historians are consumers of general laws, not producers. They do not ignore the physical or chemical general laws that dominate the working of nature and they clearly see their application in specific cases. It is rare, however, that the implication of a general law is the crucial element to be invoked to formulate a historical judgment. As the historian Marc Bloch stated, it is certainly true that it is the law of gravity that governs the fact that King X fell from his horse and died. But it is not so interesting to know. Other less general explanatory factors, such as the speed at which he was riding or the threat he was addressing are more important. As the philosopher noted, such general laws very often do not exist, or are trivial.

Third, the validity of historical statements is not predicated on the logical strength of a deductive reasoning, but on the completeness and accuracy of historical documentation, and the plausibility of the narrative reconstruction of causal linkages. It is certainly true that it is not possible to validate experimentally all causal linkages between events. However, historians collect all possible causal explanations (including those that are generated by true general laws) and select among them those that can create a plausible chain of events. In doing so they make appeal to the largest available documentation and to patterns of reasoning that are not deductive but abductive, following the "method of clues" illustrated by Carlo Ginzburg.

On the causality value of research impact statements

From this purely theoretical discussion we move towards another question: if research impact statements have historical nature, what kind of explanation do they include?

Here it is important to call into the debate the influential line of thinking that has proposed the notion of contribution, as opposed to attribution, as the logical foundation for impact assessment. According to this argument, it is impossible to control for all potentially influencing factors that may lead to a research impact. The social impact of research takes place within complex and multidimensional processes that extended over long, often unpredictable, time horizons.

Consequently, the notion of attribution, or the process by which a specific event may be logically demonstrated to be dependent upon a specific condition, must be rejected, in favour of a weaker notion of contribution. We agree with this argument with a qualification. It is one thing to reject the notion of attribution if we assume that the only causal model underlying the attribution is the nomological-deductive causality suggested by Hempel, or variants of this model that fit the way in which causality is assumed in hard sciences. It is another thing to suggest that impact statements do not include any kind of causality. We show that they indeed include causal statements, but these statements must be understood in the light of a theory of historical, not nomological, causality.

In order to examine this issue we adopt a recently developed technique in text mining called Semantic Hypergraphs (Menezes and Roth, 2019). This technique overcomes one of the most important limitation of Natural Language Processing techniques, that is, the ability to examine individual word, or short sequences of words (n-grams), due to computational limits of the algorithms. With Semantic Hypergraphs the meaning of the text is not reconstructed via the statistical analysis of frequency and clustering of words, but by the construction of higher-level topological structures in which the meaning of words is derived from their relational position with all other words. The unit of analysis is a sentence, that is a chunk of text included between two periods. The authors develop a systematic language that allows the automatic processing of sentences. We have applied this technique to the REF collection of impact case studies, following the flowchart in Figure 1 (source: Bonaccorsi et al. 2021a).

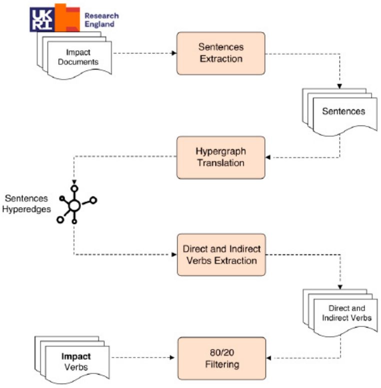

Figure 1. Workflow for the extraction of impact verbs from the REF corpus.

By looking at the structure of sentences we have identified the following elements
i) Direct impact verb
ii) Indirect impact verb
iii) Agent
iv) Topic
The technique allows a clear distinction between impact verbs and non-impact verbs. Impact verbs imply an action of something over something else. This structure is systematically discovered in sentences included in the REF reports. Impact verbs can be direct or indirect, depending on their position in the sentence (technically speaking, the rank in the depth of sentences). On the basis of this distinction and of statistical definitions, it is possible to clearly identify impact sentences and non-impact sentences. At this point we have a powerful tool to ask questions about the distribution of impact vs non-impact sentences across the collection of REF documents. We build up an indicator (IR) as the ratio between impact and non-impact sentences. We find a number of interesting insights:

- Impact sentences have a clear causal structure: they try to demonstrate that X has produced a change in Y
- To achieve the goal of showing the causal effect there is a preparation, mostly of descriptive type, that is done by means of non-impact sentences
- Reports in SSH make larger use of non-impact sentences, meaning that they need to establish a larger and more detailed descriptive evidence before claiming for impact
- The verbal structure of reports, that is, the pattern of utilization of direct and indirect verbs, is not different between SSH and STEM

We interpret these findings as suggesting that research impact statements do have a causal structure, with no difference between SSH and STEM. At the same time we find an interesting difference, in the sense that the construction of the causal statements is longer, more articulated, more complex in SSH reports.

We deepen this issue by introducing the notion of credibility of historical statements in our second paper (Bonaccorsi et al. 2021b). While for professional historians we may assume that rigorous methodological standards are adopted, as it is clear from the methodological and epistemological debate discussed above, the same cannot be said for REF reports. They are written by researchers, or university administrators, or consultants. They have inevitably a rhetorical and instrumental value: the must persuade the evaluators, call their attention to the importance of the impact, and obtain a high score. Remember that within the framework of REF, no less than 20% of funding is allocated on the basis of the impact assessment.

Nevertheless, the authors of the REF reports clearly understand that all these instrumental and practical goals cannot be achieved at all if the statements are not credible. Since they are placed in the past, the readers do not have any experimental control on them. But they mentally reason about the plausibility of the narrative reconstruction. By knowing the pragmatic orientation of the authors, the readers must challenge the credibility of the arguments.

We examine this issue by applying to the causal argumentation the criteria for historical explanation proposed by the philosopher Carl Hammer (2008). According to this philosopher, historical statements have causal power if they include "partial sufficient conditions that are normative, identifiable, manipulable, and not easily replaceable" (Hammer, 2008, 198). We refer the readers to our paper for a full scale, but non-technical discussion of these criteria. By applying these criteria to the main areas of SSH research (social sciences, humanities) and STEM (medicine, technology) and to their main fields of social impact, we derive a kind of theory of credibility of research impact statements. According to this theory, the aim of credibility is more difficult in SSH than in STEM. This is because STEM causality statements may make reference to an established repository of highly structured and formalized processes, in some cases standardized in the public regulation or business practice. During the pathways of impact, the achievement of causal effects is witnessed by the production of formal and socially identified intermediate outputs (e.g., clinical trial, patent, prototype). The description of these chains by the authors of REF reports activates in the mind of evaluators a pattern of recognizability and familiarity. The causal linkages suggested at each of the junctures of the pathway are highly credible. This is not the case for SSH. Here the chain is longer and more fragile. We elaborate on this issue in the final sections of this paper.

Mapping users of research

In two other papers (Bonaccorsi et al. 2020; 2021c) we make use of another technique from machine learning, i.e., Named Entity Recognition. We identify all names in REF documents that refer to social groups, or groups that may be the intended or unintended, direct or indirect beneficiaries of the research of universities. These groups are mentioned in a variety of ways in REF reports. We use a lexicon-based approach, by filtering the REF texts with a lexicon of users with 76,857 entries, developed after extensive research.

With the help of this lexicon, it is possible to saturate the semantic space of research beneficiaries, identifying all social groups that are implied in the impact process. After the extraction we are able to obtain two applications. The first is a mapping exercise, in the tradition of science maps. We draw the entire map of users of research of UK universities, modulating the granularity of the representation. We then cluster the user groups by using community detection techniques. A very informative map is reproduced in Figure 2 (source: Bonaccorsi et al. 2020). All identified clusters are consistent and well delineated. By modulating the granularity we can zoom further in the representation.

The second application is the construction of indicators. Since our lexicon saturates the semantic space, we are in a position to define indicators with appropriate statistical properties. We define the following indicators:

- Frequency
- Diversity
- Specificity

We run the calculation on the entire REF collection and then separately by discriminating between SSH and STEM. This offers some interesting insights.

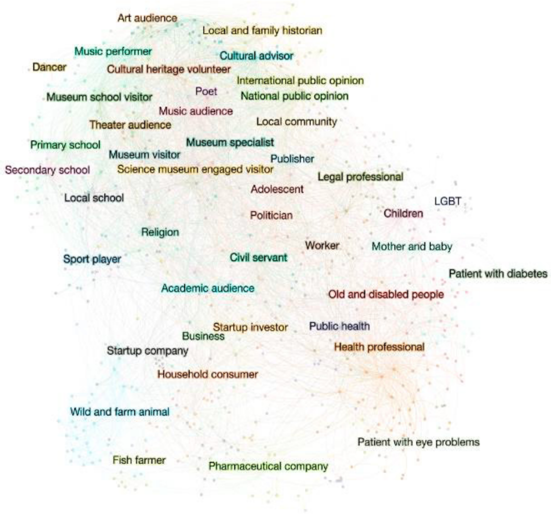

Figure 2. Map of users of research of UK universities.

Lesson learnt and future developments

In the next sub-sections, we develop some implications from this research program and discuss some extensions and new applications.

Towards the construction of indicators of research impact

The construction of indicators in S&T is a complex process, with epistemic, social and political dimensions. With respect to the epistemic dimension, there are several requirements that have been clearly outlined by the literature. Among them, we call the attention on the role of completeness.

When using statistical indicators, researchers and policy makers implicitly rely on the ability of statistical authorities to produce data that correctly refer to the universe under analysis. It is interesting to observe that in the field of S&T indicators this assumption is not warranted. This is why the overall use of data from, say, publications and patents is predicated after a standard methodological caution, of the form “we know that patents do not capture all innovation activities, but..” or “we know that indexed publications do not represent all scientific production, but…”. After a while, such clauses are omitted and often forgotten, with the exception of a stream of critical studies that remind us about the limitations of statistical indicators and of simplified input-output models.

The community of S&T indicators is reasonably cautious in accepting the use of data from Machine learning sources, such as text mining. One important reason is that it is not possible to define the reference set and establish its representativeness.

We suggest that this state of affairs can be greatly improved with the use of lexicons. Lexicons are human-made, controllable, improvable cognitive structures. If they are left open to public consultation and correction, they can incorporate corrections and updates, almost in real time. We argue that with well-designed lexicons it is possible to achieve the saturation of a semantic field. If this is true, then there are no conceptual obstacles to the construction of indicators.

If a lexicon saturates a semantic field, then the automatic extraction of whatever semantic structure in a corpus of text will deliver consistent results. They might differ depending on the specific algorithm, but the difference can be clearly explained and made transparent.

In previous research we have developed a lexicon that includes all social groups that have been hitherto considered in all social worlds in which people can be aggregated (e.g. work, profession, health, economic, social and demographic conditions, mobility, hobby, sport, entertainment, culture and education, crime), combining hundreds of published sources. We have no formal demonstration of completeness. At the same time we ask- do we have completeness, say, in patents as indicators of technology, or indexed publications as indicators of science? Certainly not, but we know reasonably well the limitations of these indicators, so that we can safely use them for a number of relevant applications.

We suggest that lexicons can do the same job for us. If we saturate the semantic field in terms of textual descriptions of relevant phenomena, then we can start to build up indicators that have proper statistical properties.

Research impact assessment in SSH

Another area in which we see clear implications from our approach is the hot debate on research impact assessment in SSH. It has been repeatedly and convincingly argued that asking SSH research to demonstrate impact in the same way as it is done for STEM is a serious mistake, with potentially far reaching implications. In particular, it might be used to justify a differential treatment of SSH and STEM in the funding of research. Under the pressure of government demand for impact and demonstrable results, decision makers and funding agencies may find it safer to maintain support for STEM research and to cut, or postpone, the support to SSH. After all, it is often said, researchers in SSH work for long time horizons and do not compete for discoveries. This means that if funds for SSH are delayed or reduced, there is no risk for the national scientific competitiveness.

With our studies we establish the following points:

- Researchers in SSH are able to identify their audiences and talk extensively (i.e. frequently) and intensively (i.e. with a variety of names) about social groups that may benefit from their research. Hence it is not true that SSH research underestimate the importance of addressing social groups as target for the impact.
- At the same time, they find more difficult to identify specifically and in a granular way their target groups, given the generality of their research.
- In order to claim that their research has produced an impact they use the same semantic structure than STEM (impact sentences with direct and indirect impact verbs + agent + mode) and the same set of verbs, implying an effort to build up causal statements.
- They however make use of a larger share of non-impact sentences in the articulation of their impact reports, given a stronger need to introduce the complex social context for the impact.
- They build longer causal chains.
- They make use of a larger number of agents.

From these quantitative findings we obtain a relatively clear picture of the differences between the ways in which research produces an impact in STEM and SSH. In order to build up a credible reconstruction of the historical pathway that has led to the impact, researchers in SSH must invoke many more agents (two times than in STEM) and describe a longer chain of causal linkages. Now from the theory of historical explanation suggested by Hammer (2008) we derive the implication that longer chains and chains with more agents are *more fragile*. This means that it is more difficult to satisfy the requirements of normativity, identifiability, manipulability and non-replaceability that are needed to establish causality in historical statements. At each juncture of the causal chain it is more difficult to credibly argue that X has indeed been a partial

sufficient condition for Y, because there might be many other factors at place or many independent agents whose actions and motivations may not well known.
Given this pattern, we advocate an approach to research impact assessment that makes full justice for these differences.

Impact mapping

Finally, we suggest a new area of application of text mining methods, i.e. mapping research institutions from the perspective of research users. This area would be complementary to the well established area of science mapping, in which institutions are represented in 2D maps on the basis of the disciplines they cultivate, or the topics that their research are addressing. We give an example below, by showing the user maps of two UK universities.

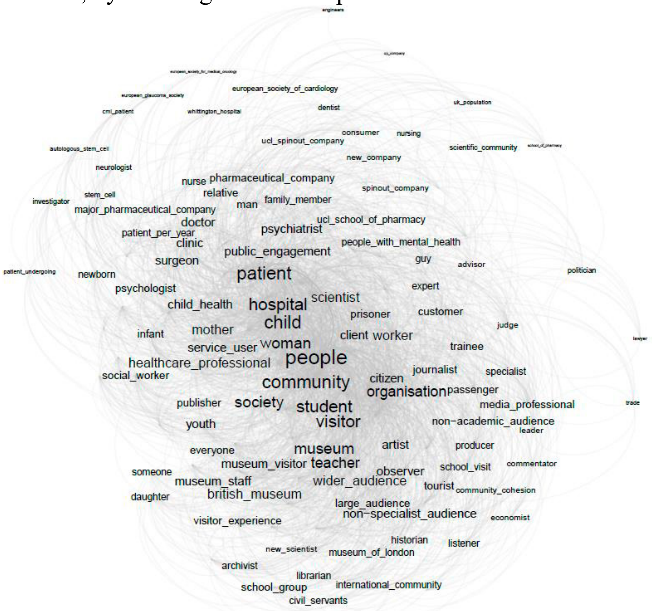

Figure 3. Map of user groups of research of University College, London.

In Figure 3 we see the map of UCL, a top research-intensive university with an international visibility. It can be observed a strong orientation towards user groups in the health sector (patient, hospital, child, woman, mother, healthcare professional community), as well an orientation towards users of cultural heritage (museum, museum visitor, student, visitor, British Museum), while on the contrary the business audience does not seem prominent.

Figure 4 shows the same map for the University of Sheffield. It seems that the main orientations here are largely different: one is towards a local audience (local school, local community, person, community, young people), another is directed towards business actors (organization, company, leader, customer, manager). Much less prominent, contrary to UCL, are the health sectors and the cultural heritage.

There will be a need to refine the analysis and perhaps to develop quantitative indicators after controlling for the robustness of classification obtains by clustering the names of user groups.

We hope there will be opportunities in the near future to extend and refine the methodologies, with an aim to improve the theoretical foundations and the methodological sophistication of research impact assessment.

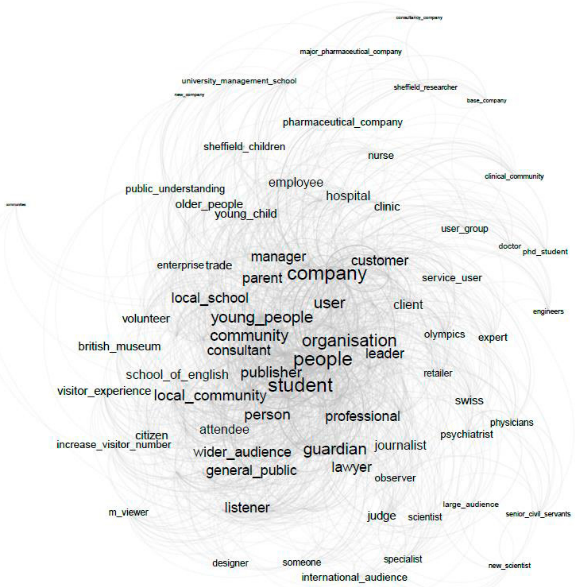

Figure 4. Map of users of research of University of Sheffield.

Abstract

The paper applies topic modeling to the collection of ERC-funded proposals, interim reports and relative publications, with the aim of measuring in a novel way the degree of interdisciplinarity and addressing several open research questions which broadly aim at understanding how environmental conditions can favour the blossoming of interdisciplinarity. Without venturing into potential interpretations and explanations, we present a series of quantitative results linked with the above questions, while deliberately maintaining a descriptive attitude.

Introduction

The issue of interdisciplinarity (henceforth, ID) is again on top of the table for decision makers, funding agencies, and researchers as well. And, again and again, the issue remains open and problematic. Why is ID, at the same time, so requested and appreciated by society, and so difficult to adopt, implement, recognize, and prize by funding agencies, research institutions, and researchers?

In this paper we offer two contributions to a large and growing literature. On the technical side we experiment the use of advanced text mining techniques, namely optimal topic modeling, to describe and measure ID of research (henceforth, IDR). This follows from a recognition of the literature, that emphasizes the limitations of previous efforts to measure ID with the help of metadata of publications, such as classification schemes of journals (Subject Categories) and citations. Topic modeling has been applied to ID in a few papers in recent years, with promising results. We extend this line of investigation.

On the substantive side, we aim at addressing a number of research questions that are at the core of the debate on ID and which can be summarized as follows:

a) Do we see systematic differences in the level of ID by scientific discipline?

b) Is the propensity to undertake IDR influenced by organizational factors, such as the institutional affiliation (universities vs Public Research Organizations, henceforth PROs)?

c) Is the propensity to undertake IDR dependent, in a recognizable way, on the life cycle of researchers? Are young, or mid-career, or aged researchers more inclined to submit proposals with higher levels of ID?

These questions are clearly crucial in policy making: if decision makers want to promote IDR, for example to address complex societal challenges, they must know under which conditions IDR is likely to flourish.

To tackle the above questions, we examine the research projects funded by one of the world largest funding agencies, the European Research Council (ERC). From the open archive of ERC we extract the abstract of the funded research projects in the period 2007-2018 and integrate them with interim reports that funded projects must submit during the support period as well as with the abstract of the scientific publications produced by each project and indexed either in the open repository OpenAire or in the bibliometric database Scopus. For this documentation we extract the words that describe the research project (full text of the abstract) and the list of publications cited by each scholarly work linked to each project. We build a novel dataset by reconstructing the biographic information of Principal Investigators (age, country, affiliation) and his/her list of publications (in particular, date of first publication).

We deliberately maintain an exploratory and descriptive attitude. There is large need to understand data qualitatively and with simple quantitative analysis, before entering into modeling exercises. We clearly have two limitations: due to institutional policies we can observe only winning project (so we are not in the position to run a counterfactual exercise), and submission to the ERC are not representative of the average research landscape but rather of the frontier, excellent research at the European scale.

The interest of the findings, however, will make justice of the proposed approach.

Related Works

In this section we address separately two streams of literature: the large stream of studies that try to define and measure ID (sub-sections 2.1 and 2.2) and the studies that identify possible antecedents at epistemic, institutional and individual level (sub-section 2.3).

Open issues in the definition and measurement of ID

ID has a complex meaning, that go deeply into epistemological and sociological debates. We do not enter here on these debates but follow the literature in assuming that ID is a multidimensional construct. Given the importance of the issue, there have been several efforts to identify, define and measure new indicators that might approximate the multidimensionality of the construct (Porter et al. 2006; Wagner et al. 2011). According to a classical conceptualization diversity can be defined in terms of (i) variety (number of disciplines); (ii) balance (distribution of disciplinary contributions); and (iii) disparity (distance or degree of difference between contributing disciplines) (Rao, 1982; Stirling, 2007). These definitions may lead to remarkably different measures of ID (Wang et al. 2015).

A consistent literature has defined ID by applying measures of diversity to the distribution of articles and citations by Subject Category (Morillo et al. 2001). According to this approach, the journals cited in the reference list of articles are classified by Subject Category and a citing-cited matrix is generated. After defining the metric of diversity it is possible to reduce the dimensionality of the resulting matrix and to project the disciplinary profiles on a map (Rafols et al. 2010; Carley and Porter, 2012; Cassi et al. 2017; Carley et al. 2017).

Following another approach, the diversity of disciplines is defined by the co-citation of articles in journals in different Subject Categories (Moya-Anegón et al. 2004; 2007; Porter et al. 2019). The most common definitions of diversity are the Rao-Stirling measures (Rao, 1982; Stirling, 1997), the Zhang et al. true diversity (Zhang et al. 2016), in addition to the standard measures of cosine distance (Porter et al. 2007; 2008) and Jaccard distance. Different measures of diversity place different emphasis to its dimensions and have different statistical properties, which are the object of critical examination. Klavans and Boyack (2009) have compared systematically the diversity measures and the resulting maps and support the use of cosine distance (see also Leydesdorff and Rafols, 2012). Ciotti et al. (2016) criticize the use of Jaccard measure as it is not independent on the size of the discipline. Fontana et al. (2018) support this view (i.e. the probability of integration between disciplines depends on the absolute and relative size of disciplines) and add a dynamic dimension (i.e. the probability of integration depends on the growth of disciplines). These contributions make it clear that the adoption of alternative definitions of ID and of diversity measures may lead to very different outcomes. As Leydesdorff and Rafols (2011) put it, “different indicators may capture different understandings of multifaceted concepts”.

The Topic Modeling approach to ID

Partially in response to the limitations of the literature based on the structure of citations a recent stream of literature has been exploring the potential of Text mining techniques, applied to the words appearing in titles, abstract, or keywords of articles, less frequently on the full text. By using a variety of algorithms (in particular, Latent Dirichlet Allocation, LDA: Blei et al. 2002) and clustering procedures (Topic modeling) it is possible to represent the content of scientific papers (Rosen-Zvi et al., 2004; Lu and Wolfram, 2012; Gerrish and Blei, 2010; Wang et al. 2011; Nichols, 2014). In this case there is no need for ex ante classification, as in the Subject Category case, so that all limitations of the classification are removed. ID can be defined directly on the maps of topics.

The idea behind topic modeling as a technique for measuring ID has been taken on board by the National Science Foundation (henceforth, NSF) in the USA. According to NSF, the advantage of topic model approach on measuring ID is that its algorithm uses data drawn from the research itself, rather than from institutional structures through which the research was produced (Nichols, 2014).

Lu and Wolfram (2012) compare citation-based and word-based methods with topic-based techniques. By using LDA it is possible to uncover relationships between topics that would remain otherwise hidden due to terminological classifications. Also peripheral authors with few citations might be found central in terms of new topics. At the same time they call attention to the limits of topic modeling: there is no optimal rule for the determination of the number of topics, the label of the topic is assigned by convenience by the researcher, and the units of observation are single words and not more complex and long semantic units.

We emphasize that the methodological debate is not just of technical interest, but is crucial also for the hot debate on ID that takes place at epistemological level, as well as in research assessment and policy making. If measures of IDR are flawed, they deliver wrong messages to decision makers. There is therefore a keen interest in contributing to the methodology.

Why ID so difficult?

As stated above, ID is paradoxical, in the sense that there is large gap, so to say, between its demand, which is sustained and growing, and its supply, which is scarce. In this sub-section we explore three main areas that have been the object of disparate contributions, in which there are potential antecedents for this gap. They are: (a) epistemic, or disciplinary effects; (b) institutional effects; (c) individual, career-related effects.

Epistemic and disciplinary effects

Huutonieni et al. (2010) make the important distinction between addressing the issue from an instrumental and pragmatic perspective or from a more long term, conceptual, cognitive and epistemological perspective (Boon and van Baalen, 2019). From the latter perspective it must be admitted that we do not have a full scale theory of the intensity in which ID is practiced in different disciplines and of the underlying reasons. Several authors offered important insights, but no general results (Silva et al., 2013).

Somewhat less is known about ID in Social Sciences and Humanities. Garnier et al. (2013; 2014) evaluate a NSF program (Human and Social Dynamics) explicitly aimed at promoting ID within SSH and STEM (labeled cross-disciplinarity). They find a change in an integration measure before and after the program (2004-2008) and argue that without a specific program it would not have taken place spontaneously. They therefore recommend the adoption of targeted funding and specific requirements in grant calls.

On the other hand, researchers in SSH tend to cite contributions from STEM in an increasing way. Liu et al (2017) document a sharp increase in STEM citations in SSH papers in China but warn that there is an inverse U-shaped relation between the extent of interdisciplinary citations and the scientific impact.

Summing up, we expect large differences across disciplines, but we do not have a theory supporting specific predictions.

Institutional effects

The literature has raised a number of concerns on the relation between institutional features of science systems and ID. Let us distinguish between funding institutions (government, funding agencies) and performing institutions (universities, PROs). With respect to funding, several authors have shown that IDR has consistently lower funding success (Metzger and Zare, 1999; Bromlsam et al. 2016; Kwon et al. 2017). Various explanations can be offered: panel of reviewers have less experience, the matching between projects and assessor expertise is more difficult, and it is easier to justify and explain the funding of conventional projects. Metzger and Zare (1999) strongly suggested the adoption of targeted funding programs.

With respect to performing institutions, much less is known. Universities may be at advantage since they have large variety of disciplines. In principle, social interaction among colleagues of different background may be facilitated (Cummings and Kiesler, 2005). Some studies have compared universities with a broad coverage (generalist universities) with dedicated or specialist universities (mainly in applied fields). Bonaccorsi and Secondi (2017) find that generalist universities outperform specialist ones in research productivity across all European countries (Bonaccorsi et al. 2021a; 2021b). In any case, these studies do not measure ID but overall productivity. On the other hand, when IDR requires prolonged interaction over time, PROs may be more flexible in arranging dedicated structures, relaxing researchers from the constraint of teaching. Also in this case we must explore the issue without a strong guidance from the literature. We are able to examine whether researchers who submit more interdisciplinary projects are affiliated to universities or PROs.

Age and career effects

An intriguing issue is the relation between the propensity of scientists to engage into IDR (either individually or within interdisciplinary teams) and their research career. We can distinguish two intertwined issues: a cognitive or epistemic issue, and an institutional or incentive issue. In some sense, they are the combination, at individual level, of the two powerful forces examined above, namely epistemic and institutional effects.

At the cognitive or epistemic issue we ask under what conditions do individual researchers conceive research ideas that require interdisciplinary knowledge to be addressed scientifically. Do they have deep issues in mind since their early years and develop research programs to address them later during their career? Or rather, do they focus initially on a narrow disciplinary focus and learn only later the need for opening their mind to other disciplines?

The cognitive or epistemic issue is inextricably linked to the problem of incentives. Is IDR good or evil for early stage researchers? Is the academic career enhanced or damaged by IDR?

Here the prevailing literature has been fairly sharp in proposing that the institutional systems based on publish or perish places severe penalties to IDR (Rafols et al. 2012; Chen et al. 2015; Wang et al. 2017). Other authors offer a more articulated view. For example, Lariviére and Gingras (2010) show that there is not a general pattern of correlation between ID and citations. There are large differences across disciplines. More recently, Okamura (2019) has challenged the negative view by showing that, in the population of highly cited papers (top 1% annual citation counts) increasing by one the number of disciplines leads to 20% increase in field normalized citations.

This debate is also important for policy makers: if they want more IDR but IDR is penalized in the academic career, simple financial schemes may not be enough.

Data and Methodology

Data

The analysis is conducted on the abstracts of the ERC scientific production. In particular, we focused on analysing the projects funded by the program from 2007 to 2018 and the publications which acknowledge financial support by those projects. This textual corpus is cross-linked with information on the respective researchers (i.e., to the PIs of the different projects) and with information about the institutions where those projects were effectively carried out. Since the funding scheme of ERC is conceived within an open access framework, we could make use of a series of open platforms to retrieve the above information: UNiCS[1], CORDIS[2], OpenAire[3] and ETER[4] (Mosca et al., 2018). These platforms give us the possibility to gather data about (i) the projects funded, (ii) the publications published thanks to the funding project, (iii) the principal investigators of the projects and (iv) the hosting institution of the project. Moreover, we gathered additional data at the level of publication, researcher and institution. With respect to publications, we extracted: the average reference age (namely the average distance between the publication year of a document and the publication year of the references) and the subject areas assigned by Scopus. For what concerns researchers, we collected their academic biographies (using Scopus) and we measured the distance (in year) from the winning year of the project to the year of their first publication (as PhD). Finally, for what concerns institutions, we gathered the foundation year (using ETER).

From topic models to ID

The measure of ID relies on the definition of an ID index calculated from the results of the topic modelling applied on the ERC scientific corpus. In particular, after removing the stop-words and stemming the texts, we used the LDA method to extract the topic models. As well as other unsupervised algorithms, LDA required a careful assessment of the reliability of the model resulted from the computation. In this case, we performed a concurrent analysis of 4 different metrics (Griffiths et al. 2004, Cao et al. 2009, Arun et al. 2010, Deveaud et al. 2014) to choose the best number of topics.

In LDA the topic distribution is assumed to have a sparse Dirichlet prior distribution (Ng et el., 2011). Considering the goal of the present paper, given a set of D documents and a chosen number of T topics, the main output of the LDA is a matrix of probability distribution (β_{dt}) that quantifies the probability β of a document d of belonging to the topic t. In this framing, an interdisciplinary topic would be one that groups documents spanning several pre-defined disciplinary classifications: for this reason, we shall consider the panel structure of the ERC program (which is structured into 3 main areas, namely Life Sciences, Physical Sciences and Engineering and Social Sciences and Humanities, which branch in turn into 25 panels) as the main reference point to calculate an index that explains the ID of a topic. When a principal investigator submits a project, she or he chooses a panel to which the contribution of the research belongs.

So that, given the Dirichlet distribution resulted from the topic models, we follow the assumptions of Leydesorff (2011): we determine the diversity of topics measuring how they are distributed among the three panels. Thus, the ID Index of a topic S_t is calculated as follows:

$$S_t = \frac{H(t)}{\log\ 3} = \frac{-(\gamma_{PE,t}\log(\gamma_{PE,t}) + \gamma_{SH,t}\log(\gamma_{SH,t}) + \ \gamma_{LS,t}\log(\gamma_{LS,t}))}{\log 3}$$

[1] https://unics.cloud/

[2] https://cordis.europa.eu/

[3] https://www.openaire.eu/

[4] https://www.eter-project.com/#/home

H(t) is the Shannon Entropy calculated among the probabilities that topic *t* belongs to the panels. PE, SH and LS represent respectively the "Physics and Engineering", "Social and Humanities" and "Life Sciences" panels.

Given the ID of a topic, it is possible to employ the document-topic probability matrix β_{dt} to calculate the ID of documents, researchers, institutions and disciplinary fields as follows:

$$S_d = \sum_{t=1}^{T} S_t \beta_{dt}; \qquad S_r = \frac{1}{n_r}\sum_{d=1}^{n_r} S_d; \qquad S_i = \frac{1}{n_i}\sum_{d=1}^{n_i} S_d; \qquad S_s = \frac{1}{n_s}\sum_{d=1}^{n_s} S_d;$$

S_r measures the ID a document *d*. S_r measures the ID of a researcher, with n_r equals the total number of documents produced by the researcher *r*. S_i measures the ID of an institution, with n_i the total number of documents produced by the institution *i*. S_s measures the ID of disciplinary field, with n_s the number of subject areas that Scopus attributes to the document. Note that S_r and S_i are calculated considering only the abstracts of the projects, while S_s is calculated considering only the publications.

Main findings

Descriptive statistics

We gathered a total sample of 41,379 abstracts (9,365 projects and 32,014 publications) and data about 1,062 institutions and 7,056 researchers. After performing the LDA algorithm, we evaluate the results identifying the best number of topics according to the assessment of state-of-the-art metrics (see crf. "*From topic models to ID*"). The best model resulted in 200 topics. The projects funded by the ERC and their related publications have an average degree of ID at around 0.45. The average degree grows over time. Figure 1 shows that the average degree is between 0.43 and 0.44 in 2008-2010 and 0.46 in 2018. We have no comparison with other institutions and/or periods, given the novelty of the indicator adopted. Nevertheless, the data show a slight increase in the decade if one discards the fluctuations of 2015-2016, which are generated by the change in Framework program between FP7 and H2020.

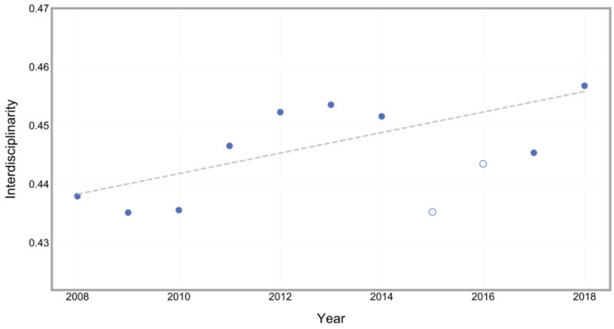

Figure 1. Dynamics of the ID degree. Year 2008-2018.

Disciplinary effect

There are large differences across disciplines in the degree of ID. The largest values are found in Physical and Engineering sciences (PE) in PE6 and PE10. On average, the degree of ID of PE fields is comparable to Life Sciences (LS).

Interestingly the lowest values are found in Social Sciences and Humanities (SH). The least interdisciplinary projects are found in SH2, SH5 and SH6, with SH1 at short distance.

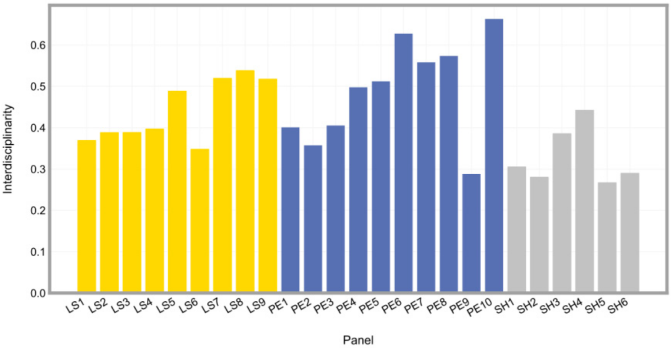

Figure 2. Degree of ID across disciplinary areas in the ERC panel.

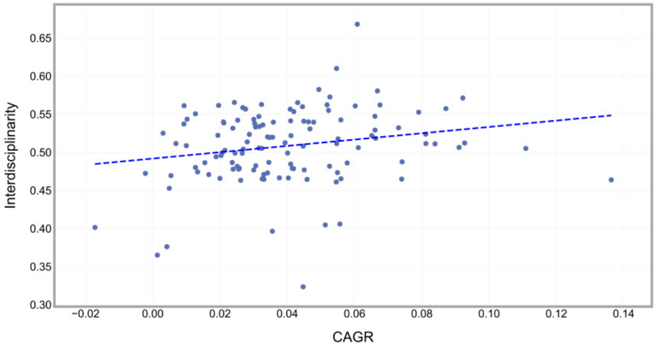

Figure 3. Relation between the rate of growth of publications (Compounded Annual Growth Rate 2008-2018) in the main field of the research project and the degree of ID.

There is a positive, although moderate, relation between the rate of growth of scientific disciplines and the degree of ID (Figure 3).

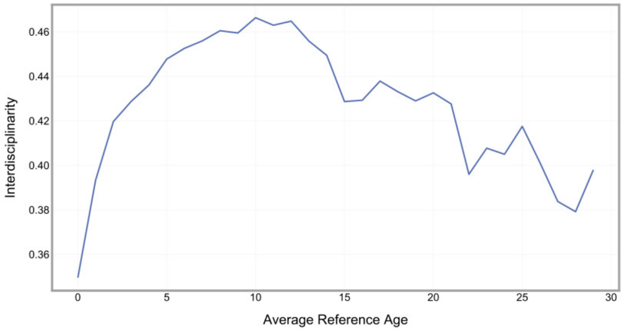

Figure 4. Relation between the average age of the papers cited in the ERC projects and the degree of ID.

We can interpret this finding in various ways. Fast growing disciplines may offer more opportunities for exploring the intersections and boundaries with other disciplines. Or, rather, they may result from the merge or convergence between previous established disciplines (as in the classical case of nanoscience), so that they maintain a dialogue with the originating fields. Or there is a demographic factor at place: fast growing fields may attract young researchers who are more oriented towards ID. For the time being, we cannot disentangle these effects.

On the contrary, we have a sharp result with respect to the structure of citations of other papers that the winners of ERC projects place in their documents. The list of publications cited in the abstract of the project can be considered a knowledge tree that makes explicit the origins of the research idea, as well as the state of the art that the applicants aim at innovating. What we find is that the projects with the largest degree of ID cite papers that are, on average, 10-11 year old (Figure 4). In other words, more interdisciplinary projects do not cite very old papers, but also do not cite very young papers. The former finding is perhaps trivial: applicants to ERC aim at improving over the state of the art and it would be difficult to believe that it includes very old pieces of knowledge. If they take as reference very old state of the art, it means that the field is not very dynamic (perhaps with the important, but very small, exception of unsolved mathematical problems, in the venerated tradition of Hilbert's list).

The latter finding is, on the contrary, surprising and interesting. Successful researchers that operate at the frontier do not use in their proposals and in the interim reports the very last papers. Is this in contradiction with the notion of frontier research? We offer an epistemic interpretation, as follows. ERC applicants do know they will be evaluated by top scientists in all disciplines and know that very young results need to be validated. The initial validation is likely to be done within disciplinary boundaries. There seems to be a *gestation period*, in which young results are progressively validated by their own discipline and become known outside the discipline. Remember that we compute the average age of the cited papers. The list of references may well include very young papers, but they are embedded into a knowledge structure which is relatively mature.

Institutional effects

It is perhaps true that PROs claim they support more IDR than traditional universities. The plain truth is that there is almost no difference between the two types of affiliation (Figure 5). No statistical test needed. [5]

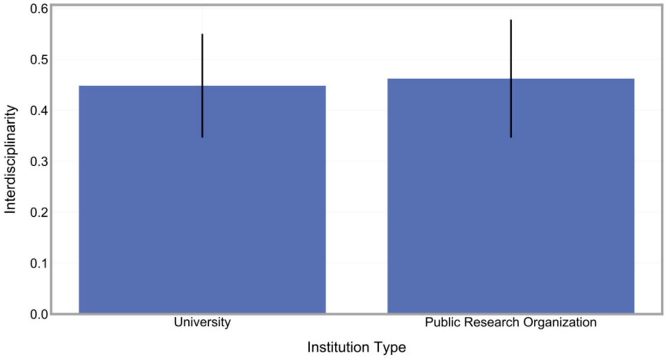

Figure 5. Average degree of ID by type of affiliation of ERC applicant.

In the absence of a robust theory that establishes a linkage between the institutional type (university vs PRO) and the propensity to engage into IDR, we leave this result to open discussion. On the contrary, we find moderate evidence that younger institutions are more likely to be the affiliation of ERC applicants with a higher degree of ID. With few exceptions, a high average degree of ID, as well as a larger variance across projects, is found in institutions established in the last two centuries (Figure 6). Combining the findings from Figure 5 and 6 it seems that the nature of the institution does not matter, but the age of the institution plays some

[5] Anyway, the ANOVA test of difference of means is rejected (p-value 0.278197).

role. We might be tempted to conclude that younger institutions try to differentiate from established institutions by adopting and nurturing a more interdisciplinary approach. The evidence however is only suggestive: conclusions are premature.

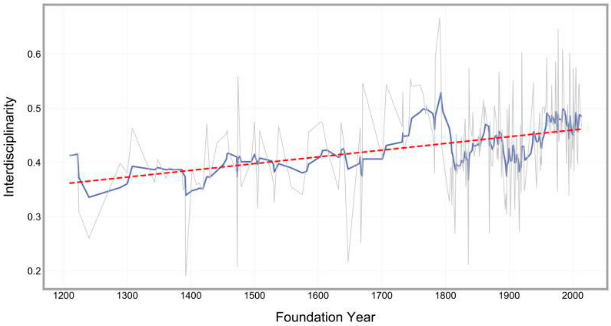

Figure 6. Relation between the age of the affiliation (foundation year of the institution) of ERC applicants and degree of ID.

Individual effects

As stated above, we have collected the biographies of the ERC winners and created a variable that measures the distance (in year) from the year of the PhD. This is an important information, since it dictates formally the eligibility of candidates to different ERC schemes. In particular, Starting Grants are dedicated to young researchers whose PhD degree has not been awarded more than 7 years before, while Advanced Grants do not place any constraint on the age of Principal Investigator. As it can be seen in Figure 8 the distribution of age of applicants has a modal value at 17 years after the PhD, while the bulk of the distribution is in the 10-17 years after the PhD. Researchers applying for Advanced Grants are not young post-doc, but rather young established scholars.

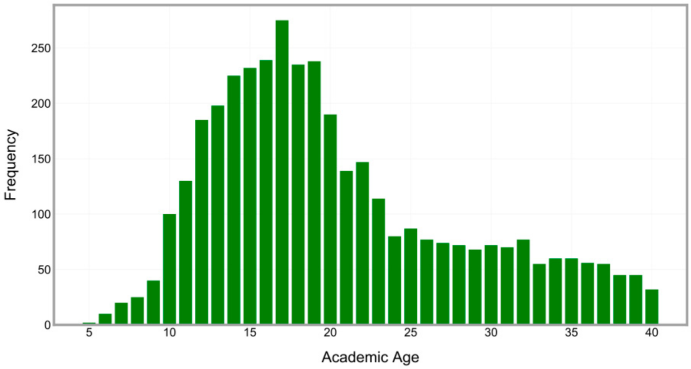

Figure 7. Distribution of ERC winners by academic age (number of years after the PhD).

Having such a large range in the distribution of academic age of ERC winners it is interesting to investigate whether more interdisciplinary projects are proposed by younger or older researchers. What we find is again striking: the peak of ID is achieved in projects in which the PI is 25 year older than the PhD, that is, is found in his/her ‘50s.

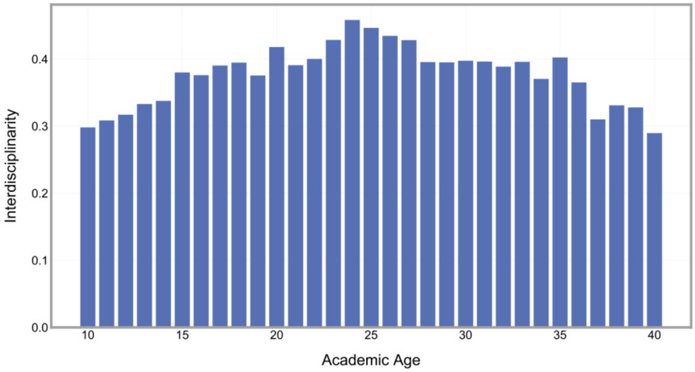

Figure 8. Distribution of the academic age of ERC applicants (number of years since PhD) by degree of ID.

Discussion and conclusions

The notion that IDR arises from young research and from young researchers is not supported. Young researchers must demonstrate first their contribution to their own discipline, focusing on internal topics, and react to the career and incentive systems. It seems that successful scientists that engage into highly interdisciplinary projects have already established their academic excellence. Whether this excellence has been gained with purely or interdisciplinary projects is not observable with our data and must be kept open. However, if ID would be an attribute of researchers, or a personal attitude, then we would see it at any age in the selected proposal. On the contrary, the degree of ID grows very little in the interval between 10 and 15 year of academic age.

An alternative conceptualization, which we find more persuasive, is a sort of life-cycle theory of individual propensity to ID. This conceptualization combines insights on the age of researchers and the age of cited literature. It goes as follows. All researchers are born disciplinary. Some of them maybe cultivate in their mind very audacious research questions that require out-of-the-box research approaches. But they do not take the risk of making them the core of their scientific production at the initial stages of the career. They know they are evaluated by senior colleagues on the basis of their contribution to the discipline. If they are successful they gain reputation and recognition. By going deeper and deeper into scientific problems they may come to appreciate contributions from other disciplines. They devote more time to read journals that are rarely cited by their colleagues but promising. They engage more freely into discussions without disciplinary boundaries. At some point in time they understand that entering into other fields, or collaborating actively with researchers from other fields, is promising, intellectually rewarding, creative, and original. They understand that the disciplinary recognition of this work will be delayed, because most of their colleagues will not accept or appreciate the break of boundaries. Nevertheless, they are no longer under the threat of delivering contributions that are immediately recognized by colleagues. They are established. Maybe their reputation may be at stake, not their tenure or salary. An intriguing question is how to verify whether researchers with a strong interdisciplinary orientation had this approach since their early years- but they did not show it in projects and publications. This would require additional research effort.

Abstract

Training new scientists is essential to ensure that the scientific workforce is sustained and able to produce new findings in the future, but academic careers are shortening for each successive cohort. We aim to connect the shortening of academic careers to larger trends in the growth and turnover rates of the academic workforce. Using publishing data to estimate the distribution of career ages in the academic workforce of the United States, we find that the number of researchers entering the workforce is consistently scaled over time to replace leaving researchers at a ratio of 1.27, indicating a continued exponential growth of the workforce. However, as a large proportion of researchers depart academic science in the early career stages, we argue that the population of the early career workforce turns over every few years to fulfill essential positions within academic research rather than to replace retiring researchers. The implications of this may be that new researchers are trained to fulfil necessary research roles vacated by departing early career scientists rather than to ultimately achieve long-term tenure track positions.

Introduction

Training new scientists is essential to ensuring that the scientific workforce is sustained and able to make advancements. For established researchers, the mentorship of young researchers allows for the reproduction of the scientific community, and the doctoral degree is often considered the mechanism through which established researchers produces the next generation that will replace them as they retire (Larson et al., 2014; Malmgren et al., 2010). As PhD trained scientists face an overwhelmingly competitive job market for long-term academic positions, many observers argue that these issues may be the result of over-training based on faulty assumptions about the number of academic positions available for trained PhDs (Bourne, 2013; Perlstein, 2014). However, it is possible that these conditions are endemic to the structure of the academic workforce, particularly if early career researchers are an essential working population in it. As the pressure for scientists to publish frequently mounts, adding qualified team members to scientific endeavors may also be seen as a way to increase productivity.

When considering the context of team science, the fact that researchers in training frequently fulfill crucial roles on the research team may be a greater immediate motivation for scientific training, rather than the speculation that new faculty will eventually be needed to replace retiring professors. Previous studies indicate that graduate students have contributed to over

30% of papers published in Canada, indicating that they contribute considerably to the advancement of science during their training (Larivière, 2012). The division of labor in scientific working groups also often delegates essential research tasks, including lab maintenance, data collection, and analysis, to PhD students and postdoctoral researchers (Holden, 2015; Larivière et al., 2016; Robinson-Garcia et al., 2020; Walsh & Lee, 2015). In this way, the full participation of early career scientists in publication suggests that research training itself is entwined with the motivations of team-based science. Here, we use academic publishing data, we examine the dynamics of entrance and exit from the academic wing of the scientific workforce of the United States, and we connect concerns about the shortening of academic careers to trends in the growth and turnover rates of the academic workforce.

Methods

Publication data for this paper was obtained publication from the Web of Science (WOS), to which the author disambiguation algorithm from the Center for Science and Technology Studies (CWTS) at Leiden University was applied (Caron & Van Eck, 2014). Data covers the years 1980 to 2018. As academic systems vary dramatically across countries, we focused only on the US scientific workforce, which is defined as researchers for whom at least 85% of their papers have a US affiliation. The entire publication history of these researchers (N=3,525,183) was considered, including papers published outside the US.

For each year, we identify the researchers for whom this is the last year that they appear on any publications as a proxy for the end of their academic research career. To adjust for disambiguation errors, we filtered out authors who had only published one paper. We inferred the primary field for each researcher based on the broad subject category for the majority of each authors' papers; in the case of ties, the first field to appear is assigned as the primary field given our particular focus on early careers. Because that the dataset starts in 1980, the number of researchers identified as starting their careers in the years shortly after 1980 are over-represented. Similarly, after 2010 an increasing proportion of active authors would be misclassified as leaving academic science when their last publication is a couple years before the end of the dataset. To account for this, we limit the analysis to 1990-2010.

Results

Consistent growth in science and the replacement rate

We find that for each year between 1990 and 2010, the ratio of publishing researchers entering the overall academic workforce (publishing their first paper) to those leaving (publishing their last paper) stays consistently around a mean value of 1.27 (Fig. 1). We define this ratio as the replacement rate, meaning that in aggregate for every person leaving the academic workforce, an average of 1.27 people enter it. This finding remains consistent with the established finding that the size of the academic workforce increases at an exponential rate, as the ratio is above the equilibrium point of 1.

Different fields exhibit different behavior, and Figure 1 also shows the replacement rate for a selection of fields: Physics (1.16), Health (1.60), and Engineering and Technology (1.25). Physics demonstrates a gradual decrease in its ratio over time, indicating a slowing of growth between 1990 and 1998. Physics' replacement rate stands in contrast to Health, which exhibits a much higher stable ratio than any other field. Engineering and Technology exhibits a growth rate that is consistent with the overall growth rate of all fields in the dataset, but with greater annual fluctuation. The consistency of the overall ratio of entering researchers to leaving researchers suggests that the science workforce exhibits a stable capacity for growth, such that the entry of researchers in training is balanced by a proportionate number of researchers leaving academic environments that require regular publication.

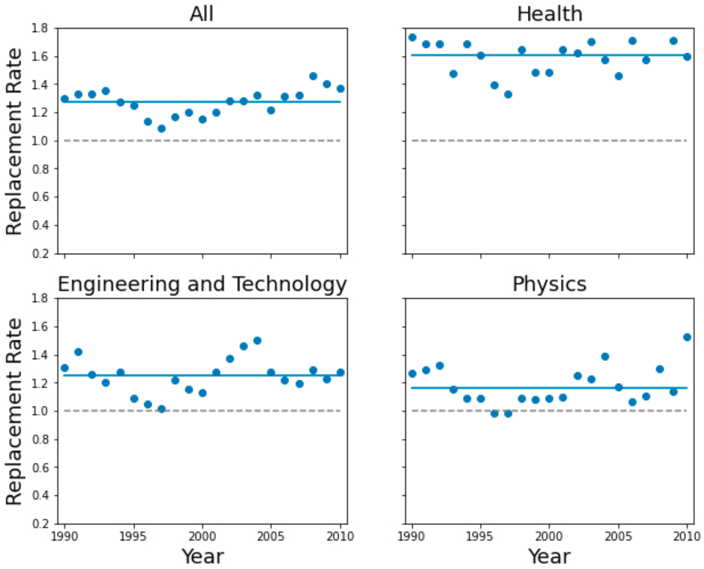

Figure 1. The ratio of researchers entering to leaving the workforce in each year, both overall and in a selection of 3 fields. The mean value (solid line) and the equilibrium value at 1.0 (dashed line) are depicted for comparison.

Turnover rates in academic science

The turnover rates of scientific fields indicate the proportion of each field in academic science who will be exiting academic science in each year, whose position will need to be replaced in the following year. Even as the size of the academic workforce grows exponentially, the mean turnover rates for all fields (0.15) and Engineering and Technology (0.16) both remain stable over time, with standard deviations of 0.008 and 0.012 respectively and without significant increasing or decreasing trends (Fig. 2A).

While we have highlighted Engineering and Technology as an example over time, we also find differing turnover rates for the extended field list (Fig. 2B), which are suggestive of field differences in team structure. Chemistry (0.18), Engineering and Technology, and Biomedical Research (0.17) exhibit the three highest field turnover rates, which may indicate a faster cycling of researchers through positions in the academic research team. The lowest turnover rates in Mathematics (0.10), Social Science (0.10), and Earth and Space (0.11) may indicate that research positions in these fields are more stable or that researchers tend to be in longer term positions when they begin authoring academic papers.

Share of researchers departing academic science from each career age

As the entry of new researchers is balanced against the departure of existing researchers, we investigated the career ages at which researchers stop publishing, presumably leaving the academic workforce. Out of the population of scientists departing academic research in each year, the share of departing researchers from each career age increases as the career age decreases (Fig. 3).

In all presented years, researchers with career ages of 2 years or less comprise 50% of the departing population, a career age that is likely to be during or shortly after the PhD training period. These proportions are largely consistent over time, and the large share of early career

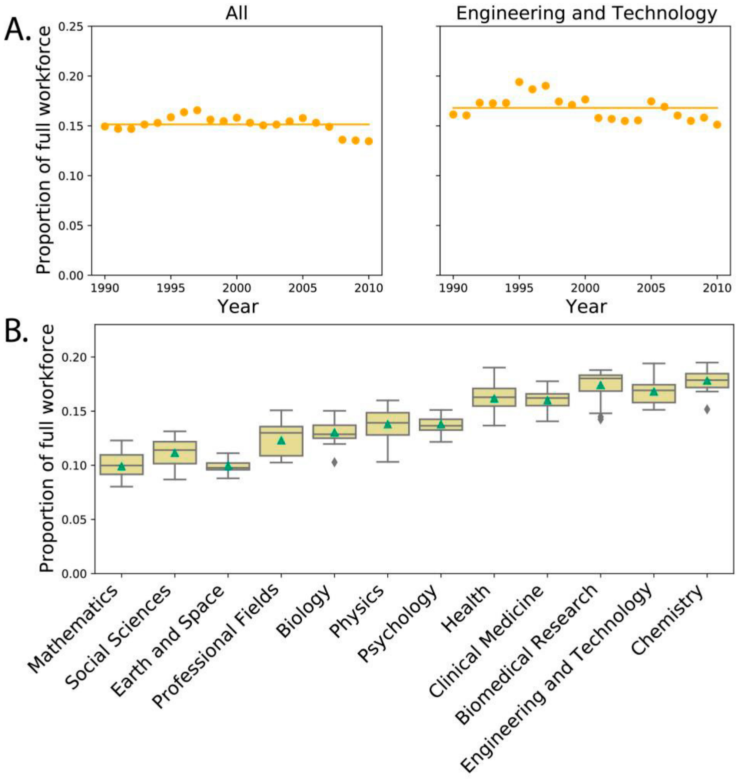

Figure 2A. The proportion of the total workforce who leave in each year, in all fields and in Science and Engineering, with the mean depicted as a flat line. B. The distributions of field specific turnover rates per year, with the mean as a triangle.

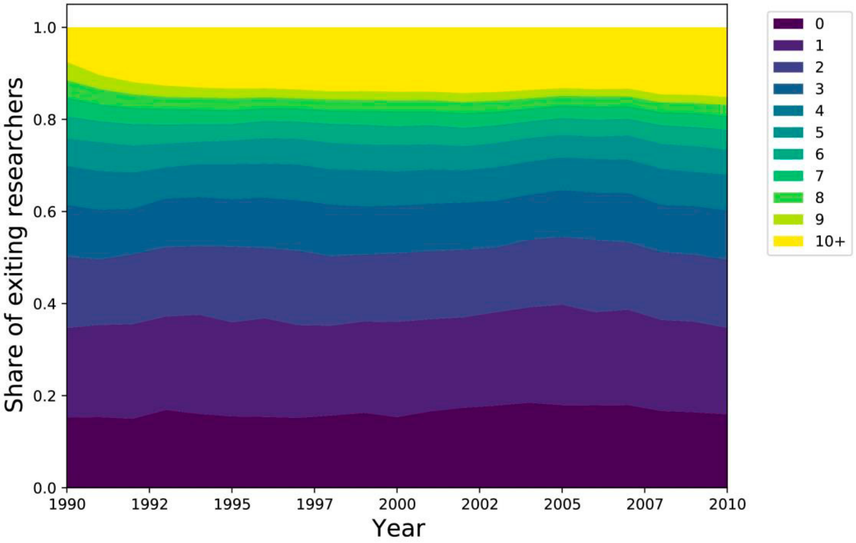

Figure 3. The share of researchers exiting academic science from each career age.

researchers suggests that the turnover within academic science occurs primarily in the scientific positions that require less research experience.

Discussion and Conclusion

Using an individual's range of publication dates, we have calculated the career ages of researchers in the academic workforce. Although there is an increasing number of researchers entering scientific fields each year, we find that there are commensurate increases in the number of researchers who leave academic science each year. We also find that as an average of 15% of researchers depart academic science each year, and these departing researchers tend to be in very early career stages. A frequent interpretation of the decreasing availability of long-term academic positions is that academic research has reached a crisis point where an oversupply of PhDs are trained for the number of available tenured positions (Cuthbert & Molla, 2015). These interpretations often rest on the traditional understanding of academic science in which tenured professors train students in order to fill similar tenure-track positions. However, Milojevic et al. have previously found that as research careers in academia shorten there may be a population of researchers whose roles are best characterized as temporary (Milojević et al., 2018). Our findings that most departures from academic science occur in the early career support the interpretation that the entry of scientists into PhD training may serve the shorter term goal of filling early career positions on research teams rather than the longer term goal of reproducing tenured faculty.

Furthermore, we find that the turnover rates and the share of departures at each career age have remained fairly stable over time between 1990 and 2010. Although academic researchers whose careers end involuntarily experience this as a scarcity of long-term academic positions, we argue that the prevalence of shorter careers within academic science may in fact be a larger condition of the working environment with team-based science. As such, the continuous entry of new researchers seems to be required to fulfil early career positions that are vacated either by researchers attaining sufficient experience for senior positions or departing academic science. In this way, it may be more accurate to argue that a larger proportion of early career roles are necessary to team science than ultimately can be accommodated in the long-term rather than a scarcity of tenure track positions.

We recognize that using the length of the publication career as a proxy for career age may be a limitation to our findings as there are field differences for when researchers typically publish their first paper and that researchers are publishing prior to earning their PhD more frequently now (Waaijer et al., 2016). In addition, we exclude researchers with only one publication, which may cause an underestimation of attrition rates. However, as both of these limitations should result in an underestimation of the extent to which scientific careers have been shortening, we feel confident that the interpretation of our results remains valid.

The high turnover rates within academic science are not reflective of an exodus of trained researchers from science because ample opportunities for scientific research are present outside academia as well. Although we are unable to identify the proportion of researchers who envision their academic work as training for industry careers, our finding that the fields with higher rates of turnover (Chemistry, Engineering and Technology, and Biomedical research) are also fields with strong ties to industry, suggests that scientists in these fields may be more likely to pursue industry positions after their training period. In this way, fields with a high probability of short careers among their participants could be interpreted as industry feeders. Researchers in industry are still active participants in scientific research, and with near 40% of doctorates entering large industry research firms by some estimates, industry hiring has been presented as a reliable way to transfer expertise from academia to the greater society (Zolas et al., 2015).

Voluntary departure for research opportunities in the government or private sector are common reasons for PhD recipients to leave academic research (NSF NCSES 2019). However, this does not invalidate the fact that many PhD trained researchers who desire to pursue long-term academic careers are stymied by a low availability of long-term tenure track positions (Bourne, 2013; Perlstein, 2014). Despite these factors, long term academic positions are still frequently framed by advisors as the preferred outcome of PhD training (Sauermann & Roach, 2012). These expectations and the nature of PhD training may need to be adjusted to reflect the reality that large proportions of scientists who participate in academic publishing during their training periods will not ultimately pursue long-term careers within academic science.

Abstract

Industry 4.0 is espoused by business leaders and policymakers as an innovation concept to capture value from *cyber-physical convergence*: the exploitation of manufacturing and industrial data to boost performance. In recent years, academics have labelled and promoted their works in terms of this concept, resulting in growth of the research domain. Yet precise definition and operationalisation of the notion of *cyber-physical convergence* itself has received little attention. We here describe a modular text-mining approach that builds on the technological underpinnings of Industry 4.0 to operationalise *convergence*. In doing so, we identify a list of relevant keywords that corrspond to five data-centric capabilities: Monitoring, Analytics, Modelling, Transmission and Security. These capabilities set the stage for further bibliometric work to systematically delineate the *convergence* research domain and track its growth, as it interacts with Industry 4.0.

Introduction

In the early 2010, the German Government coined the innovation policy concept “Industrie 4.0” (also known as Industry 4.0”) to capture value from Germany’s manufacturing and industrial sectors by championing *cyber-physical convergence* – the combination of the cyber (as embodied by the Internet) and physical worlds (Kagermann, Wahlster, & Helbig, 2013). A key focus of Industry 4.0 is to influence the production of scientific knowledge (Plattform-Industrie-4.0, 2019, p. 41). Indeed, policy interest has been accompanied by growth in academic research worldwide, where Industry 4.0 has been used to label and promote, among other things, various types of advanced technologies (e.g., augmented reality (Masood & Egger, 2019)), production models (e.g., lean production (Mrugalska & Wyrwicka, 2017)) and business models (e.g. sustainability (de Man & Strandhagen, 2017)). These apparent policy impacts, however, must be viewed against a literature where little or no effort has been made to systematically define *convergence* and delineate the research domain that Industry 4.0 seeks to influence. It is no surprise, therefore, that attempts by the bibliometric community to evaluate scientific output associated with Industry 4.0 have tended to be *ad hoc* and imprecise in scope (see, for example, Muhuri, Shukla, and Abraham (2019)). This reflects both a conceptual and boundary gap, ignoring which will limit effective measurement of research performance indicators, and hamper funding allocations (Boswell & Smith, 2017).

In this paper, we contribute definitionally and methodologically. We examine the technological underpinnings of Industry 4.0 as elucidated by its original proponents, and characterise *cyber-physical convergence* in a manner that closely aligns with these underpinnings. Our characterisation focuses at the level of manufacturing and industrial data. With this approach we separate random signifiers associated with the concept. Next, we operationalise the definition using natural language processing methods. In doing so, we identify five data-centric capabilities: (i) Monitoring, (ii) Analytics, (iii) Modelling, (iv) Transmission and (v) Security. These capabilities collectively specify, for the first time to our knowledge, a boundary that can delineate the *cyber-physical convergence* research domain.

In the next section, we discuss the technological considerations of Industry 4.0, based on which we characterise *convergence*. In Section 3, the definition is operationalised and capabilities are identified. Section 4 presents our discussions and concluding remarks.

Technological underpinnings of Industry 4.0

We identified and reviewed a set of foundational policy and technical literature (Geisberger & Broy, 2015; Hellinger & Seeger, 2011; Kagermann, Wahlster, & Helbig, 2013) (foundational because this literature frames Industry 4.0 through the lens of their original proponents) to enable understanding of the technological foundations of *cyber-physical convergence*. Table 1 presents a definition of *convergence* according to the German National Academy of Science and Engineering (or Acatech) that has played a central role in establishing and driving the Industry 4.0 economic, social and technological narrative in Germany.

As evident from the definition, data is the fundamental driver of *cyber-physical convergence*. The definition underscores a set of data workflows, whereby data is first sensed (or collected) from machines. The collected data is then subjected to a series of processes, which culminates in the generation of actionable insights. Clearly, this definition does not equate *cyber-physical convergence* with new advanced technologies. Advanced technologies such as augmented reality will not necessarily produce a *convergence* phenomenon unless the data that they produce is collected, processed and then applied to drive strategic decisions. Conversely, even legacy machinery can be classified as being convergent if their data is effectively captured and monetised (Kagermann, Wahlster, & Helbig, 2013). This definition is useful in that it provides a way to separate out random signifiers for the purpose of operationalising it.

Table 1. Definition of *cyber-physical convergence* according to Industry 4.0

Concept	*Definition (according to Acatech)*
Industrie 4.0 Geisberger and Broy, (2015, p. 64)	*Convergence* involves the ability of manufacturing systems to: (a) capture physical data from the environment in parallel via sensors and to merge and process this data – and to do so both locally and globally and in real time; (b) use the information that they have gathered to interpret the situation in terms of predefined goals; (c) detect, interpret, deduce and forecast malfunctions, problems and threats; (d) integrate, regulate, control and interact with components and functions; and (e) carry out globally distributed and networked control and regulation in real time.

Operationalising *cyber-physical convergence*

To operationalise the above definition of *cyber-physical convergence*, there is a more basic question to address first – how exactly do researchers working in the domain use the term "data" in their publications? This question is pertinent because it concerns translating the data-centric capabilities of Table 1 into a controlled lexicon of keywords.

Building a lexicon of relevant keywords

Figure 1 shows our overall lexicon building methodology. We extract benchmark publications from the scientific publication database Scopus and analyse them with natural language processing tools to produce an initial set of mid- and high-frequency keywords. Capturing high-frequency keywords from publications is an effective means to operationalise emerging technological domains (Shapira, Kwon, & Youtie, 2017). Mid-frequency keywords play a complementary role in this process because they reveal not-too-common words in a specific field (Luhn, 1958). The relevance of these keywords with respect to the publication corpus is determined by applying a statistical measure called term frequency-inverse document frequency (TF-IDF) (Chen & Xiao, 2016), and also by checking their meaningfulness in regards to specific word combinations (phrases). Our analysis finds a set of *convergence*-specific keywords. Next, following a modular methodology described by Mogoutov and Kahane (2007), we test these keywords for their specificity to obtain additional, complementary keywords, which are then added to the list of relevant keywords.

S1. Retrieving benchmark publications

We used a first strategy **Query 1** (Title = data AND ("industrie 4.0" OR "smart manufacturing" OR "industrial internet")) in Scopus. We selected journal and conference articles in English and German languages from 2010 to 2020 (Scopus provides English translation of a limited number of German publications). This corpus was built in June 2020. Our search returned 118 publications, consisting of all available publications that demarcated these concepts using "data". We then manually checked the titles, abstracts and keywords of the publications, and removed irrelevant ones. The final cleaned dataset contains 96 publications.

S2. Identifying relevant keywords

The titles, abstracts and keywords of the cleaned dataset were analysed using the content analysis tool QDA Miner in combination with its sister text-mining module WORDSTAT. QDA Miner provides various statistics such as TF-IDF, term frequency and the number of publications in which terms are found. We extracted individual words and phrases along with their statistical measures. The raw keyword set contained 300 unique keywords. These were manually screened to remove nonsensical/trivial terms, resulting in a parent set of 77 keywords. These keywords were then subjected to additional processing as follows. First, complementary terms related to the concepts in the parent set – "industry 4.0", "cyber-physical", "iiot", "industrial iot" – were grouped together. To these, we added the terms "factory" and "shop floor" to capture papers that express the same interpretation of *convergence*, even though these papers may not explicitly use the concepts in their title, abstract or keywords. Combining all these terms expands our search string to ("industrie 4.0" OR "industry 4.0" OR "smart manufacturing" OR "cyber manufacturing" OR industrial internet" OR "iiot" OR "industrial iot" OR "cyber physical" OR "cyberphysical" OR "factory" OR "shop floor"). This string **(Query 2)** represents a reasonably robust search space from which papers that are judged to embody *convergence* can be extracted. Second, we selected terms to operationalise *convergence*. We classified the remaining keywords in the parent set according to their frequencies (ranging from 6 to 65) and TF-IDF scores (between 8 and 48). These values were calculated in the aforementioned text mining process for all terms in all of the documents in the corpus. We selected terms with mid-to-high frequencies (equal to or greater than 30) and TF-IDF weights (equal to or greater than 24) because they were judged to be associated with key research topics, and they produced highly pronounced relevance signals, indicating their importance within their respective publications. Based on these criteria, eight keywords were selected: "monitoring", "sensing", "analytics", "modelling", "transmission", "network", "communication" and "security" (Table 2).

Table 2. Capabilities with relevant keywords and phrases

Capability	*Relevant keyword*	*Relevant phrases (Examples)*	*No. of publications with this keyword*	*Total frequency of the keyword*	*TF-IDF score of the keyword*
Monitoring	Monitoring	data monitoring	12	31	27.9
	Sensing	data sensing, sensor data	14	33	27.4
Analytics	Analytics	data analytics, industrial analytics	24	65	47.8
Modelling	Modelling	data modelling	20	42	28.4
Transmission	Transmission	data transmission, real-time transmission	10	35	34.2
	Network	software-defined networking	22	51	32.4
	Communication	data communication	16	32	24.8
Security	Security	cybersecurity, security in Industrie 4.0	15	38	30.5

Each of these eight keywords represents a specific data-centric capability. The meanings of these keywords were then examined in relation to specific phrases, and also by manually checking titles and abstracts. Association between specific words mean that a distinct aspect of the domain is being discussed. Thus, phrases like "data monitoring", "sensing data", "data acquisition", "data analytics", "data modelling", "data transmission" and "data communication" (Table 2) helped place the keywords in the specified context, and categorise them into five capabilities: Monitoring, Analytics, Modelling, Transmission and Security.

S3. Enriching the lexicon at capability levels

To enrich the lexicon with relevant keywords, we pursued a modular query enrichment methodology similar to Mogoutov and Kahane (2007), whereby subfield keywords were extracted in another round of querying in Scopus (using Query 2) and then tested using QDA Miner (as discussed above) for inclusion into the lexicon. Table 3 shows a total of 16 keywords of the enriched lexicon that can collectively delineate the *cyber-physical convergence* research domain (additional relevant keywords extracted in this step are marked in bold) into five data-centric capabilities (Note: Although it has a negative connotation, "attack" was identified as relevant and popular in our text-mining approach because researchers use it in different security-related contexts: "to block an attack", "encryption-based cyber-attack" or "securing machines against attacks").

Table 3. Enriched lexicon to operationalise and delineate *cyber-physical convergence*

Capabilities	*Brief description of capabilities*	*Scopus search query for step S3*	*Keywords included in the final lexicon*
Monitoring	Collection of data from manufacuring and industrial processes	(TITLE ("monitor*" OR "sens*") AND TITLE ABS (Query 2))	monitoring, sensing, **acquisition, collection**
Analytics	Analysis of the collected data to extract useful information	(TITLE ("analytics") AND TITLE ABS (Query 2))	analytics, **learning, neural network, intelligence**
Modelling	Virtual modelling of the states, conditions and behaviours of systems	(TITLE ("model*") AND TITLE ABS (Query 2))	modelling, **simulation**
Transmission	Transmission of data across different software and hardware systems	(TITLE ("transmi*" OR "network*" OR "communicat*") AND TITLE ABS (Query 2))	transmission, network, communication, **wireless**
Security	Cybersecurity to safeguard critical manufacturing assets	(TITLE ("secur*") AND TITLE ABS (Query 2))	security, **attack**

Discussion and conclusions

This paper presents a text-mining approach that builds on the technological underpinnings of Industry 4.0 to define *cyber-physical convergence*. This definition is then operationalised using a modular query building process that allows us to characterise *convergence* into five data-centric capabilities (corresponding to a total of 16 relevant keywords).

We recognise that our text-mining approach has limitations. There may be differences regarding what other experts and stakeholders consider important as to the definition of *cyber-physical convergence*. This may affect the choice of keywords that we have identified. Nonetheless, the fact remains that our attempt to closely align with the Industry 4.0 definition of *cyber-physical convergence* will allow us to separate out signifiers and delineate the research domain more precisely.

Our attempt in this paper forms part of a broader research to investigate policy interactions with academic research growth and evolution. In the next stages of this work, we will apply these keywords (with appropriate inclusion and exclusion terms) to perform a bibliometric search of the *cyber-physical convergence* research domain.

Beyond the Web of Science: an overview of Brazilian papers indexed by regionally relevant databases

Abstract

The Brazilian evaluation system of research and graduate education is under revision. For scientific publishing, policymakers and evaluators consider a more standardised assessment, trading some current qualitative aspects for expanded use of journal-based indicators from international databases such as the Web of Science. This paper aims to provide evidence for a better-informed discussion, analysing the complete data set of Brazilian articles published from 2013-2018 regarding: i) coverage by the WoS and regionally relevant databases (e.g., Latindex, SciELO); ii) incidence of the local language in the country's publications, and the impact it has on coverage by regional and international databases; iii) disciplinary variations and disparities in thematic coverage across languages and databases. Results show half of the Brazilian article output is not found in the WoS, and the normalised distribution of indexed publications across disciplines is hugely unbalanced. Publications not in WoS are predominantly in Portuguese, with a significant share indexed by regional databases, often addressing topics not covered in WoS. The main conclusion is that Brazilian science goes beyond WoS, and evaluators should strive for a sound and comprehensive assessment to capture its complexity, instead of trading it for restraining, short-sighted simplicity.

Introduction

Brazil counts with a national evaluation system which is conducted by the Brazilian Agency for Support and Evaluation of Graduate Education (CAPES). As the name of the agency in charge suggests, such evaluation focuses on masters and doctoral courses, but the Brazilian Society for the Advancement of Science (SBPC) indicates over 95% of all Science & Technology research conducted in the country comes from these graduate courses. Thus, it is possible to state that evaluating graduate education is nearly the same as assessing the whole science system in Brazil (Nobre et al., 2017; SBPC & ABC, 2020).

First conceived in the 1970s, the evaluation of graduate programs was initially intended to better allocate funding for the development of science in the country. Over time, the model grew in size and complexity, becoming a high-stakes assessment of almost 8000 master's and doctoral courses organised into nearly 5000 research units or programs (PPG). Every four years, all PPG in the country go through a compulsory, government-funded evaluation that grades them on a scale from '1' through '7'; the last representing the highest level of excellence. Positive results not only guarantee status for the PPG and the institutions that promote them, but also implicate in an increase in funding, a higher number of available scholarships, and access to a wider range of grants. In comparison, a low performance will not only lead to funding cuts, but it can also threaten the programs' existence. For instance, research units graded '1' or '2' are no longer allowed to enrol new graduate students and must suspend their activities completely as soon as the last of the currently enrolled students graduate (CAPES, 2017; Nobre et al., 2017).

While an additional study is being conducted to explore the complexity of the national evaluation system in Brazil, for this paper it is relevant to know that the actual evaluation relies heavily on mixed methods. Disciplinary and interdisciplinary panels from 49 distinct evaluation fields perform the assessment of PPG with qualitative and quantitative data collected yearly from every research unit in the country. From the available evidence, several dimensions are assessed by the committees in charge, from infrastructure to educational results and societal impact of the PPG. Scientific production is, as expected, one of the most valued dimensions in the process, including specific evaluation of distinct types of output such as books, technical and artistic products, conference proceedings, and papers, among others.

The assessment of papers published by graduate programs in the country follows the principles of the broader evaluation system: each of the 49 research areas receives a comprehensive list of each PPG's publications, together with a series of indicators gathered and calculated from national and international databases. Panels composed by established researchers in each area interpret the available information – combined with their inherent knowledge in the field – and generate what is known as Qualis Journals: a nine-level classification system for all journals used by Brazilian researchers during the evaluation cycle (Barata, 2016; CAPES, 2021b).

Qualis has been an essential element in Brazilian evaluation since 1998. The classification system evolves over time to reflect the advancements in scientific publishing as well as in information systems (Barata, 2016). To promote changes in the current evaluation cycle (2017–2020), CAPES established a working group to review Qualis procedures (CAPES, 2018). In a preliminary report, the group states that the new assessment model must induce internationalisation of both publishing and journal indexing. The initiative proposes to reduce the qualitative perspective, attributing to journal-level indicators – such as *jif* and *h5* – most of the responsibility for the final classification (dos Santos et al., 2019).

Considering the evaluation literature strongly discourages practices which rely heavily on indicators to assess scientific productivity, especially those dependent on journal-level metrics (Hicks et al., 2015), it is not surprising that a consensus has not yet been found among the research-area representatives working with CAPES. Several disciplines, especially those in the Social Sciences and Humanities (SSH), are concerned with the proposal for a 'New Qualis', especially because the current focus is on adding weight to the value of publications indexed by databases such as the Web of Science (WoS) and Scopus, while undervaluing the ones indexed by regional databases, mostly in local language. As a consequence, even though ordinance no. 150 (CAPES, 2018) established a three-month deadline for publication of a detailed report by the Qualis Journals working group, almost three years have passed, and the document remains unpublished.

The main goal of this research is to contribute to this current debate around the 'New Qualis', primarily by investigating topics that may shed light over concerns such as: i) How is the coverage of Brazilian papers in international databases? ii) How representative is the local language for the country's publications, and how different is the coverage from regional to international databases? iii) In case significant differences are found, how extreme are the disciplinary variations? iv) From a thematic standpoint, are there research topics that have more space in regional databases?

Methods and data

The central data set that supports the current research comes from all Brazilian graduate programs. It is a virtually complete list of all publications produced in these programs, by both faculty members and student body alike. There are two main reasons why this data set covers the majority of the actual output from graduate programs. The first one lies on the aforementioned high stakes of evaluation. Since performance relates to funding and to the continued existence of research programs, their directors, university pro-rectors, and all PPG researchers are concerned with the quality of the data provided. The second reason is that, for many years, CAPES has counted on information systems to collect PPG data to perform the evaluation. Distinct systems have been developed over time and the data collection is now conducted through the Sucupira Platform: an integrated system that is robust enough to deal with the size of the Brazilian National System of Research and Graduate Education (SNPG). The platform is not only open continuously for data submission, but it grants the general public direct and real-time access to all of it. This means all PPG researchers and stakeholders become part of a relevant auditing system. As such data is subsequently audited by the committees in charge of the evaluation, there is also an authenticity layer of control (CAPES, 2021b; Siqueira, 2019).

Integrated data sets from graduate education in Brazil are made available through CAPES' Open Data platform (CAPES, 2021a). In this research, the R language (R Core Team, 2020) was used to combine and clean eight of the available data sets which relate to four distinct categories in the database: i) general information from graduate programs ii) scientific output from graduate programs iii) detailing of bibliographic production from PPG iv) authorship details of papers and reviews. The most recent Qualis rankings were subsequently gathered from the Sucupira Platform (CAPES, 2021b) and combined with the broader data set.

The resulting data include all papers published from 2013 to 2018, totalling more than 1,3 million records of around 750 thousand individual publications. The reason for the difference is that CAPES' records are PPG based, which means publications co-authored by researchers from distinct research programs will be recorded for each individual PPG. Publications from 2019/2020 were not yet included in the study because data for those years are only partially available, with relevant details such as DOI and journal ISSN still missing (CAPES, 2021a).

Once the work on the core data was completed, a series of complementary databases were consulted to enrich the resulting data set. For that, key fields like DOI, ISSN, and additional information on author last names, journal volumes/issues, page numbers and titles of publications were all used to match the consolidated data with the following additional sources:

i) SciELO – bibliographic database structured on a cooperative model of Open Access (OA) journals, which are selected based on a set of quality and operational criteria. The network focuses on the scientific communication needs of developing countries, especially those in Latin America and the Caribbean. It was first established in Brazil and now extends to 15 other countries, including Portugal, Spain, and South Africa (SciELO, 2021).

ii) RedALyC – similar to SciELO, it is a network of OA journals focused on scientific output from Latin America and the Caribbean, while also extending to other Portuguese and Spanish speaking countries. It reaches 26 countries and establishes a series of criteria to include journals in its database (RedALyC, 2021).

iii) Latindex – another network focused on OA publishing. It reaches 23 countries, mostly Spanish or Portuguese speaking ones, counting with a directory of 29.192 indexed journals. Even though the broader coverage may be quite useful to map the Brazilian scientific output, only a small percentage of these journals have been through the compliance process with the Latindex methodology, which includes criteria similar to those adopted by the other two networks mentioned. These quality-assured journals form a Latindex subset of 2265 journals, known as Catalogue 2.0 (Latindex, 2021).

The enriched data set created in this research allowed a series of analyses on coverage of the selected regional databases, publication languages, research areas, and more. Nevertheless, at least one international database was also needed, and the Web of Science (WoS) was chosen to complement the research. According to Chavarro et al. (2018), this database is one of the main data sources used to obtain bibliographic data for many quantitative research assessments, and this includes the impact factors which inform the Brazilian Qualis classification of journals.

Findings and discussion

From 2013 to 2018, CAPES' database of scientific production lists a total output of 752.453 papers and reviews, published in 29.679 distinct journals (merging ISSN for electronic and print versions). All of them were classified under the Qualis criteria which, in the current scale, consists of grades A1, A2, A3, A4, B1, B2, B3, B4, and C/NP (A1 being the top grade). Each disciplinary committee determines the score attributed to each of the possible grades, and individual publications receive corresponding points during the evaluation process, except C/NP. This rank is reserved for low quality or predatory journals, as well as those which the committees consider lacking scientific rigour (e.g., non-peer-reviewed publications) (CAPES, 2021b).

To best represent the universe of valid journals, all results in this paper exclude those which were ranked C/NP, as well as any others which may have been disqualified by the evaluators during the data auditing process. As a consequence, the number of considered papers drops to 585.945, published in 23.508 journals. The filtered CAPES database was then matched with the Web of Science (WoS), following the guidelines described by Visser et al. (2021). A total of 9.597 journals (40,8%) were found in the database, with 298.170 papers published (49,4%). Figure 1 shows the results of this analysis.

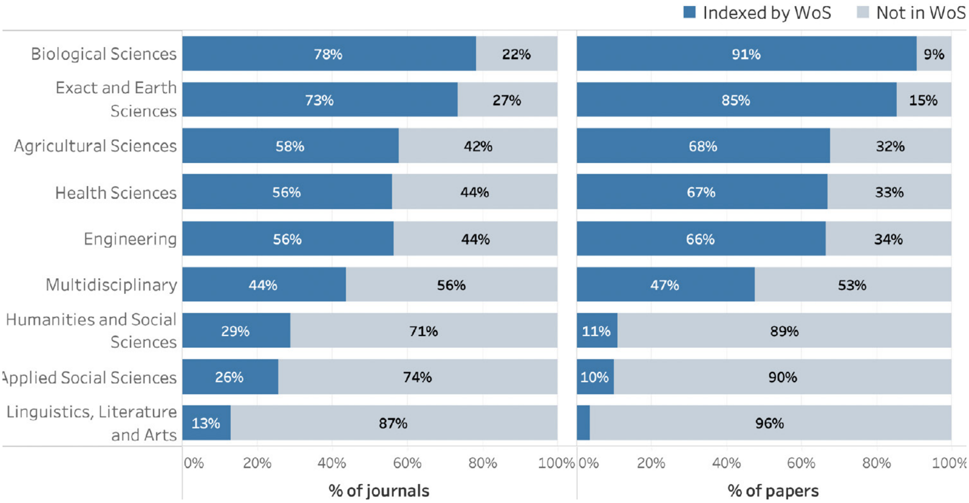

Figure 1. Percentage of journals and papers indexed by WoS (2013 - 2018), according to research areas adopted by CAPES

As Figure 1 shows, there is a considerable difference in WoS coverage when results are grouped according to the nine research areas defined by CAPES: a meso-level aggregation of the 49 evaluation fields conducting the evaluation process. As it can be seen, 78% of the journals used by Biological Sciences PPG to publish their papers (2013–2018) are indexed by the WoS. In contrast, the same is true for only 13% of those from Linguistics, Literature, and Arts.

From the papers' perspective, it can be noted that the number of publications in research areas with broader WoS coverage tends to be even higher. For instance, 73% of Exact and Earth Sciences journals are indexed by WoS, and this number rises to 85% when looking at the paper level. Opposite to that are all Social Sciences and Humanities (SSH), where the percentage of papers in the Web of Science is even smaller than their journal coverage, indicating a lower-than-average number of publications in such journals.

Of course, caution should be used to interpret disciplinary differences observed in Figure 1. Scholars such as Tijssen et al. (2006) and Chavarro et al. (2018) have already highlighted the dangers in analysing differences in database coverage across research areas, as large variations are often influenced by internal biases in the database's own coverage. Nevertheless, for the trained eye, Figure 1 seems to paint a very extreme picture.

To help analyse if the disciplinary variation in the Web of Science coverage is more prominent for Brazilian scientific publications, Figure 2 was designed from data collected from the bibliometric version of the WoS core collection hosted at the Centre for Science and Technology Studies (CWTS). All papers and reviews from the 2013-2018 period were included in the visualisation designed using the VOSviewer software (van Eck et al., 2009), and the publications were grouped according to the micro-level field classification (Waltman et al., 2012).

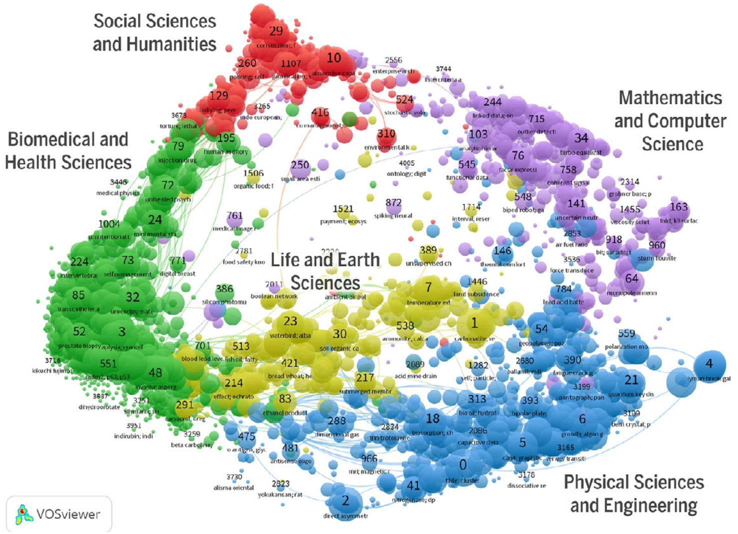

Figure 2: Scientific production indexed by the Web of Science (2013-2018), mapped according to CWTS micro-level field classification

Figure 2 shows 4013 clusters of publications in the WoS database. The size of the circles represents the number of publications in each cluster and their positions are calculated from the citation traffic between all papers. Five main fields of science are shown, and they confirm that there is a proportionally smaller number of SSH clusters and publications in the database. To see how Brazilian scientific publishing relates to the broader WoS coverage, Figure 3 maintains the configuration from the previous map but including only Brazilian papers and reviews, with resized circles according to the proportion of the country's available publications.

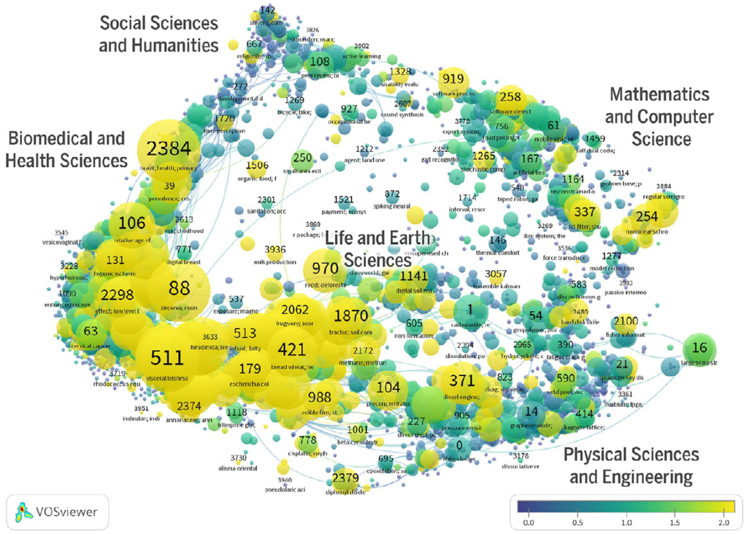

Figure 3: Brazilian scientific production indexed by the WoS (2013-2018), mapped according to CWTS micro-level field classification

The size variation of clusters in Figure 3 is evidently more pronounced than in the previous map, and the colour overlay helps understand the significance of that. Cluster colours pointing to 1.0 in the included scale imply the proportion of Brazilian publications is around the same as for the global database. Lighter colours mean Brazil produces a higher proportion in these fields, and the darker colours mean the exact opposite. The resulting visualisation shows Brazilian publishing is proportionally higher across the Biomedical and Health Sciences, and in some Life and Earth Sciences clusters. Isolated points of higher relative productivity can be found in other research areas, but most other clusters are underrepresented.

The main message from Figure 3 seems to be that Brazilian publishing behaviour within the Web of Science amplifies the coverage biases already observed in the whole database. To confirm this perception, the internal coverage calculation described by Moed and Visser (2007) will be applied. This indicator analyses the extent to which the articles included in the WoS cite other articles which may or may not be found in that same database. From the number of missing references, it is possible to infer the percentage of scientific publications that are not indexed by the Web of Science. Figure 4 shows the results of the analysis but grouping the CWTS field classification systems in their macro-levels, for clarity purposes.

Figure 4: Scientific production mapped according to CWTS macro-level field classification for (a) complete WoS database (2013-2018), and (b) only Brazilian publications, with relative internal coverage overlay

Figure 4a shows the 23 broad disciplines of CWTS macro-level field classification. The colour clustering follows the same scheme seen in Figure 2, and the size of each circle indicates the number of papers in the WoS database (2013–2018). To design Figure 4b, the data was filtered to show only the Brazilian publications with proportionately resized clusters. As in the previous VOSviewer maps included in this paper, it is possible to see differences in the publication distribution across fields from (a) to (b). For instance, Brazil tends to produce relatively more in most Life and Earth Sciences clusters, but much less in the single SSH cluster.

To design the colour overlay seen on Figure 4b, the average internal coverage (Moed & Visser, 2007) was calculated for each of the 23 broad disciplines in both data sets: the complete one seen in (a) and the Brazilian one displayed in (b). The results show, for example, that internal coverage in (a) for the largest Biomedical and Health Sciences cluster is of 91%, for the most prominent Life and Earth Sciences is of 73%, while for the single SSH cluster is of only 34%. The numbers for Brazil are slightly lower in (b), at 88%, 65%, and 27%, respectively. This means Brazilian publications are citing a larger percentage of works not indexed by the WoS.

A second step for the colour overlay on Figure 4b was to calculate the ratio between the broader database internal coverage and the Brazilian one. For SSH, for instance, this would mean 0,27 / 0,34, indicating Brazil's relative coverage is of 79% of the outcome seen for the unfiltered database. The results displayed in the overlay show Brazilian internal coverage is lower across all 23 broad disciplines, and the largest variations are seen exactly on clusters that already registered low coverage in the broader database. This analysis confirms the original impression that coverage biases in the Web of Science are exacerbated in Brazilian output. Is this a result of publishing barriers or a matter of choice to publish in journals indexed elsewhere?

Maybe the answer can come partially from scholars such as Gibbs (1995) and Tijssen et al. (2006), who discussed challenges that researchers in the developing world need to face to overcome publishing barriers. Among them are both disciplinary and language obstacles, as English journals dominate databases such as the Web of Science, with much less room for Portuguese or Spanish publications. This is a significant problem for Brazil, as the most recent Education First Proficiency Index (2020) – which ranks 100 regions according to English Skills – places the country in the low proficiency group (53rd position). Besides that, the British Council (2014) reports only 5% of Brazilians have some knowledge of English, while only ⅕ of those present some level of fluency. The numbers are also not good, yet less abysmal, when researcher population is considered. According to Vasconcelos (2008), who analysed data from the *curricula vitae* of over 50 thousand Brazilian scientists, around 33% of them declared to be proficient in English. Even disregarding biases from the self-declaration of proficiency seen in the CVs, still only a third of Brazilian researchers would not find language an obstacle to publish in English. Considering these language limitations, Figure 5 shows all Brazilian papers from the 2013–2018 period, isolating the publication percentages according to WoS coverage and the main language reported for the individual papers.

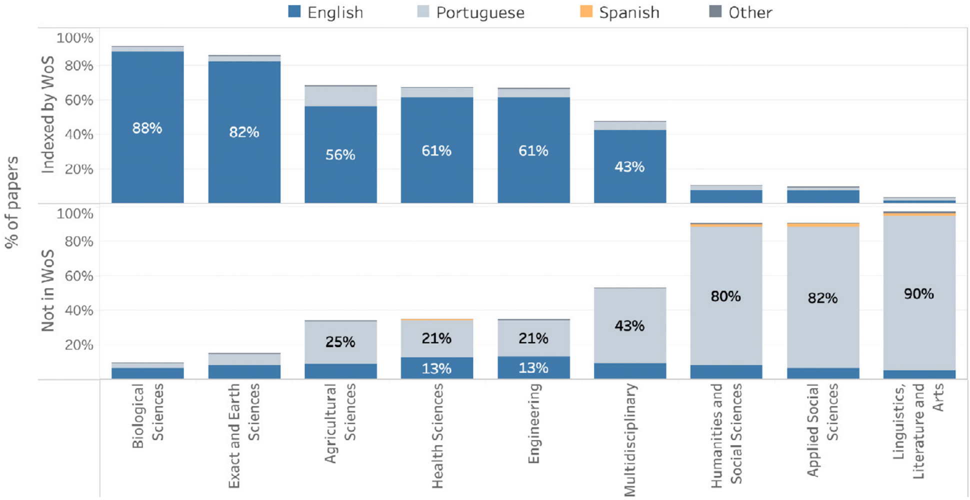

Figure 5: Comparison of language profile of Brazilian papers (2013-2018), in and out of WoS, according to research areas adopted by CAPES

Disciplinary differences are, once again, strikingly evident in Figure 5. Most of the Brazilian papers indexed by the Web of Science are in English, and publications not covered are mostly in Portuguese. SSH papers in local languages account for more than 80% of publications in all three research areas. The Multidisciplinary field is also impressive as publications are nearly split in the middle regarding WoS coverage, with language participation mirroring each other.

Figure 5 also shows that there is only a very small share of papers in Spanish or other languages, which add to less than eight thousand publications (a little more than 1% of the total).

After identifying that most papers not indexed by the Web of Science are in Portuguese, even in research fields such as Health Sciences and Engineering, we may wonder if such publications would be found in regionally relevant databases. Figure 6 shows the results of such analysis by mapping the whole set of Brazilian publications (2013–2018) with the Latindex, SciELO, and RedALyC databases.

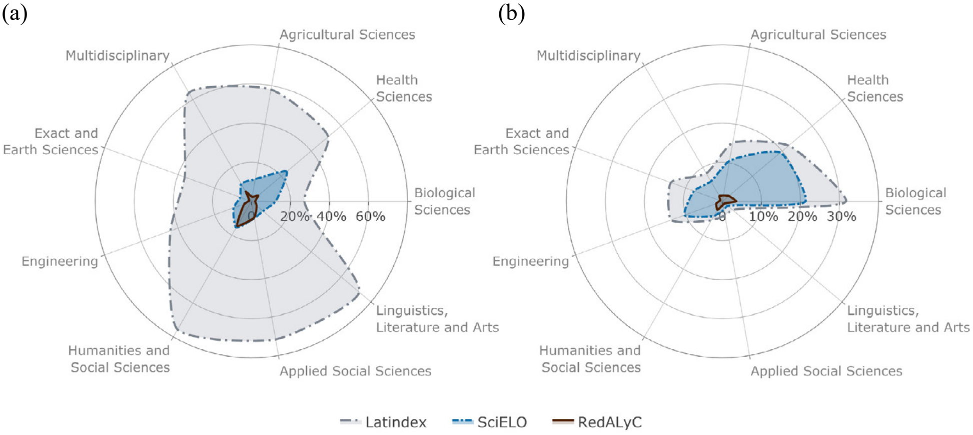

Figure 6: Brazilian papers (2013-2018) not indexed by the WoS but available at Latindex, SciELO, or RedALyC in (a) Non-English and (b) English

The two polar charts included in Figure 6 show the percentage of publications in each of the CAPES-adopted research areas that can be found in Latindex, SciELO, and RedALyC. The left chart shows non-English publications, which we have seen are mostly in Portuguese. The broader Latindex directory covers a significant percentage of papers not found in the WoS, reaching nearly 80% in the Humanities and Social Sciences, with its lowest coverage in Biological Sciences, where it is of around 30%. SciELO and RedALyC, counting with more curated collections, cover a smaller share, but over 20% of the 'missing' Health Sciences papers are included in SciELO, for example. For English publications not included in the WoS collection, Figure 6b shows that there is very little to find in RedALyC, but Biological and Health Sciences have a significant share of papers in SciELO and Latindex. The much larger Latindex coverage that was seen in Figure 6a is no longer present, which may indicate the predominance of Spanish and Portuguese journals in this bibliographic database.

By the investigation of only three established Latin American databases, it becomes evident that the local language scientific publishing is finding alternative outputs for publication. From this initial inspection, other databases might be explored, and a study by Alonso-Gamboa et al. (2012) highlighted some interesting alternatives for the future. Among them are LILACS, a Health Sciences database covering 901 journals from 26 countries: and PERIÓDICA, a database of around 1500 Science & Technology journals from Latin America and the Caribbean.

After that, there is still a pertinent question to answer: Are Brazilian researchers investigating significant research topics which are only covered by regionally relevant databases? To answer that, all titles from the 585.945 papers and reviews published in Brazil in 2013-2018 were exported to a corpus file which went through Neural Machine Translation into English. This corpus was used to generate a term map using VOSviewer software (van Eck et al., 2009), which can be seen in Figure 7.

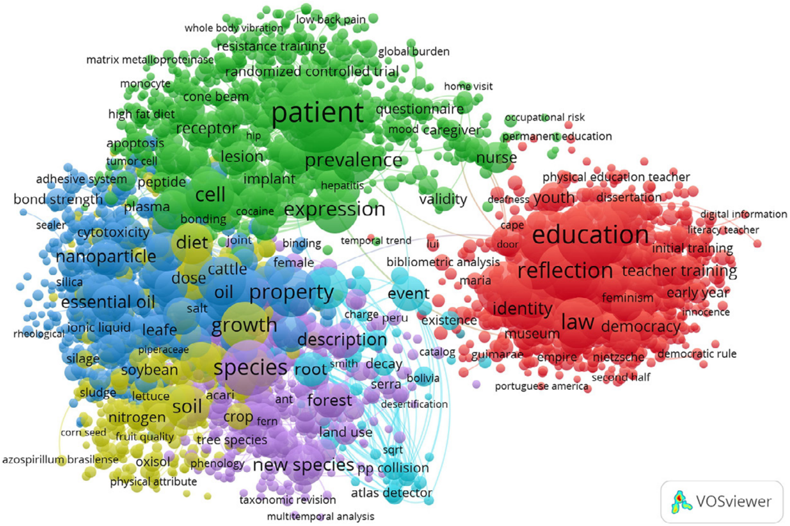

Figure 7. Term map generated from titles of Brazilian papers (2013-2018)

Figure 7 shows five different colour clusters with an evident relation to some of the main fields of science. Biomedical and Health Sciences appears in green and it is quite a significant cluster, in line with what has been seen about the Brazilian publishing profile. Other clusters seem to cover Life and Earth Sciences, with relevant topics related to Agricultural and Environmental Sciences, and a minor light-blue cluster goes into Physical Sciences and Engineering. Another large cluster is detached to the right of Figure 7, showing in red what evidently represents Social Sciences and Humanities. The fact that SSH research topics seem to be isolated from the rest becomes clearer with a colour overlay applied to the term map, as displayed in Figure 8.

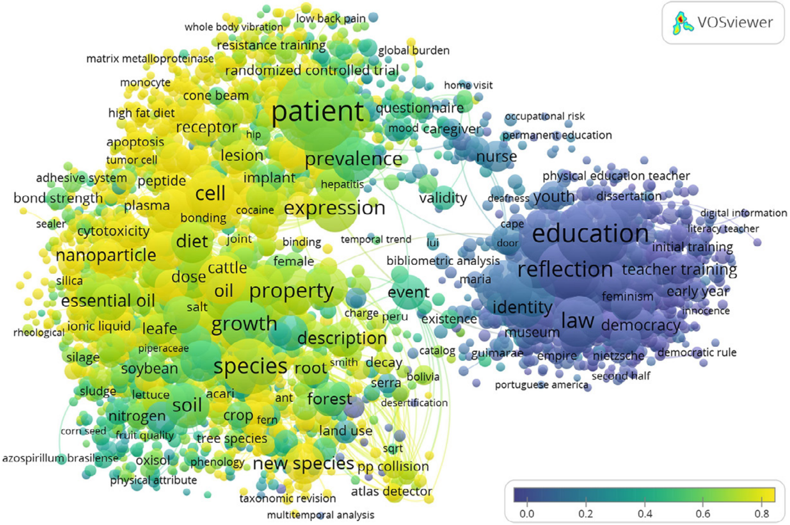

Figure 8. Term map generated from titles of Brazilian papers (2013-2018), colour-coded by Web of Science coverage

The overlay on Figure 8 was possible because, while exporting the publication titles to create the corpus, a score file was also produced, indicating if each individual paper was indexed by the Web of Science or not. From that, the SSH island seems even more detached, as most clusters are close to zero in the scale, meaning nearly all publications on the subject are not indexed by WoS. A small group of clusters in the left border of SSH reaches around 20% coverage, being weak links to other main fields of science.

Considering the left group of research topics displayed in Figure 8, some of the Biomedical, Health, and Life Sciences clusters shown at the top left, in light colours, are quite noticeable, as nearly 80% of the occurrence of such topics are in WoS indexed papers. Several other clusters are shown in shades of green, which mean their incidence is relatively balanced regarding WoS coverage, fluctuating between 40% to 60% in the presented scale.

Discussion and conclusions

A recent study conducted by Chavarro et al. (2018) investigated the extent to which the inclusion in the Web of Science would be an indication of journal quality. Among their findings was that journals with similar characteristics and editorial standards often receive unequal treatment due to their place of publication, discipline, and language. The authors warn research evaluators against the assumption that WoS and similar databases would assess journals without bias, joining several other scholars such as Alperín (2014), Garfield (1995) and Mounier (2018) in a call for caution in developing countries, with particular emphasis on Latin America.

In Brazil, policymakers and evaluators are engaged in ongoing discussions over a proposal for changes in the assessment of journals and publications that would trade a significant share of the qualitative methods currently adopted in favour of more journal-level indicators from WoS-like databases. This study adds to the warnings about qualitative dimensions of such databases and shows further science can be found in regionally relevant databases as well, where topics overlooked by the Web of Science are covered.

The data presented here show that WoS indexes around 41% of the qualified journals Brazilian researchers use to publish their work, accounting for just under 50% of the country's papers. Disciplinary distribution is hugely unbalanced, and the analysis of internal coverage for the broader WoS versus the Brazilian set of publications shows the existing biases in the database are taken to extremes in Brazil's case. That means disciplines such as the Social Sciences and Humanities, with already low coverage in the Web of Science, are even more underrepresented in Brazilian publications.

When it comes to using WoS indicators for evaluation, Moed and Visser (2007) describe four possible types of bibliometric studies from an internal coverage inquiry. The first type is known as a 'pure' WoS analysis, as it would be possible to rely solely on WoS source journals to analyse citation impact when internal coverage is over 80%. Types 2 and 3 – with coverage-ranges at 60–80 and 40–60, respectively – would require different levels of expansion in the sources covered, whether by including target articles not published in WoS source journals (2) or adding articles in proceedings volumes from a range of subsequent years (3). In case WoS coverage in a field is below 40, the mere value of a citation analysis based on WoS data should be questioned, even if target or source universes are expanded (Type 4 study).

The internal coverage analysis at the micro-field level classification for Brazil reveals that the bibliometric studies recommendations for the 4013 clusters would be: Type 1 – 43%; Type 2 – 29%; Type 3 – 14%; Type 4 – 14%. The problem is that of the 1741 clusters eligible for a 'pure' WoS analysis, 979 are in the Biomedical and Health Sciences, and 626 are in the Physical Sciences and Engineering, while only 19 are in Mathematics and Computer Science and eight in Social Sciences and Humanities. Even though for Mathematics, 48% of the clusters suggest a Type 2 study, 64% of those in SSH are ranked as Type 4. Consequently, we should question the mere value of the provided indicators for any quality assessment.

While these findings should be enough for policymakers designing Brazilian evaluation to step back from expanding their reliance on indicators from WoS-like databases, this research has also shown that most of the Brazilian scientific output not indexed by the Web of Science is written in Portuguese. That is particularly important for Brazil, as only a third of the researcher population states to have achieved some level of English fluency. Local language publications mean more people can produce and consume science, and societal impact may be even more relevant than citation metrics.

Since a significant share of local language papers could be found in Latindex, SciELO and RedALyC, future studies on identifying other high-coverage regional databases are recommended. Such databases cover various research subjects, some of them widely overlooked or just absent from the WoS indexed publications. Besides that, they usually have a core concern to promote the expansion of OA journals.

For instance, the Directory of Open Access Journals (DOAJ, 2021) – a community-curated online service with freely available data on OA details for 15.874 journals – reveals very interesting results when crossing its database with this project's data set. Around 62% of the Brazilian papers indexed by Latindex, SciELO or RedALyC were published in DOAJ listed OA journals. These are nearly 170.000 papers, of which almost 140.000 were in diamond OA, with no costs for authors. In contrast, only 25% of the set of articles indexed by WoS were published in DOAJ listed journals, and 63% of those were made open only through APC charges.

The presented numbers are consistent with a comprehensive study by Pavan and Barbosa (2018), which analysed OA publishing for Brazilian authored articles in WoS. Using data from the 2012-2016 period, the authors estimated 59% of OA papers in the database were in APC journals, at an average cost of USD 1492,27 per article. For a country like Brazil, where only 50% of PhD candidates receive monthly stipends (with values under USD 450), the high cost for OA publishing is a considerable problem. It's not that researchers would pay for publishing themselves, but the fact is the average APC cost of three papers could fund a whole year of stipends for a PhD candidate.

In conclusion, this research has shown that while adopting international indicators from established databases might seem like a good simple solution to improve local science, the reality is that databases such as WoS tell only half of the whole story. Brazilian scholarship is not only about state-of-the-art publications in top journals; it is also about regionally relevant topics, often destined to a Portuguese speaking audience; it is about access to publish and consume science, given the socioeconomical reality of the country. Brazilian science goes beyond the Web of Science, and a sound and comprehensive evaluation system should strive to capture its complexity, instead of trading it for restraining, short-sighted simplicity.

Abstract

Evaluating the value of a research article is critical in scholarly communication. Recently the traditional methods of scientific evaluation based on informetric indicators and peer review have been challenged. Inspired by a theoretical method, entitled the Anna Karenina Principle (AKP), we propose an evaluation method to assess the research value by combining both qualitative and quantitative methods. In this RIP, we interviewed six researchers to testify the four dimensions of evaluating science studies, including the content value, the academic impact, the practical implication, and the society value. Combining with the AKP, we put forward a three-layers evaluation hierarchy for further quantitative measurement.

Introduction

Justifying the significance of research articles is a key process and an on-going activity in scholarly communication and scientific evaluation. At present, there are two common methods to evaluate individual research articles. One is informetric indicators, including citation, impact factors and other quantitative indicators. The other one is qualitative approach, which is represented by peer review. However, both of them have been undertaken with concerns in science community. The qualitative approach has the issue of the professional responsibility of reviewers and the expertise concerns (Grainger, 2007), which meets the challenge to unify the standard for giving opinions on article (Kangas & Hujala, 2015). Quantitative indicators cannot guarantee the quality of articles either (Bornmann & Daniel, 2008). Another unfortunate is that articles with potential breakthrough findings, which are most likely challenging the common sense, can be considered as the outlaw of scientific norms (Zeng et al., 2017). This phenomenon has happened in the history of science multiple times. Therefore, this paper aims to put forward a quantitative evaluation method based on a qualitative theory to evaluate the value and importance of individual research articles, and provides a new idea for improving the evaluation system of scientific research.

Research design

Theoretical foundation of evaluating individual articles

The essence of research articles evaluation is to evaluate the contents of the articles. The evaluation of individual research papers should undertake the level of semantic context as the core aided by various indicators from metadata level. Therefore, this paper puts forward an evaluation system of individual research articles from four dimensions.

(1) The content value of the article. The worth of a scientific paper should be reflected in the academic knowledge expounded in the article. The purpose of analyzing the content of the article is to find the valuable part except for the language of the article, then to go deep into the knowledge that the article attempts to achieve, and eventually to assess the potential academic and social value of this article (Evangelopoulos et al., 2012). Compared with other evaluation methods, it pays more attention to the comprehend the content of the article (Habib & Afzal, 2019) and can be applied to various sciences.

(2) The academic impact of the article. Currently, bibliometric indicators are the most commonly used method for research evaluation (Ellegaard & Wallin, 2015), which can be used to measure the academic impact of researches. One of the best ways to visualize the scientific development remains quantitative visualization. In such way, researchers normally could have a vision from (Lund, 2019). Even though the quantitative indicators are facing some challenges nowadays, the quantitative metrics can be a valuable assistant measurement for evaluation.

(3) The practical implications of the article. A valuable scientific paper not only needs to make novel discoveries, but also to give other researchers the opportunity to apply them. On the one hand, extensive application can give researchers more chances to discuss the article. On the other hand, it can actively promote the development of the discipline and provide favorable circumstances of the discipline (Prabhakaran et al., 2018).

(4) The society value of the article. Another key for research articles to be drawn upon attention by the society and public is that the authors present the work actively. With the rapid development of information technology and social media, some important researches will not only get attentions in the academic community, but also have great repercussions in the social community. In this way, researchers can speed up their careers when they building reputations in both areas (Fiala et al., 2017). In addition, research articles usually reflect somewhat the level of scientific output of the author's affiliations. And these organizations also have a certain impact on social development (Bana e Costa & Oliveira, 2012). Therefore, the evaluation of research articles cannot ignore its social value.

The philosophical relationship between the foundation and the AKP

Before proposing our evaluation system, a brief explanation of a theory involved in the system is needed. The Anna Karenina Principle (AKP) was introduced from science into scientific evaluation by Bornmann and Marx (2012) to describe that the success of a scientific work depends on many factors, and the absence of any one factor would lead to failure. Bornmann and Marx laid out eleven prerequisites: Solid evidence, Interest among colleagues who take up on the ideas, Verifying evidence from independent research groups, The paradigm should make possible (correct) predictions, Suitable techniques for the required measurements, A theory that provides a plausible explanation of the empirical findings, The paradigm is simple and elegant, The paradigm has great explanatory power, The paradigm has a catchy name, The last crucial step is achieved, and The researcher has stubbornness in thinking and good networking with colleagues in the field. According to this paper, if all these prerequisites mentioned above are included in a research, this research could to be considered to have made a great scientific outcome. If a research article can be considered with significant findings, this article must have met the prerequisites involved in the AKP.

These eleven prerequisites of the AKP are in line with the four values we proposed in this paper. First, the content value emphasizes that the evaluation of individual research articles needs to pay attention to the content of the article. The AKP offers a solid understanding of the evidence and the appropriate techniques, all of which can be gleaned from the context of articles. Secondly, AKP refers to the importance of citations in various prerequisites of AKP, which supports the academic impact of a study. Thirdly, the premise of the article implication is based on the reader's deep understanding of the article, therefore, the precise representation of an article is the key to present its implication value. The AKP addresses the importance of language and results presentation, which is corresponding to our third dimension. Finally, the AKP points out that a healthy community contributes to the success of scientific research in different infrastructure, which shows that scientific research needs the participation of both academics and society. Therefore, we adopt AKP to be a theoretical support for the evaluation method.

The structure of evaluation hierarchy

We conduct researcher investigations to decompose the four aspects of theoretical foundation we mentioned above and to investigate the consistency of AKP in the four aspects. In this primary research, we interviewed six subjects in different research areas of Library and Information Science, one in the US and other five in China. Each online interview was undertaken 30 to 40 minutes in December 2020. A total of eleven questions from the four aspects are as follows. The content and significance of the structural questions are illustrated.

(1) Understanding of the value of individual research articles. We would like to examine how researchers understand the most important value to a research article and the reasons in the theoretical sense. In this way, we can compare with our first aspect and AKP prerequisite, such as solid evidence.

- What are the factors you think the most important to conduct a research/a study/ to publish? For example: innovation, related research, research design, presentation of results, social impact, communication characterization, application potential.
- What would make you see a study as "Successful Science"?

(2) Understanding of the value of individual research articles through one's own scientific research experience. Unlike the first one, to testify the consistency with the implication value, this aspect focuses on either review practice as a reviewer or research process as a researcher.

- How do you think the current evaluation system in science community? What is your experience in terms of being a reviewer?
- Which section you pay the most attention on when you review a paper/a grant/an award? For example, originality, relevant research, research design, results representation, implication to the society, communication representation, usage potential.
- When you are required to evaluate a paper or a grant, which parts do you focus on most?
- How do you promote your own work? What are the factors that would influence your citing and promoting behavior?

(3) Understanding of the four dimensions in our evaluation system. After answering the above questions, we put forward the four dimensions in our evaluation system to these experts. The goal was to ask these interviewees whether the dimensions we proposed were a summary of their evaluation of individual research papers. If there are differences, we can also correct our hierarchy through these questions.

- How do you think the four dimensions?
- Expect for what you mentioned, do you think these four aspects can summarize your understanding?

(4) Finally, we inquired the subjects about the relationship between the four dimensions and the AKP. We aim to find out the resemblance between the four dimensions in our evaluation system and the AKP from others' perspective. Presumably, if we can confirm that there is indeed a philosophical relationship between the two, then the AKP can be regarded as an important theoretical support for the evaluation system proposed in this paper. Before asking the following questions, we introduced the basic information of the AKP to the subjects.

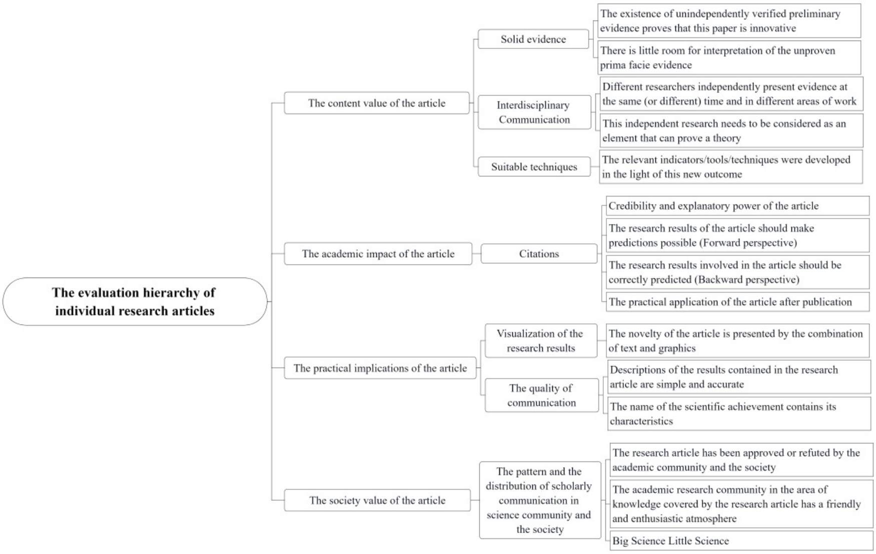
- How do you understand the AKP?
- Do you think the AKP can be a theoretical basis for evaluating individual research articles? Why and why not?

- What do you think is the relationship between the AKP and the four dimension we mentioned earlier?

We documented all audio files and converted them into texts. With the help of decomposing the interview text, we breakdown the four dimensions in line with the AKP into a preliminary evaluation system with three levels. Then we revisited three subjects to inquiry their opinions on the whole system and made further improvement.

Results

Through the understanding of the AKP and the interview with the LIS researchers, this paper comes up with a method with three levels which can be used to evaluate individual research papers. Level 1 is the basis of the hierarchy, which contains four dimensions. Both Level 2 and Level 3 are derived from the interviews with subjects and, based on discussions with the subjects, we corresponded these conditions to each of the four dimensions of Level 1. In this system, it can be found that from the four dimensions of Level 1 to the different requirements of Level 3, it is the result of further decomposition of the evaluation dimension by qualitative approach. The determination of Level 3 can also be used to prepare for further quantitative measurement. The evaluation hierarchy is shown in Figure 1.



The evaluation hierarchy of individual research articles
The content value of the article
Solid evidence
The existence of unindependently verified preliminary evidence proves that this paper is innovative
There is little room for interpretation of the unproven prima facie evidence
Interdisciplinary Communication
Different researchers independently present evidence at the same (or different) time and in different areas of work
This independent research needs to be considered as an element that can prove a theory
Suitable techniques
The relevant indicators/tools/techniques were developed in the light of this new outcome
The academic impact of the article
Citations
Credibility and explanatory power of the article
The research results of the article should make predictions possible (Forward perspective)
The research results involved in the article should be correctly predicted (Backward perspective)
The practical application of the article after publication
The practical implications of the article
Visualization of the research results
The novelty of the article is presented by the combination of text and graphics
The quality of communication
Descriptions of the results contained in the research article are simple and accurate
The name of the scientific achievement contains its characteristics
The society value of the article
The pattern and the distribution of scholarly communication in science community and the society
The research article has been approved or refuted by the academic community and the society
The academic research community in the area of knowledge covered by the research article has a friendly and enthusiastic atmosphere
Big Science Little Science

Figure 1. The evaluation hierarchy of individual research articles

For the content value of the article, it includes three requirements in Level 2 and five requirements in Level 3. The first one is solid evidence. It is one of the prerequisites included in AKP, which means a scientific paper with significant research result must have adequate scientifically evidence to support the theory and/or method that the research is proposing. According to Bornmann (2012), core questions in science should be solved and steered in a new direction by the evidences which confirmed independently. In addition, novelty is the most common measurement to assess the value of a study, such scientific results should therefore have less room for interpretation in previous studies in the certain research areas. The interpretation of solid evidence also makes these two requirements a further step in this condition. The second requirement is interdisciplinary communication. Interdisciplinary communication refers to the specific research activities in which research subjects were created and interdisciplinary knowledge were developed according to the internal relations among disciplines. Currently, science community collaborate across disciplines. Even according to the Nobel Prize winners, there are no success in science if one only replies on one specific discipline. When evaluating the content of a research article, the reviewers may focus not only on how many researchers and theories this paper covers, but also on whether the theories proposed in this paper can be used as the theoretical basis for other disciplines. The last one is suitable techniques, which is also a vital prerequisite in AKP. A research could be expected to conduct new techniques for the measurement or verification. In response, the attention on whether new indicators or tools have appeared in the articles is important for evaluating.

For the academic impact of the article, citations are an important indicator of the quantitative analysis method, and citation indicators are increasingly applied in some subject areas to support qualitative evaluation (Kousha & Thelwall, 2011). For an article, the citation from different aspects can represent different meanings of the article. The structural interview also received several feedbacks on different applications of citation. We were told to conclude into four conditions. First is the credibility and explanatory power of the article, which can be presented in terms of the citation number of the article. The second is the analysis of the article from the aspect of forward perspective and backward perspective, which means whether the article has the potential to predict the trend of the subject through the citation distribution. Another one is that the practical application of the article after publication is related to the number of the citations of its application papers. Measuring these conditions can reflect the academic impact of individual scientific articles.

As for the practical implications of the article, we found that the subjects attach great importance to the presentation of the article and believe that good presentation can help promote the article. The visualization of research results and the quality of communication are the two factors affecting the application value of the article. If an obscure research article can be understood by other scholars or the general public, it shows that it has the possibility to be applied by others in some appropriate fields. It is easy for the readers to understand the content of the article by visual presentation of the combination of words and images, which has a positive effect on the further discussion and application of the article. A well promoted article must have composed of not only structured content but also a solid quality of communication skills. Additionally, a catchy name of the core idea, an easy-to-understand title, and a precisely simple description of research result would have been benefits for the article.

For the society value of the article, we focus on the pattern and the distribution of scholarly communication in both science community and the society. If a scientific article can be shared and discussed smoothly in both communities, it has the potential to promote not only the development of the discipline, but also the development of society. Meanwhile, it requires an enthusiastic and friendly atmosphere for the discipline to let researchers have opportunities of presenting articles in different places. Most importantly, the society value is reflected in the contribution to the society. If a scientific research is awarded as social significance, such as the Nobel Prize, the value must have been tested.

Conclusion and future research

In this research in progress, a new evaluation method was proposed by the understanding of the Anna Karenina Principle and a structural interview, which aimed to provide new ideas for the evaluation of individual research articles. We introduced a well-known theoretical approach of measuring success in sciences, the Anna Karenina Principle, as one of our fundamental theories. The prerequisites of AKP were examined to be in line with other theories in this paper. Combining with such in four dimensions, such as the content value, the academic impact, the practical implications, and the society value, we proposed a three-layers evaluation system, aiming to combine the qualitative analysis and quantitative analysis to improve the integrity and credibility of scientific evaluation.

The preliminary research will continue improving the hierarchy system by interviewing other researchers from outside of LIS area, government stakeholders, and public if necessary. The following research will focus on the quantitative measurement. Our current plan to decompose the Level 3 analysis is to continuously ask opinions on breakdown each requirement one by one with quantitative measures which we have data access or acquirable data. Sketchily, we will organize another round of interviews with questions, such as "How to determine the number of other disciplines that have discussed the research theory", "Can we transit the language property of the article into measurable indicators", "How to obtain the number of articles published in different approaches". We will gather all the actionable metrics or approaches. Last not the least, we will present the evaluation results as a way outside of box. Instead of giving weights to each indicator and resulting in another ranking or index, we will illustrate the results into the article context so that the readers would clearly have the image of the value and the impact of this article.

Abstract

This document describes the GeoAcademy project, whose main objective is to automatically geolocate scientific articles, downloaded from general scientific databases such as Scopus or WoS. This geolocation is carried out on the content of the document, either through the capture of possible geographical coordinates that the document has, or toponyms that may appear in the document through an algorithm created for this purpose. In the methodology we explain the steps that have been taken in this project to create a sample database with articles that deal with Sierra Nevada (Spain) and the creation and design of the algorithm. The results show the technical data of the application of the algorithm on the database and its success rate, as well as a description of the platform created to graphically display the geolocated documents on a web map. Finally, in the discussion, we define the difficulties encountered, the possible bibliometric applications and its usefulness as a tool for viewing and retrieving information

Introduction

Geolocation is the possibility of locating information in specific geographic spaces to treat and process it (Ramos Vacca & Bucheli Guerrero, 2015). Technological advances in restitution by aerial photogrammetry and digitized cartography have contributed to this (Cortés-José, 2001), as have new procedures for cartographic writing and map printing, the appearance around 2005 of Google Maps, Bing Maps, OpenStreetMap and numerous programs to create maps such as OpenLayer, Leaflet, CartoDB or MapTiler (Cascón-Katchadourian & Ruiz Rodríguez, 2016). In the field of scientific evaluation and bibliometrics, geolocation techniques have been commonly used to locate scientific articles based on the origin of its authors (Catini et al., 2015). However, few studies have been devoted to analyzing a set of scientific publications based on their geographical coordinates and geolocating them on a map.

We would like to highlight here two current initiatives due to their importance and because they include several institutions behind their prototyping. One of them is GEOUP4, this "web portal shows on an interactive map the geolocation of the academic items of the repositories of the UPC, UPCT, UPM and UPV polytechnic universities grouped in the UP4 Association" (http://geo.up4. is/). The other project is JournalMap (https://www.journalmap.org/) a cooperative project between the USDA-ARS Jornada Experimental Range in Las Cruces, NM and the Idaho Chapter of The Nature Conservancy. This is one of the components of another tool called Landscape Toolbox. It is a project that geolocates scientific production based on the geographical location where the study is carried out to observe which areas have been studied and in which there are gaps. The present paper links with these two projects. Our study is

original and useful since it aims to geolocate the scientific articles in an automatic way through algorithms created for this purpose and not in a manual or semi-automatic way.
More specifically, there are three main objectives for this project, firstly (1) to develop an algorithm that allows the coordinates to be extracted from a collection of documents to identify exactly which places these studies deal with. The second objective (2) is that once the locations have been identified by the algorithm, they will be displayed on a map through an online platform. In the third objective (3), the platform will integrate a layer of bibliometric and/or altmetric information that will allow one to know the volume of production according to coordinates as well as different data on the scientific and social impact. It should be mentioned that in this paper will be presented only the results of objectives 1 and 2 applied to a set of scientific works that study the Sierra Nevada mountain range (Granada, Spain)

Material and methods

In order to create a collection of documentary information about Sierra Nevada, a search was done in the Scopus database. The Scopus database has been chosen for the facilities it offers for exporting full-text documents, thanks to Scopus Document Download Manager. With this type of search, we wanted to find scientific articles that dealt with the Sierra Nevada mountain range located in the province of Granada (Spain). As there were other mountain ranges with the same name in other parts of the world, the search for the term Spain or Granada was added. This search found 623 articles. The second step was the processing of the information for storage. After the pertinent manual verification work (the geolocation of the documents is automatic, not the selection of the sample), there are 447 documents with a complete associated pdf (not only the abstract or title) and which are openly accessible, the other 176 (623-447) records do not have an associated pdf, are incomplete or are not an open publication, of which 424 are about the Spanish Sierra Nevada and not about the Sierra Nevada of California or Peru. The third step was the identification of the coordinates. Although there are many types of coordinate systems, the most common that this project has found in the sample are the following types and subtypes of coordinates: the geographic coordinate system and the coordinate system UTM (Universal Transverse Mercator). The geographic coordinate system is subdivided into sexagesimal (degrees, minutes and seconds) and decimal (degrees and decimals). The UTM coordinate has multiple variants in that the authors express them in different ways, with or without the letters of the cardinal points, specifying the use or not (in our case it is 30S). Finally, in environmental studies, they usually use a subdivision of the use 30S, which is used in army maps and which is reflected in articles with VG, VF, WG and WF. Finally, our database contains 424 bibliographic references linked to their corresponding PDFs. This database has been used for the design and training of the algorithm.
For the geolocation of the contributions, we have developed a text mining algorithm based on the extraction of information through regular expressions and toponyms - keywords (see Figure 1). To carry out this automatic geolocation process, we design an algorithm based on 4 stages:

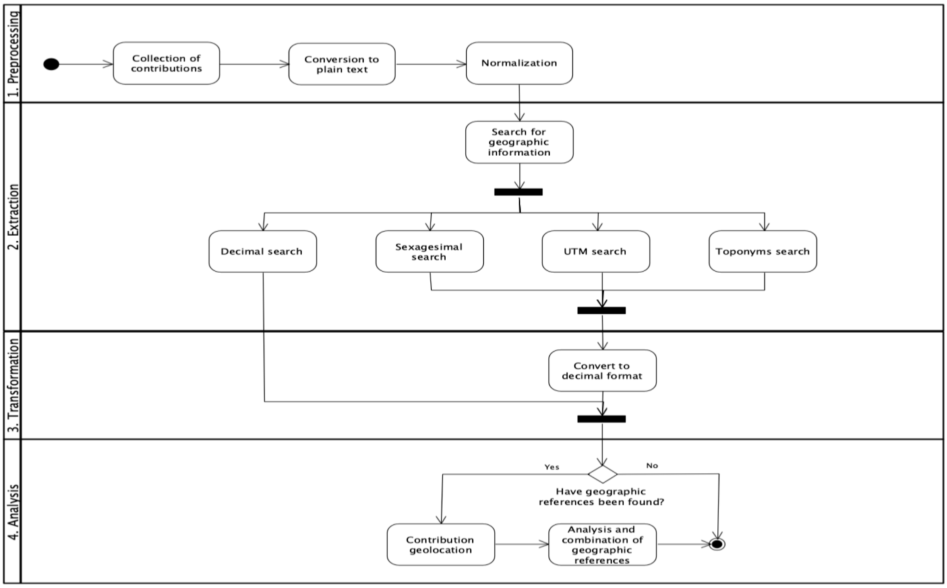
1. Preprocessing: In this stage, the contributions of the sample are processed in PDF format, converting the text of each one to a processable format (plain text), normalized and without all unnecessary information. For the conversion of PDF files to plain text, we have used pdftotext which is an open-source command-line utility.

2. Extraction: Search and extraction of geographical references in the text using two methods, (i) regular expressions for the search of geographical coordinates in their different formats (decimal, sexagesimal and UTM) and (ii) search of the frequency of appearance of place names. The database of toponyms for this study has been developed by combining all sources of public and georeferenced information of the Junta de Andalucía such as NGA and ITACA of the Andalusian Institute of Statistics and Cartography.

3. Transformation: In order to georeference the results obtained on an interactive map, all the results are processed to unify them in decimal format (latitude, longitude). To convert between the different geographic representations, we have used Proj4js1 which is a library to transform point coordinates from one coordinate system to another, including datum transformations.

4. Analysis: Finally, once we have all the information that has been extracted in the same format, a small analysis is carried out to decide, through heuristic behavior, if it is possible to geolocate the contribution. For this, we have mainly followed three criteria: (i) if geographic coordinates and place names have been found, we combine this information to select the coordinate that is textually closest to the most frequent place name; (ii) if only geographic coordinates have been identified, it is geolocated within the most referenced area; and (iii) if only toponyms have been recognized, we geolocate it in the one with the highest frequency as long as it exceeds a certain threshold (this threshold is calculated as the simple mean of the frequencies of the toponyms in the entire sample of this study)

Figure 1. Algorithm workflow.



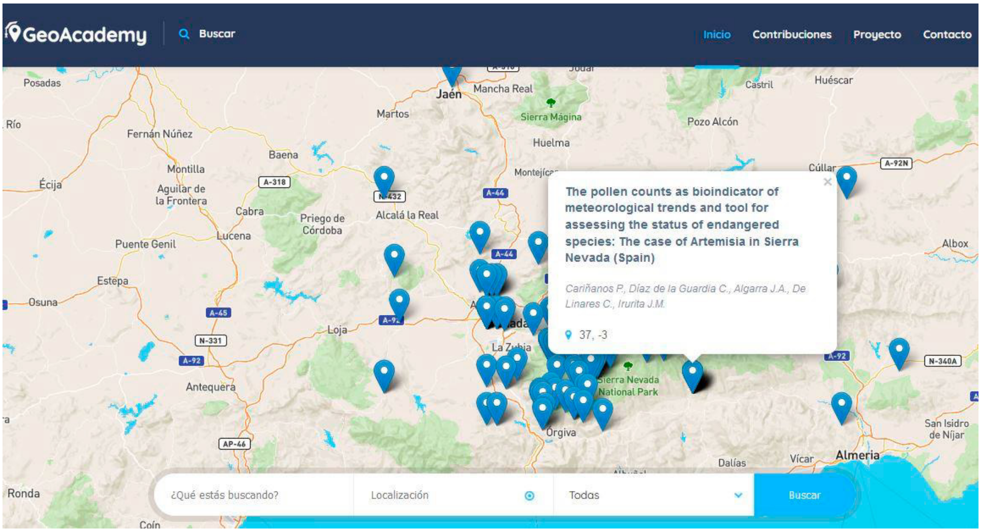
Results

Table 1 shows a summary of the results of the algorithm (figure 1) of automatic detection of geolocations being applied to the collection of 424 scientific articles on Sierra Nevada. In total, the algorithm has been able to geolocate 157 articles with coordinates, 37% of the total. One of the tools used to increase the number of geolocated articles and elements has been the use of place names that have allowed us to geolocate 5025 place names of 189 different articles. There are 2.6 place names on average per scientific article. Finally, the number of works that have been geolocated using the algorithm is 346, that is to say 81.6% of the original document collection has been located, either by coordinates or toponyms. It should be mentioned that one of the fundamental aspects to improve the success rate of the algorithm has been the use of place names.

Table 1. Indicators and general statistics in the algorithm training process

A) General indicators related to geolocation by coordinates	
A1. Number of articles analysed in the study:	424
A2. Number of articles containing geographical coordinates (157 + 43 (images) + 5	205
A.3 Number of articles containing geographical coordinates identified by the	157
A.4. Percentage of articles geolocated through geographical coordinates (A3/A1)	37.03%
B) Indicators related to geolocation by place names	
B.1. Number of place names identified by the algorithm	5025
B.2 Number of articles geolocated by place names	189
B3. . Percentage of articles geolocated by place names (B2/A1)	44.57%
C) Findings	
C.1 Number of geolocalisations achieved (coordenates + place names) (A.3+B.2)	346
C.2. Percentage of articles geolocated from the the total number of articles (C1/A1)	81.6%

Once objective 1 had been achieved, focus moved to the creation of an application to view scientific articles on a digital map based on the different coordinates they contain. The portal that has been developed currently contains the collection of documents on Sierra Nevada that has been analysed in this paper. The portal is operational at the following web address in beta format: https://geoacademy.everyware.es/.



The pollen counts as bioindicator of meteorological trends and tool for assessing the status of endangered species: The case of Artemisia in Sierra Nevada (Spain)

Cariñanos P., Díaz de la Guardia C., Algarra J.A., De Linares C., Irurita J.M.

37, -3

Figure 2. GeoAcademy application showing geolocated locations for the Sierra Nevada collection of articles.

As we can see in Figure 2, the geolocations detected by the algorithm are distributed, by clicking on each one we see the reference information of the paper and a link to view it. At the bottom you can filter by type of document you are looking for (article, conference, thesis, etc.) or you can search by keyword. The different tabs give us access to a traditional search engine with filters and a search radius, as well as a tab where the project and its members are described, as well as a contact form. Likewise, each scientific work that has been processed includes both the metadata of the databases (in this case Scopus) and all the metadata generated automatically by the algorithm. In our portal, the coordinates in decimal format as well as a complete list of the identified place names are added to the bibliographic description.

Discussion

This study contains a number of limitations that we proceed to list and which have mainly to do with processing. The first problem relates to the processing of PDF documents. We found several that did not have an associated pdf, for others the pdf requires payment, or only the title or the title and abstract are available. This limits the number of results you can cover. Secondly, the coordinates have some formal standardization, whereas in practice each field of knowledge has different guidelines for writing the coordinates, with greater variability with the UTMs that the algorithm has overcome without problems. Another problem is that several studies show the coordinates in image form, that makes them more difficult to extract, although in the future through OCR technology they could be captured. At the linguistic level, words with multiple means in the toponymy can be problematic, which can give both false positives and false negatives.

The success rate of the Geoacademy algorithm on all documents is 81.6%, a high percentage for this type of study. We will continue to train the algorithm with much larger documentary collections related to other geographical features. Likewise, it will be applied in other contexts, such as archaeological where most of the articles include precise geographic coordinates. It could also be applied to digital humanities, since interesting projects are being carried out where historical works are geolocated through the place names that appear in them.

The third objective of this work is to provide the platform with a layer of information capable of representing information of a bibliometric and altmetric nature, that is, of scientific and social impact. In this sense, future development implies providing the GeoAcademy platform with the following functionalities 1) Filter locations based on indicators (Impact Factor, Number of citations, Altmetric Attention Score ...) 2) Use of geoposition markers differentiated according to values of the indicators. Likewise, the platform will present a bibliometric summary of the different coordinates and locations, offering bibliometric information at a level not currently seen. Future developments could include its inclusion with an industry tool such as bibliometrix.

It would also be very interesting if users of large scientific databases such as Scopus or Web of Science, having performed a search with a list of results, could see said list geographically on a map, applying our algorithm for a better user experience. That is to say, to integrate our project in their platforms. Finally, numerous studies do not work with geographical points, we are currently working on how to show these studies on our platform

Abstract

Star inventors generate superior innovation outcomes. Their capacity to invent high-quality patents might be decisive beyond mere productivity. However, the relationship between quantitative and qualitative dimensions has not been exhaustively investigated. The equal odds baseline (EOB) framework can explicitly model this relationship. This work combines a theoretical model for creative production with recent calls in the patentometrics literature for multifaceted measurement of the ability to create high-quality patents, extending the recent results obtained with forward citations. The results provide evidence in favor of the EOB across all quality indicators and that inventors' capacities to create quality patents can be measured to potentially identify star inventors in a way that explicitly takes the intricate relationship between overall productivity and patent quality into account. Furthermore, the rankings of inventors in terms of quantity or quality are overall more dissimilar than similar, confirming that quantity and quality can be measured as orthogonal dimensions. This result is of particular interest for organizations and for the society: incentives and compensation schemes that focus only on a quantitative assessment of inventors' output risk to neglect a relevant part of the innovation production.

Introduction

Star inventors are considered of extreme interest since they generate superior innovation outcomes (Groysberg & Lee, 2009; Oldroyd & Morris, 2012; Zucker & Darby, 1997). However, their identification is not immediate and can rely on different measures: is quantity of output sufficient or are quality indicators needed? Relatedly, disentangling inventor productivity and the quality of their patents is quite challenging because quantity and quality are intricately related (Forthmann et al, 2020a; Simonton, 2009). In addition, researchers have called for more multifaceted measurement of patent quality (Lanjouw & Schankerman, 2004; van Zeebroeck, 2011; Caviggioli et al., 2020).

In this study, we focus on patent inventors and their capacity to invent high-quality patents, which might be decisive beyond mere productivity (Rothaermel & Hess, 2007). The most frequent methods to define a star inventor in the literature considered when the inventor is either extremely prolific (quantity) or is involved in the creation of outstanding inventions (quality). However, the relationship between the two dimensions has not been exhaustively investigated in light of what can be considered determinant for the identification of stars as agents to increase the production of valuable innovations. The relationship between quantity and quality of inventions can be explicitly modeled within the framework of the equal odds baseline, EOB (Simonton, 2004, 1988). We use and extend the EOB framework to explicitly take the relationship between quantity and quality into account and thus provide useful diagnostic information for the identification of star inventors. Specifically, we incorporate latent variables into a multifaceted extension of the EOB that is based on multiple quality indicators derived from patent bibliometrics. This way the measurement of quality is isolated from quantity, implying that quantity and quality can be measured as orthogonal dimensions.

All the analyses are carried out at the individual level for a large sample of inventors with at least one US granted patent between 2008 and 2010. Different operationalization strategies are introduced to support the identification of prolific scientists and of outstanding inventors along different aspects of quality: technological complexity (through three indicators: the technological scope, the generality and originality indexes) and the value of an invention (measured by the number of citing families and by the geographical scope).

Research framework

Star individuals

The relevance of star scientists is not limited to a direct increase of output (Groysberg & Lee, 2009) but they also support organization activities (Kehoe & Tzabbar, 2015) and improve the attraction of resources and skilled personnel (Lacetera et al., 2004; Hess & Rothaermel, 2011). They also indirectly foster the productivity of peers and collaborators thanks to learning and emulation (Lockwood & Kunda, 1997). Although there is consensus on the presence of a general positive impact of star individuals, it is worth reminding that in some cases the literature identified negative effects in organizations due to coordination costs and conflicts (Groysberg et al., 2011; Swaab et al., 2014). Furthermore, hiring stars is often expensive (Groysberg et al., 2011) and thus it should be considered a critical activity. The findings of the literature support the need to improve the understanding of the way to identify exceptional scientists.

The identification of stars has taken different approaches in the literature, with respect to the examined field of activity and the different operationalizations of the criteria to distinguish outstanding from common individuals. In general, to be a star the individual must engage in disproportionately high performance relative to most other workers in their field (Aguinis & O'Boyle, 2014). The examined performance has been measured under different perspectives ranging from productivity (Lahiri et al., 2019; Zucker et al., 2002; Kehoe & Tzabbar, 2015), impact (Azoulay et al., 2010; Rothaermel & Hess, 2007) and, in some cases, visibility or celebrity (Oldroyd & Morris, 2012).

Star individuals have been studied in several contexts with particular attention to scientists/scholars (Azoulay et al., 2010) and inventors (Hohberger, 2016), thanks to data availability, namely articles and patents. Stars in these two categories have been similarly addressed by considering either their productivity in terms of quantity of output, in most cases through the number of articles or patents, their impact relying on a measure of quality such as the received citations (Liu, 2014; Hohberger, 2016; Hess & Rothaermel, 2011), or a combination of them (Kehoe & Tzabbar, 2015; Agrawal et al., 2017).

The equal odds baseline

The equal odds baseline (EOB) is a statistical model for the relationship between quantity and quality of scientific productions that is embedded within a comprehensive theoretical framework for scientific productivity (Simonton, 2009, 1988). In the EOB the number of inventors' high-quality patents H (i.e., the number of hits) is linearly regressed on the total number of patents T:

$$H = \rho T + u_i. \tag{1}$$

In Equation 1, ρ refers to the hit-ratio and u_i is a random error term for inventor i to take individual differences between inventors in hit-ratios into account (Simonton, 2009). The EOB further implies that individual hit-ratios H/T are uncorrelated with T because otherwise it would follow that the relationship between H and T is non-linear (Simonton, 2004). In other words, a positive linear correlation between H and T is a necessary but not sufficient condition for the EOB (Forthmann et al., 2020b, 2020a). The EOB further proposes an intercept of zero and a hit-ratio that equals the ratio of average H and average T. These implications of the EOB allow evaluation of model fit based on established criteria within the framework of structural equation modeling – *SEM* (Forthmann et al., 2020b, 2020a). The SEM approach to study the EOB has been further extended to allow quantifying if residual variance $Var(u)$ is larger as compared to a strict EOB with *Var*(*u*) = 0. This approach can be used to examine if individual differences are present in a given dataset (i.e., hit-ratio variance is larger than mere sampling error variation; Forthmann et al., 2020c). Indeed, the presence of individual differences in hit-ratios are a prerequisite to measure quality as a latent variable based on residuals resulting from multiple quality indicators.

A multifaceted extension of the equal odds baseline

Patents can be evaluated for a variety of quality criteria (Lanjouw & Schankerman, 2004; van Zeebroeck, 2011) and researchers have called for a multifaceted perspective on patent quality. However, the EOB has not yet been formulated in a way that takes multiple quality indicators into account. The current work aims at extending the EOB in this regard by formulating the EOB as a SEM in which individual differences in hit-rates are explained by a quality latent variable. In other words, the error term u_{ij} for inventor i (i = 1,…,I) and quality indicator j (j = 1,…,J) will be modeled by the following equation

$$u_{ij} = \lambda_j \eta_i + \varepsilon_{ij}, \tag{2}$$

with latent factor η_i as the capacity to create high-quality inventions, λ_j being the loading of the jth indicator on the capacity factor, and ε_{ij} the remaining error left unexplained after taking quantity and the capacity for quality into account. Inserting Equation 2 into Equation 1 yields a multifaceted EOB

$$H_{ij} = \rho_j T_i + \lambda_j \eta_i + \varepsilon_{ij}. \tag{3}$$

Specifically, the multifaceted EOB proposes that η and T are uncorrelated which allows for independent assessment of inventors' capacity for quality and productivity (i.e., quantity of output). As an extension of Equation 1, the model in Equation 3 can also be estimated within the SEM framework (Bollen, 1989). In SEM, a proposed path model and its implied covariance matrix and mean vector are examined for their discrepancy to their empirically observed counterparts. Useful models have a model-implied covariance matrix and mean vector that are close to the observed covariance matrix and vector of means (Bollen, 1989). Closeness of a proposed model and data in SEM can be evaluated by various established indices (West et al., 2012). In this approach, regression coefficients ρ_j and λ_j are estimated by maximum likelihood (or its robust variants), for example. Estimates of the latent capacity η_i can be obtained by means of empirical Bayes or Bartlett's method (Estabrook & Neale, 2013), for example. This model is illustrated for the five quality indicators used in this study (Figure 1 and further details in Section 3). In this illustrative example capacity for quality is unidimensional and if measurement of quality is assumed to support the identification of star inventors such a simple model might be appealing. However, the measurement of patent quality can be decomposed in two main dimensions: technological complexity and value (Caviggioli et al., 2020; van Zeebroeck & van Pottelsberghe, 2011). Technological complexity refers to the number of components, their degree of inter-dependence and decomposability (Singh, 1995; Wang et al., 2013). Technological complexity requires knowledge combinations from multiple domains (i.e., multidisciplinarity). Following this, the number of backward citations is often used as an indicator of technological complexity (van Zeebroeck, 2011; van Zeebroeck & van Pottelsberghe, 2011). Patent value as conceptualized in this work refers to the technical merit (forward citation count can be an indicator) of potential market size (as quantified by geographical scope) of the invention (e.g., Caviggioli et al., 2020a). Consequently, Equation 3 needs to be extended to a two-dimensional model that includes one latent variable to reflect technological complexity and a value latent variable. In the current work, we sought to empirically test the fit of inventor data to the EOB when quality is measured by multiple indicators and try to explain hit-ratio variation by means of a latent capacity to create high-quality inventions. Specifically, we wanted to compare a unidimensional model (i.e., quality capacity modeled as one latent variable; Lanjouw and Schankerman, 2004) with a two-dimensional model that reflects technological complexity and patent value (Caviggioli et al., 2020; van Zeebroeck & van Pottelsberghe, 2011).

Aim of the current research

The main aim of this study is to extend recent findings and theorizing on the EOB in several ways. First, we extend recent results obtained for forward citations of patents (Forthmann et al., 2020a) to other indicators because patent quality is a multifaceted construct (Lanjouw & Schankerman, 2004). Second, new EOB theorizing allows quantifying the amount of residual variance accounted by mere sampling variation (Forthmann et al., 2020c). This is useful to accurately estimate the amount of hit-ratio variation that is attributable to between-inventor differences. The presence of between-inventor variation in hit-ratios is essential for the measurement of capacity for patent quality. In this vein, the EOB is extended in this work to incorporate a latent quality variable that potentially explains individual differences in hit-ratios within a SEM framework. Finally, we aimed at comparing a unidimensional model with a two-dimensional model that incorporated latent variables to measure both technological complexity and patent value. Importantly, a reasonable fit of the data to either the unidimensional or two-dimensional multifaceted EOB implies that inventors' capacities to create quality patents can be measured to potentially identify star inventors in a way that explicitly takes the intricate relationship between overall productivity and patent quality into account.

Method

Data sources

The main data sources are PatentsView and PATSTAT. PatentsView is a data warehouse sourced from USPTO-provided data on published patent applications (2001-present) and granted patents (1976-present). It provides disambiguated inventors' names from the application of an algorithm that uses discriminative hierarchical coreference. Patent level data from PatentsView are linked to PATSTAT, the largest repository of patent data in terms of coverage and available information, maintained by the EPO with the collaboration of the main patent offices[1].

The analyses will be carried out at the level of inventors and the examined sample is defined by applying the following steps. The starting sample includes all the inventors with at least one US granted patent filed between 2008-10[2], corresponding to 725,577 disambiguated names in PatentsView. All the 4,297,710 granted patents associated to the selected inventors are linked to PATSTAT where further information is collected[3].

All the selected patents are associated to their INPADOC family (2.9 million families). Patent families represent a unit of analysis that is closer to invention: multiple patent documents regarding the same filing are collapsed to a single unit, providing a more accurate measure of inventors' productivity (OECD, 2009; Martínez, 2011). Furthermore, country extensions can be identified providing information on the geographical coverage. The earliest filing year and the IPC subclasses of each family are collected and several patentometrics are calculated following the approach described in (Caviggioli, et al., 2020). For each inventor it is thus possible to identify the portfolio of inventions and create portfolio level measures (these variables are described in the next section in detail) as of 2010 in terms of productivity. The cut-off year is required to consider a subsequent time window sufficiently large to calculate quality indicators such as citations and to account for potential delays in the publication of documents.

With the aim to clean the sample from potential errors in the original data, either in name disambiguation or in patent family identification, those inventors reporting a portfolio-level earliest filing date prior to 1981 (3.2%) were excluded. Inventors with no IPC codes associated to the portfolio were also eliminated (0.01%).

The final sample is a selection of 703,977 inventors active in the years 2008-10 and with a patenting history of maximum 30 years in 2010: each patent portfolios represent the cumulated inventions up to 2010. Table 1 reports the distribution of the portfolio size in the sample.

Table 1 Distribution of portfolios of inventions across selected inventors

Portfolio size [from	 to]	Number of inventors	Perc.	Cumulate
0	1	214226	30.4%	30.4%
2	5	252228	35.8%	66.3%
6	10	108368	15.4%	81.7%
11	50	119041	16.9%	98.6%
51	100	8032	1.1%	99.7%
101	500	2062	0.3%	100.0%
501	max	20	0.003%	100.0%
	Total	**703977**	**100%**	

Variables

Several measures of quality are calculated with the aim to test their relationship with the inventors' productivity (i.e. the number of patent families between 1981 and 2010). Each variable is computed at the level of patent family and in a second step is aggregated at the level of patent portfolio. Initially, we examined the fit of the data to the EOB for each of the five quality indicators in separation by means of correlations and a check of the presence of individual differences in the residual (Forthmann et al., 2020c). In a next step, we fitted the multifaceted EOB as a SEM model with the package lavaan (Rosseel, 2012) for the statistical software R (R Core Team, 2019). Model fit was based on fit indices such as the RMSEA, SRMR, CFI, and TLI according to existing cut-offs in the SEM literature (West et al., 2012). Using these fit indices is particularly helpful when examining the EOB in very large datasets because even small and negligible deviations from the EOB become easily statistically significant (Forthmann et al., 2020a). SEM model fit indices indicate if the data can be adequately described by the EOB when sample sizes are large. Finally, we estimated Raykov's reliability for the latent quality variables to quantify measurement precision (Raykov, 2009).

Table 2 provides an overview of the different variables that are introduced as indicators of various aspects of quality.

Technological complexity is described through three indicators: the technological scope, the generality and originality indexes. The technological scope counts the number of different IPC subclasses associated to patents (Lerner, 1994): the count is extended to the family level by considering all the family members. It provides a measure of multidisciplinarity: the broader the scope, the greater the complexity and the potential range of technological areas where it can impact (Harhoff et al., 2003). The originality and generality indexes were first introduced by (Trajtenberg et al., 1997) and are calculated considering the concentration of the different technological fields among the cited and citing patents of every focal document respectively. Both variables are computed in their unbiased version as described in (Hall & Trajtenberg, 2004) and IPC subclasses (four-digit IPC codes) are selected as technology fields. Coherently with the general approach, the patent citation network is generated at the level of INPADOC families, excluding intra-family citations. The generality index is a forward-looking measure describing the width of the technological advances. The originality index represents the scope of the underlying research.

The value of an invention is measured by the number of citing families and by the geographical scope. The forward citations provide a measure of the technical value (van Zeebroeck and van Pottelsberghe, 2011). The indicator considers only citations occurring in the first five years after the filing to account for the different time of exposure to the “risk” of receiving a citation (Caviggioli & Ughetto, 2016)[4]. The geographical scope indicates how large the expected market for the patented technology is. It is calculated as the number of jurisdictions in which patent protection is sought (Lanjouw et al., 1998; Agostini et al., 2015).

The construction of the indicators follows the approach proposed in van Zeebroeck (2011) but at the patent family level: each indicator of quality is calculated from the ranking of the examined patent family in a reference cohort, defined by a common technological sector and year (as a percentile). The reference sample consists of all the patent families associated to the US granted patents filed between 1981 and 2010. The sectors are identified by considering the concordance table between IPC codes and 35 technical fields developed by the WIPO[5]. The reference time is the earliest filing year among the family members. This approach allows calibrating the indicators with respect to each technological area and potential trends occurring in the time frame. When a patent family is associated to more technical fields, the indicator assumes the value of the highest percentile. For example, if an invention is developed in the fields “Optics” and “Pharmaceuticals” and the examined family ranks 60th for forward citations among all the inventions in the former and 80th in the latter, then the selected score for the considered family is 80.

Once all the indicators are calculated for each family, they are aggregated at the portfolio level. For each inventor, the number of outstanding inventions in the portfolio are counted. Such top inventions are identified when they are above the 95th percentile in the corresponding sector-year cohort (i.e. the family level indicators are equal or above 95). The number of excellent inventions according to each examined indicator is provided for all the inventors. Note that a single patent family could be above the excellence threshold in none, one or more of the indicators of quality.

Initially, we examined the fit of the data to the EOB for each of the five quality indicators in separation by means of correlations and a check of the presence of individual differences in the residual (Forthmann et al., 2020c). In a next step, we fitted the multifaceted EOB as a SEM model with the package lavaan (Rosseel, 2012) for the statistical software R (R Core Team, 2019). Model fit was based on fit indices such as the RMSEA, SRMR, CFI, and TLI according to existing cut-offs in the SEM literature (West et al., 2012). Using these fit indices is particularly helpful when examining the EOB in very large datasets because even small and negligible deviations from the EOB become easily statistically significant (Forthmann et al., 2020a). SEM model fit indices indicate if the data can be adequately described by the EOB when sample sizes are large. Finally, we estimated Raykov’s reliability for the latent quality variables to quantify measurement precision (Raykov, 2009).

Table 2 shows summary statistics of the variables. Additional variables are built to improve the model specifications and control for inventor’s characteristics. Since the selected sample includes inventors at different stage of their career a proxy of their expertise is introduced as the number of years since the first filing date. PatentsView database provides also data on inventors’ gender, as a result of the method explained in (Office of the Chief Economist, 2019). Note that data coverage is not complete (the gender is missing for 9.1% of the inventors in the examined sample).

Analytical approach

Initially, we examined the fit of the data to the EOB for each of the five quality indicators in separation by means of correlations and a check of the presence of individual differences in the residual (Forthmann et al., 2020c). In a next step, we fitted the multifaceted EOB as a SEM model with the package lavaan (Rosseel, 2012) for the statistical software R (R Core Team, 2019). Model fit was based on fit indices such as the RMSEA, SRMR, CFI, and TLI according to existing cut-offs in the SEM literature (West et al., 2012). Using these fit indices

is particularly helpful when examining the EOB in very large datasets because even small and negligible deviations from the EOB become easily statistically significant (Forthmann et al., 2020a). SEM model fit indices indicate if the data can be adequately described by the EOB when sample sizes are large. Finally, we estimated Raykov's reliability for the latent quality variables to quantify measurement precision (Raykov, 2009).

Table 2 Summary statistics of the examined variables

Measure	Indicator	Obs.	Mean	Std.Dev.	Min	Max
Quantity						
Inventor's patent portfolio size	Count of patent families having earliest filing year between 1981 and 2010	703,977	7.25	13.82	1	1041
Quality						
Excellent inventions as number of patent families above the 95th percentile in the portfolio in terms of:						
Technological complexity - Multidisciplinarity	Technological scope (count of IPC-4-digit)	703,977	0.26	0.87	0	103
	_ Share of portfolio		0.05	0.16	0	1
Technological complexity - Redeployability	Generality index	703,977	0.50	1.60	0	176
	_ Share of portfolio		0.07	0.20	0	1
Technological complexity - Novelty	Originality index	703,977	0.49	1.68	0	294
	_ Share of portfolio		0.07	0.20	0	1
Value – Technical merit	Count of Forward citations (5-years window)	703,977	0.59	1.93	0	198
	_ Share of portfolio		0.08	0.20	0	1
Value - Potential market size	Geographical scope (count of countries of extension in the family)	703,977	0.44	1.74	0	197
	_ Share of portfolio		0.07	0.20	0	1
Control variables						
Expertise – career	Years from the earliest filing date	703,977	8.00	6.76	1	30
Gender	Dummy=1 if male	640,043	0.87	0.34	0	1

Analysis

Univariate EOB examination

First, positive correlations between patent family counts (*T*) and all indicators of *H* were found (see column 1 in Table 3). This is in accordance with the EOB which proposes that the relationship between *H* and *T* is positive and linear. Expectedly, career length was moderately positively correlated with family count. In addition, career length correlated with all indicators of H. Correlations were small to moderate. Gender did not correlate with any of the creative productivity measures. Second, the correlation between patent family counts and all average quality indicators were close to zero (see column 1 in Table 4) which again provides evidence in favor of the EOB across all quality indicators. Importantly, both control variables correlated negligible small with all average quality indicators. As a final preparatory step prior to examination of the multifaceted EOB, we checked if residual variances were larger as expected under the strict EOB which implies constant hit-ratio. This check can only meaningfully be done when the EOB displays reasonable fit which was the case here based on correlations reported in Table 3 and Table 4. Residual variance findings are reported in Table 5. All observed residual variances (i.e., the variances of the u_i) were at least twice as large as compared to the minimum expected residual variance under the EOB (i.e., the residual variance under strict equal odds). Hence, we conclude that hit-ratio variation in the data was larger than expected under strict equal odds which only allows sampling error as a unique source of residual variation. Hence the data were promising for application of the multifaceted EOB with latent variable(s).

Table 3 Correlation matrix of examined variables: quality indicators expressed as number of excellent inventions in the portfolio (EOB relevant correlations in bold)

	Variables	1	2	3	4	5	6	7
1	Count of families	1.00

Generality index	1.94	0.46
Originality index	2.19	0.46
Count of fwd cit. (5-yrs)	2.35	0.54
Geographical scope	2.56	0.41

Multifaceted EOB results

The multifaceted EOB (without any latent quality variables) displayed excellent fit (RMSEA = .004, 90%-CI: [.004, .005]; SRMR = .007; CFI = .999; TLI = .999). Next, a unidimensional model with quality latent variable η was estimated and it displayed adequate fit (RMSEA = .015, 90%-CI: [.015, .015]; SRMR = .043; CFI = .960; TLI = .939). Reliability of the latent quality variable was .92 indicating excellent reliability. The latent quality variable η was predicted by career length to a small degree (β = .14, p < .001) and negligible small by gender (β = -.02, p < .001) with an overall R^2 = .02. As compared to the unidimensional model, the two-dimensional model with latent variables for value (η_{Value}) and technological complexity ($\eta_{\text{Technological complexity}}$) displayed better fit (RMSEA = .013, 90%-CI: [.013, .013]; SRMR = .034; CFI = .977; TLI = .962). The estimated standardized model parameters for this model are displayed in Figure 1. The value and technological complexity factors correlated with a value of .35. For the two-dimensional model, Raykov's reliability was .38 for the latent variable referring to value (see the loadings in Figure 1) and .96 for the latent variable referring to the technological complexity. Hence, value was not reliably measured, whereas technological complexity had excellent reliability. The technological complexity latent variable was predicted by career length to a small degree (β = .14, p < .001) and negligible small by gender (β = -.02, p < .001) with an overall R^2 = .02 mimicking the above findings for the unidimensional model. In addition, the R^2 for the value latent variable was zero which indicated that both control variables had a negligible relationship with value.

Identification of stars

We ranked the Top-10 inventors in Table 6 according to their productivity and the latent variable estimates based on the two-dimensional model. All inventors that occurred in more than one ranking list are depicted in bold font. Inventor ID221342 was the only one that occurred in all of the three lists in the Top-10 which highlights that stars may still be able to perform across a range of indicators even when some of them are orthogonal. Nonetheless, the rankings are overall more dissimilar than similar. Notably, the value latent variable estimates (empirical Bayes) were associated with the lowest measurement precision.

Table 6 Ranking of the Top-10 inventors based on productivity, general quality, value, and technological complexity.

Rank	Count of families (*T*)	η_{Value}	$\eta_{\text{Technological complexity}}$
1	ID193111	ID204114	***ID221342***
2	**ID136246**	ID239919	**ID57671**
3	ID55711	ID55136	**ID136246**
4	ID328897	ID19594	ID353689
5	**ID57671**	**ID72014**	ID44413
6	ID104847	***ID221342***	ID210006

Conclusion

In this study, we employed the EOB framework to investigate the relationship between quantity and quality of inventions at the inventor level. This is driven by the relevance of star inventors as individuals able to generate not only more but also high-quality innovations. In particular, quality is decomposed along two main dimensions, technological complexity and value, by employing several patentometrics.

The results provide evidence in favor of the EOB across all quality indicators. Furthermore, the rankings of inventors in terms of quantity or quality are overall more dissimilar than similar, confirming that quantity and quality can be measured as orthogonal dimensions. This result is of particular interest for organizations and for the society. Incentives and compensation schemes that focus only on a quantitative assessment of inventors' output risk to neglect a relevant part of the innovation production which is more connected to the actual impact of the developed innovations.

Our work is not exempt from limitations and in particular the current empirical models do not account for organization level effects. The introduction of this further level of analysis would improve the results by considering the available resources. To perform such analyses, future studies will need to accurately identify patent assignees at the invention date and whenever inventors move to a different employer.

Abstract

A key objective of global policies on Artificial Intelligence (AI) is to foster AI research for sustainable development (SD). In this paper we examine the inclusion of this objective in AI published research by addressing three questions: 1) To what extent is AI research addressing the sustainable development goals (SDGs)? 2) Which subject areas of AI show an emerging interest in SD? And 3) What patterns of collaboration between regions of the world are being stimulated by AI? We analyzed AI papers from 2000 to 2019 using the IEEE Xplore database by: 1) Identifying the number of AI papers that address SDGs in their titles, abstracts, and keywords. 2) Developing a composite indicator based on the number of documents produced, citation impact, and inventive impact to distinguish areas with an emerging interest in SD; 3) Exploring co-authorships at three levels: region, income group, and country. The results show that a small share of papers is explicitly focused on SD, but there is an emerging interest in *Broadcast technology, Systems Engineering and Theory, Ultrasonics, Ferroelectrics, and Frequency Control, Sensors,* and *Education*. Inter-regional and inter-income group collaboration are limited, and network power is concentrated in a few countries. The results could be useful to align the connection between technical knowledge, strategic planning for S&T investment, and SD policies.

Introduction

The fourth industrial revolution is characterized by the exponential development of technologies to radically transform life on Earth (Schwab 2017). This new revolution has been advocated as an opportunity to improve business productivity, automate various manual trades, provide greater control over the quality of production, among others (Mou 2019). On the other hand, there is growing concern about the adverse effects of this revolution on the environment, the economy, and society (Harari 2017). The transformations that the fourth industrial revolution is having in the world make it important to understand its risks and potential benefits, and the role of academia, industry, government, and civil society in steering it.

From a global perspective, there is a competition for leadership in the fourth industrial revolution's determining technologies. For example, most OECD member countries are improving their digital infrastructure, educating their citizens in information technologies, supporting new technology-based companies, and research in "convergent" and "exponential" technologies (Planes-Satorra & Paunov 2019). The confrontation between China and the United States over the development and control of 5G technology (Sørensen et al. 2016) is an extreme but revealing example of the global competition situation. Consequently, several national and international agencies have begun to carry out policy studies to understand how to insert themselves into the new global value chain that is shaping the fourth industrial revolution and what international cooperation strategies can be more effective to position themselves as leaders in the technologies that drive this revolution (Kagermann et al. 2016; UNIDO 2018; Navarro 2018). Although this quest for leading technological development is valid, they tend to focus on the technical aspects of it, leaving aside other important concerns.

One such concern is if technological breakthroughs will work towards planetary well-being. If so, it is imperative to reconcile technological advancement with societal purposes (Cassi et al. 2017). Researchers have an essential role in achieving this reconciliation because they produce a good part of the enabling knowledge behind technology, and it is not uncommon that they produce the technologies themselves (Breschi et al. 2005; Zellmer-Bruhn et al. 2021).

Technologies are often seen as mere "technical" developments, but they also involve social aspects that need to be reflected upon by engineers (European Parliament 2020). For instance, AI algorithms to detect potential criminals can be biased by human assumptions on the physical appearance of people or their gender (Osoba & Welser 2017). Therefore, reflecting beyond the technical aspects of technology is needed to produce humanistic technologies. This demands engineers to think of technologies to reduce our impact on the planet because, as Jane Goodall puts it, "only when our clever brain and our human heart work together in harmony can we achieve our true potential" (Goodall 2014).

Part of achieving the true potential that Goodall talks about implies producing sustainable technologies with a clear purpose to ensure sustainable development. Therefore, it is crucial to understand to what extent engineering research, which is behind the significant breakthroughs in world technology, addresses sustainable development. In this paper, we understand sustainable development as development that aims to achieve a social, environmental, and economic balance (Chavarro et al. 2017).

We focus on AI as a ground-breaking domain of technologies and research with the power to redefine global society. Recently, the OECD issued a crucial policy paper in which they recognize that "AI should benefit people and the planet by driving inclusive growth, sustainable development and well-being" (OECD 2020). The IEEE has also made available a clear position to "Support the R&D needed to advance innovation and development in artificial intelligence and its application to benefit humanity" (IEEE 2019). Our work is a contribution to a broad question, which remains unexplored, on the extent to which "the digital era could contribute to or jeopardize sustainable landscapes (…), what is the role of digital technologies in pursuing the (2030) Agenda and how to enable a sustainable digitalization" (del Río Castro et al. 2020). Within this context we explore the following questions:

1. To what extent is sustainable development addressed in AI research produced globally?
2. Which subject areas of AI show an emerging interest in sustainable development?
3. To what extent does AI stimulate collaboration between regions of the world?

We adopt a "bottom-up" approach by identify what is already happening to achieve both technological advancement and planetary health. We look at the publications on AI available through the Institute of Electrical and Electronics Engineers - IEEE Xplore. Investigating AI from this perspective may help formulate evidence-based public policies to foster the developments that are already taking place, better understand the disciplinary map that is being configured in the world of AI, and explore the extent to which the intellectual work of engineering researchers is considering the wider uses of their technologies and their impacts on the environment and society.

Methodology

This paper focuses on AI as an enabling technology (European Patent Office 2020) that will experience exceptional growth over the next years (Klavans, Boyack, & Murdick 2020). This specific field is also one of the subjects for which there will be sustained policy support (European Commission 2020).

There are different definitions of AI (see Nilson 2010; IEEE 2019). Given this plurality, we do not attempt a conceptual definition of it. However, we acknowledge that there are at least four domains of AI that cover the range of inventions and research on the subject. These are: acting like a human, thinking like a human, acting rationally, and thinking rationally (Russell, 2010, p. 5). This understanding of AI shows its complexity, which involves multiple definitions for a range of AI applications (i.e. thinking like humans could be related to algorithms and techniques for the development of chat bots, acting like humans the humanoid robots, and autonomous robots). Efforts to develop standard AI definitions in different technological niches and social domains can be seen in IEEE (2021a).

Despite the broad spectrum of areas covered by AI as a socio-technical phenomenon, part of AI research happens within disciplines in the Engineering domain, which has established authorities, ontologies, and classifications. Because of its usefulness to locate AI within the Engineering knowledge domain, in this work we consider AI from the IEEE thesaurus perspective, which is an authoritative source for different disciplines of Engineering, including AI (IEEE 2021a). We, then, identify AI papers as those classified within the field of Artificial Intelligence by the IEEE thesaurus (IEEE 2021a).

Sample

Table 1. Number of documents on AI per year

Publication year	Number of documents	Publication year	Number of documents
2020	27,783	2009	8,606
2019	39,269	2008	7,585
2018	25,800	2007	6,022

2010	8,852		

Our sample consists of papers developed in the Engineering sciences produced from 2000 to 2020 and indexed by the IEEE Xplore database with at least one of the subjects being Artificial Intelligence (AI) (IEEE 2021a). Our database choice has to do with the availability of fine-grained classification of papers within AI that this database provides, which is required to produce meaningful analysis for experts in the discipline. Other more general citation databases could offer better interdisciplinary coverage, but the subject classifications may belong to non-Engineering perspectives on AI. In total, we have acquired 220,147 records of research articles, reviews, proceedings, and books available in this database. Table

1 shows the number of documents gathered per year and Table 2 the number of documents by type of publication[1]:

Table 2. list of documents by type

Content-Type	Number of Documents
Conference proceeding	174,694
Journal papers	40,509
Magazine papers	2,959
Early access articles	1,291
Books	634
Standards	38
Courses	20

Data classification

Two types of classifications were fundamental to understand the relationship between sustainable development and AI in engineering. The first type is a subject classification, for which the IEEE Thesaurus was used. IEEE has also made available a taxonomy aimed explicitly at describing engineering subjects. The IEEE taxonomy is derived from the IEEE Thesaurus, which is a controlled vocabulary of 10,644 terms. The taxonomy provides a hierarchical classification that represents the relationship between terms. As expert committees develop the thesaurus and the taxonomy, they integrate expert knowledge and present data in a meaningful context to engineering research communities. Although this paper is about Artificial Intelligence, we used the whole IEEE Taxonomy with its 52 categories (see IEEE 2021b) because AI papers apply different engineering knowledge fields. For each paper, we identified its root term, first, second, and third levels according to the taxonomy.

The second classification is less standard because it is aimed at identifying papers that address sustainable development. Sustainable development is not a disciplinary field, but a domain of interest linked to a long-term policy agenda, with a clear direction towards a better balance between human existence and the environment, economy, and society (Chavarro et al. 2017). For this reason, there is no clear standard or agreement on what knowledge contributes to sustainable development. In principle, all knowledge could contribute to sustainable development if it is used to improve that balance. However, some knowledge shows this intent more explicitly, for instance, in a paper that attempts to build a clean alternative to energy production. In contrast, some knowledge may not contribute directly or may even hinder sustainable development, as in the case of knowledge to produce mass destruction weapons.

Even though the classification of papers according to their relationship to sustainable development remains a challenge (Armitage & Mikki 2020), two main approaches have been developed by researchers for this task. The first one is through keyword searches curated by experts in the field (Elsevier 2020). This approach offers textual identification of elements related to sustainable development, but not semantic identification of concepts. A second approach uses machine learning algorithms to classify papers based on their similarity to a set of papers classified by humans (OSDG 2021). This approach offers a conceptual identification of papers. Still, the models can become inaccurate because of ambiguity,

[1] The search was performed over all publication fields in the database, using "artificial intelligence". The data was obtained through the IEEE Xplore API using PhP.

different sizes of the categories, and the difficulty in understanding what the algorithms' criteria favor given the entered data.

As both models have pros and cons, we performed the two classification approaches. For the keyword classification, we used Elsevier's keywords, and for the machine learning approach, we used OSDG's (OSDG 2021), which is an initiative to provide a service for text classification into the categories of the sustainable development goals. OSDG approach uses Microsoft Academic Knowledge Project and other resources as a means for topic classification. In total, the keyword approach produced 44,563 papers compared to 84,309 produced by the machine learning approach. We examined the results of the two approaches and found that the keyword approach offered classifications more consistent with our understanding of sustainable development in a random set of 1,000 papers checked manually by the team for this dataset. For this reason, we use the keyword approach here and kept the machine learning approach for further research.

In addition to discipline subject and sustainable development, we classified the papers according to different geographical categories: countries, regions, and income groups. For this, the World Bank's classification of countries was used. As the IEEE database's countries are not normalized, it was necessary to identify and extract country names from the affiliations field. This was done in two ways: first, identifying mentions of country names and well-known cities in the author affiliations field. The remaining papers for which there was an affiliation field were identified by leveraging the first classification's knowledge base, querying full-text indices to return similar records to the ones already classified. This approach provided an accuracy of classification of 97% in a random sample of 1,000 records checked manually. 17,555 out of 220,147 articles did not have an affiliation field, or it was not possible to identify their countries.

Analysis

To explore AI documents with a potential contribution to sustainable development, we performed three analyses: The first one compares the number of documents by IEEE taxonomy categories and documents within those categories related to sustainable development. This intends to answer our first research question: *To what extent is sustainable development addressed in AI research produced globally?*

The second analysis responds to question 2, *Which subject areas of AI show an emerging interest in sustainable development?* It identifies those IEEE categories that are having a critical growth rate in three aspects: the number of documents produced, citation impact, and inventive impact. Citation impact is the sum of the number of citations received by the category from other bibliographic outputs, and inventive impact is the sum of citations of the category from patents. The indicators are defined as:

$$1)\ \text{Publications} = \ CAGR_{Publications} = \left(\frac{P2019}{P2000}\right)^{\left(\frac{1}{2019-2000}\right)} - 1 * 100$$

$$2)\ \text{Citation impact} = \ CAGR_{Citations} = \left(\frac{C2017}{C2000}\right)^{\left(\frac{1}{2017-2000}\right)} - 1 * 100$$

$$3)\ \text{Inventive impact} = \ Citations\ Pat\ per\ document = \frac{CP_{Total}}{P_{total}}$$

Where CAGR = Compound Aggregate Growth Rate; Publications = is number of documents; Citations = number of citations from bibliographic outputs; and Citations Pat = citations from patents.

Concerning the citation impact indicator, we take as the most recent year 2017 because citations are delayed accumulating and may show a decrease that is not accurate. For patent citations, we provide the patent citations per document, as this indicator does not behave linearly and thus does not allow us to forecast the linear trend expected by CAGR.

Additionally, we calculated a composite indicator based on the average ranking of the three variables. A comparison between sustainable development-related production and other production is offered.

In addition to the previous analyses, we performed a third analysis to address the research question *To what extent does AI stimulate collaboration between regions of the world?* Given that there is competition among nations for leadership in this field (Mou 2019), it can be expected that cross-regional collaboration is minimum, as well as collaboration between countries classified in different income groups. We also offer a comparison between economic regions in terms of the World Bank's income categories. The indicators for performing these comparisons rely on counting papers once for each author/region. It produces the same number of total papers if there is no collaboration (authors of the papers belong to the same region). Otherwise, the number could be greater than the number of papers, given that collaboration from two authors of different regions could count as 1 for each region. The indicators are as follows:

1) Rate of interregional collaboration = Sum of documents produced by region / total documents
2) Rate of cross-income collaboration = Sum of documents produced by income category/total of documents

Finally, we performed a social network analysis of countries to identify the most central nodes through co-authorships. The literature on research collaboration at the country level is consistent in the finding that a few countries concentrate a huge amount of power in the networks, while many others stay at the periphery of collaboration (Kwiek 2020; King 2011; Wagner 2008). This gives those central countries the power to control knowledge flows and the rules of collaboration (Olechnicka et al. 2019). We explored the collaboration structure of AI papers related to SD by analyzing their betweenness centrality, which is a measure based on the number of shortest paths that cross through the nodes of the network.

Results

Consideration of sustainable development in AI research

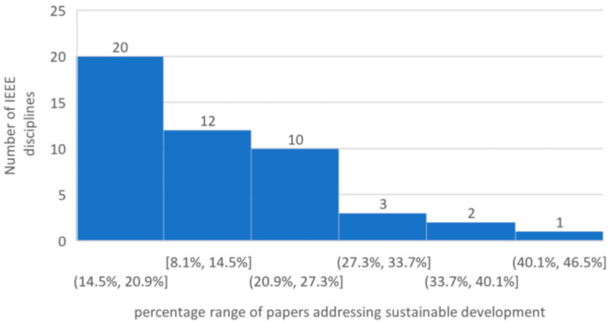

Figure 1. Distribution of the number of disciplines by the percentage of documents addressing sustainable development.

Source: Authors' elaboration based on IEEE Xplore and taxonomy

Figure 1 shows the number of documents by IEEE taxonomy category and the percentage of publications that address sustainable development. In total, 197,384 documents had an IEEE taxonomy classification. Of these, 44,563 papers were classified as sustainable development, which means that approximately 23% of papers in our dataset addressed sustainable development, based on our keyword identification. Figure 1 shows a Pareto distribution of these categories. Most of the disciplines address sustainable development between 14% and 27%. Only five disciplines address sustainable development in more than 27% of their papers, with only one reaching the limit of 40%. This hints that sustainable development is a subject highly concentrated in specific domains of AI.

IEEE subjects with an emerging interest in sustainable development.

The indicators for total AI documents, AI documents related to sustainable development, and AI documents not classified as sustainable development are in Table 3. The calculations include production CAGR, scientific impact CAGR (based on citations from bibliographic outputs), and invention impact (based on patents), as outlined in the methodology. In general, we find that sustainable development documents supersede other AI documents in production growth and scientific impact. This shows that papers in AI are increasingly addressing sustainable development subjects and that the citation rate to articles addressing sustainable development is increasing above-average citation growth. However, sustainable development documents perform below average on inventive impact as measured by patent citations per document.

Table 3. Production, scientific impact, and inventive impact indicators for AI papers for the analyzed database.

	Production (CAGR)	Scientific Impact (CAGR)	Inventive impact (patent cites per doc)
All docs	15%	7%	0.15
SD docs	22%	14%	0.11
Non-SD docs	14%	7%	0.16

Note: All docs refer to the totality of AI documents; SD docs point to AI documents related to sustainable development; Non-SD docs relate to AI documents not classified as related to sustainable development.
Source: own calculations based on IEEE Xplore and taxonomy

Table 4. Top 5 emerging subjects addressing sustainable development in AI papers

IEEE subject	CAGR Prod %	CAGR Cit. %	Pat ind.	Rank Prod.	Rank Cit.	Rank Pat	Avg rank
Broadcast technology	34.3	44.1	0.007	2	5	17	8
Systems engineering and theory	33.9	29.7	0.019	3	17	6	8.67
Ultrasonics, ferroelectrics, and frequency control	33.8	51.5	0.004	4	2	22	9.33
Sensors	32.0	36.8	0.010	9	9	12	10
Education	41.5	64.0	0.000	1	1	33	11.67

Note: CAGR stands for Cumulative Aggregate Growth Rate. Prod stands for documents, Cit. stands for the sum of citations, Pat ind refers to patent citations per paper. Rankings with lower values must be understood as being at the top of the list. Each ranking refers to the ordering of the values of CAGR and Pat ind. The average ranking is the mean of the three rankings in the columns.

The above indicators allowed us to derive a ranking of emerging areas in AI and sustainable development. The ranking was calculated as the average of the rankings in the three above indicators for each IEEE subject area. It identifies the subjects that show a more pronounced growth in the number of documents and citations in bibliographic outputs, and a higher score in patent cites per document. Table 4 shows the top 5 subjects.

Table 5 shows the correlation coefficients between the three rankings above. The correlations show that production growth is moderately and positively associated with scientific impact as measured by citation growth. However, inventive impact as measured by patent citations per document is weakly related to production and scientific impact. This means that even if sustainable development papers increase their production and citation growth, this does not necessarily indicate that sustainable development-related knowledge will make its way into the development of technologies.

Table 5. Correlation coefficients between the ranking of production, the ranking of scientific impact, and the ranking of inventive impact.

	Production Ranking	Scientific impact ranking	Inventive impact ranking
Production Ranking	1	0.6	0.3
Scientific impact ranking		1	0.1
Inventive impact ranking			1

Collaboration in AI papers related to sustainability between regions, income groups, and countries.

Production of AI papers indexed in IEEE Xplore is highly concentrated in high-income countries from the East Asia & Pacific, Europe & Central Asia, and North America regions. Tables 6 and 7 show the distribution of papers by region and income group.

Table 6. Number of AI documents by region

Region	Docs	Docs - SD	Docs - non-SD
East Asia & Pacific	100,692	18,694	81,998
Europe & Central Asia	56,188	11,771	44,417
North America	47,738	9,990	37,748
South Asia	16,469	4,808	11,661
Middle East & North Africa	10,191	2,587	7,604
Latin America & Caribbean	7,339	1,687	5,652
Sub-Saharan Africa	1,481	461	1,020

Note: Docs refers to the total number of AI documents; Docs – SD relates to the number of documents related to sustainable development; Docs – non-SD relates to the number of documents not identified as related to sustainable development.

Table 7. Number of AI documents by income group

Income group	Docs	Docs – SD	Docs - non-SD
High income	119,397	24,263	95,134
Upper middle income	95,163	18,355	76,808
Lower middle income	21,173	6,077	15,096
Low income	203	64	139

Note: Docs refers to the total number of AI documents; Docs – SD refers to the number of documents related to sustainable development; Docs – non-SD refers to the number of documents not identified as related to sustainable development.

In general, inter-regional collaboration in AI papers between countries is low. The ratio between the total number of papers and co-authorships between regions is 1.18. Papers related to sustainable development have a lower ratio of 1.12. Papers not identified as related to sustainable development have a ratio of 1.18. This means that most papers involve only collaboration within their region.

In terms of income group, the data shows similar patterns. The ratio between the total number of papers with a country of affiliation identified and co-authorships between income groups is 1.16. Papers related to sustainable development and papers not related to sustainable development have the same ratio. As in the regional case, this means that most papers involve only collaboration within their income group.

Figure 2 shows the social network graph of country co-authorships for SD-related papers. Node size and color intensity indicate the betweenness centrality of countries, and link thickness represents the number of co-authorships between countries. The top 10 percentile by betweenness centrality is composed, in descending order, by the United States, France, China, United Kingdom, India, Spain, Japan, Austria, Saudi Arabia, Germany, Malaysia, Australia, Portugal, Croatia, and Russia. Of these fifteen countries, eleven are high-income countries, three are upper-middle income, and one (India) is classified as a low-income country. Although the top 10 percentile is dominated by high-income countries, the general correlation between betweenness centrality and income group is only 0.21, which shows that there is a diversity of countries that revolve around the most central ones. The social network analysis partly confirms the concentration of power in a few countries pointed out by the literature on collaboration and shows the emergence of new powers in SD-related AI research.

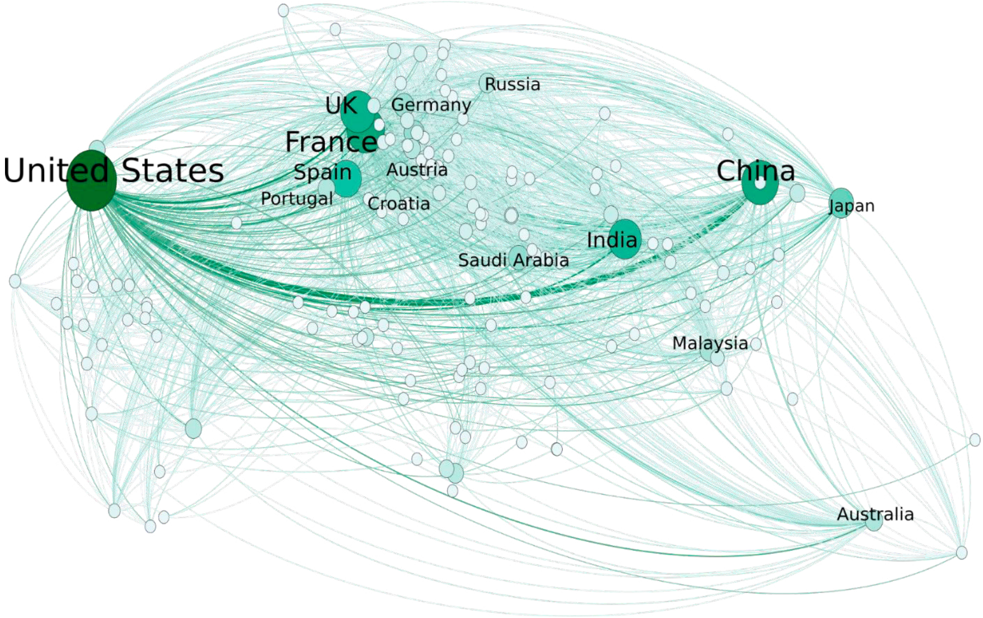

Figure 2. Co-authorship network of countries*

* Nodes positions attempt to preserve the location of countries in the Mercator projection of the world map. Size and color indicate betweenness centrality; only countries in the top 10 percentile by betweenness centrality shown for visualization.

Discussion and conclusion

In this research we addressed the questions: 1) To what extent is sustainable development addressed in AI research produced globally? 2) Which subject areas of AI show an emerging interest in sustainable development? And 3) To what extent does AI stimulate collaboration between regions of the world?

We found that AI papers address sustainable development to a small extent. In most subjects, the percentage of papers addressing sustainable development ranges between 8% and 30%. The most related subjects are P*ower engineering and energy, Geoscience and remote sensing*, *Engineering management*, and *Engineering in medicine and biology.* Even in these subjects we only found between 30% and 40% of papers related to SD. The small number of explicit references to SD in AI papers indicates that discussions on the use of AI for grand challenges such as poverty reduction, inequality, peace, among others, are not central to the engineering AI literature. Motivating engineers to break their silos and explicitly reflect on the connection between their technologies and society will help increase the value of AI research beyond technical progress and efficiency gains.

Global AI research policies could build on our finding that SD is an emerging concern for engineering researchers in certain subjects such as *Broadcast technology*, *Systems engineering and theory*, *Ultrasonics, ferroelectrics, and frequency control*, *Sensors,* and *Education.* Understanding in which ways AI is being linked to SD by engineers in these and other fields could help to design strategies to make AI more relevant for grand societal challenges. Engineering education is one key field in which interdisciplinary research about sustainable development could have a profound impact, given the cross-cutting nature of education to the development of all engineering fields.

In terms of collaboration, our findings show that inter-regional and inter-income group collaboration is not very frequent. The data shows that 1 in 7 papers will produce an inter-regional or inter-income group collaboration. This pattern may be a reproduction in research of the competitive environment for leading technological development, as pointed out by the literature (Mou 2019; Sørensen et al. 2016). We also see an enormous concentration of research capacity in East Asia & Pacific, Europe & Central Asia, and North America. This shows a gap in knowledge production that confirms the technological and knowledge dependence of certain regions and reinforces the global division between centers and peripheries (Kshetri 2020). We see that this competitive and monopolistic environment is likely to produce an even greater gap between technologically advanced countries and the rest, which goes in contradiction to the stated goals of global AI policies and SD.

Based on our experience in policymaking in an upper middle-income country, we know that the technological gap will not be closed if countries at the periphery continue to be seen as mere buyers of technology and their governments continue to accept this role. Changing this mindset requires a committed public investment in R&D to create and improve local capacity to the extent that a country can be a producer and not only a consumer of AI. While being a producer will provide an opportunity to define more relevant research agendas related to the specific needs of countries and regions, being a consumer will continue to increase subordination (Dussel 2018). India and China have shown that a clear commitment to the development of local research capacity in AI is beneficial in the long term. However, individual countries cannot by themselves change the global landscape, because even if they started investing in R&D, local capacity takes time to build. If global AI policies are to support SD, and SD is a global agenda, then there should be a global commitment to build AI capacity in those countries that remain peripheral, instead of concentrating power and capacity on a few ones. This requires a change towards a more generous attitude in international relationships that is not supported by the current climate of competition between countries such as the USA, Russia, and China, and by the current rate of natural resources extraction.

The above findings are not only relevant for research policy, but also SD as a societal goal. Increasing awareness of researchers about SD and their motivation to produce socially relevant research, as well as increasing the capacity to produce such research is determining for solving some of the grand challenges of the world. More aware and motivated researchers will understand the need to collaborate with stakeholders beyond academia to produce technologies that matter for their societies, while developing new technical and social skills that will build the capacity of countries to determine and pursue their own research agendas. This is aligned with the stated aims of multilateral organizations such as the OECD and the

European Union, as well as institutions such as the IEEE, which have expressed a determined intention to produce AI research for the benefit of the economy, the environment, and society. They have produced formal statements to support this orientation of AI to pave the way to that goal. Our results offer an empirical basis for these organizations and for countries to connect AI engineering research with society. Sustainable development provides a framework to achieve this connection, which can be compared to what Jane Goodall calls a connection between our brain -committed to advancing the frontier of science- and our heart, that connects scientific advancement to the well-being of the planet.

Future research

This is an exploratory analysis that opens different avenues of research, for instance in deepening our analysis on collaboration, interdisciplinarity, and emerging subjects. Further research should also investigate the social, economic, and environmental contextual dimensions of the countries that produce AI research. On the technical side, our research can be enhanced by extending the analysis of AI through different classification standards beyond IEEE and including discussions of Artificial Intelligence interpretations as discipline and as a research field.

Acknowledgments

This work was supported by the Ministry of Science, Technology, and Innovation of Colombia (Minciencias) under Grant 848-2019 and the Colombian Society of Engineering Physics (SCIF), Colombia. We thank the IEEE for offering their open API, OSDGs for their web service to classify papers through machine learning, especially to Gusté Statulevičiūtė and Lukas Pukelis from PPMI. We also thank the Free and Open-source software community: MariaDB, R, Gephi, and Notepad++ teams for making available their software. Special thanks to an anonymous reviewer and to Professor Wolfgang Glänzel for their excellent suggestions.

Abstract

Research contributions are the most valuable information which can help researchers understand the main content of academic literature. However, existing research mainly focuses on citation analysis, rhetorical structure analysis, essential sentence extraction, and little attention is paid to the research contributions stated in the full text. This paper first introduces a fine-grained annotation scheme with nine categories for research contributions in academic literature. To evaluate the reliability of our annotation scheme, we conduct the human annotation on 3,104 sentences collected from 3,293 articles in ACL Anthology and achieve an inter-annotator agreement of 0.89 regarding the Kappa measurement. We analyze the research contributions in different types and years, showing that new methods, new models, and new theories are the most welcomed research contributions of the ACL conference. In the meanwhile, the percentage of different contributions is stable over the years. The research contribution dataset developed in this paper provides the basis for the automatic research contributions extraction and knowledge fragment recommendation. The fine-grained annotation scheme can be applied for large-scale analysis for research contributions in academic literature.

Introduction

Academic literature records the research process with a standardized structure and provides clues to track the progress in a scientific field (Fisas et al., 2016). Generally, the main components of academic literature include an abstract, introduction, related work, method, experiment and result, conclusion (Lu et al., 2018). In recent years, academic text mining using content from different components has received increasing attention from researchers. However, most of the existing research focuses on keyphrase extraction (Park & Caragea, 2020), citation content analysis (Fisas et al., 2016), rhetorical structure analysis (Sateli & Witte, 2015), essential sentence extraction (Mehta et al., 2018), and little attention is paid to the research contributions stated in the full text. Research contributions, known as the most valuable information, are required to be highlighted in the introduction when a paper is published. A research contribution relates to the research problem addressed by the contribution, the research method, and (at least one) research result (Oelen et al., 2019). For example, 'we build a transfer learning framework employing a diverse range of intermediate tasks covering sequence tagging with semantic and syntactic aspects, and natural language inference' and 'we achieve competitive performance over both strong baselines and previous works' are two contributions stated in Park & Caragea (2020). Research contributions can help researchers understand the core content of a paper and the innovation growth of science.

We can easily identify sentences about research contributions from the introduction section by following the statements like 'Our contributions are summarized as follows', 'The major contributions of this paper are', or similar statements. There are different types of contributions, for example, creating datasets, building new models, performing evaluations, etc. If these contributions can be classified appropriately, it would be helpful for knowledge recommendation, structured abstract generation, scientific evolution analysis. However, an annotation scheme for research contributions is one of the essential requirements for research contribution classification.

We studied the existing annotation schemes regarding academic literature. We noted that most of them mainly focus on context types (Angrosh et al., 2012), citation functions (Teufel et al., 2006), term functions (Li et al., 2017), and future work types (Hao et al., 2020). There is no annotation scheme for research contributions. To bridge this gap, we propose a fine-grained annotation scheme with nine categories for research contributions in academic literature. The human annotation experiment conducted on 3,104 sentences collected from 3,293 articles in ACL Anthology demonstrates the reliability of our scheme. The final annotated research contribution corpus is available for download at: https://zenodo.org/record/4483757#.YBbnw-j0mbg.

The contributions of our paper are as follows:

- We propose a fine-grained annotation scheme for research contributions in academic literature.
- We conduct the human annotation to evaluate the reliability of our scheme.
- The corpus developed in our paper provides basic training data for automatic research contributions classification.

Related Works

This paper proposes an annotation scheme for research contributions in academic literature. Therefore, the related works include research contributions analysis and annotation schemes constructed for academic literature.

Research Contributions Analysis

Research contributions analysis is a new topic, which was paid attention to recently. The Open Research Knowledge Graph (ORKG) constructed a contribution knowledge graph where each paper was summarized with its fundamental contribution properties and values (Auer et al., 2018). In ORKG, the contributions were interconnected via the graph, even across papers. It helps users to compare research contributions between different papers while writing an academic literature review (Oelen et al., 2019). Similarly, Vogt et al. (2020) represented research contributions in scholarly knowledge graphs using knowledge graph cells. Compared to ORKG (Auer et al., 2018), the Research Contribution Model (RCM) can generate a KG whose content is better and maintainable and easier understandable (Vogt et al., 2020). The ontology built by Vogt et al. (2020) provided a reference for defining the annotation categories in our study. However, it identified contributions from abstracts rather than full texts. D'Souza &Auer (2020) developed an annotation scheme to identify research contributions from NLP literature with the structure of <subject, predicate, object>. More recently, Le et al. (2019) applied research contributions identified from citing papers for evaluating the academic value of cited papers. Zhou et al. (2020) extracted academic innovation and contributions from full texts in the field of chrysanthemums using BERT. Although existing research has made certain progress in research contributions identification and representation, an annotation scheme is still needed for fine-grained analysis of research contributions.

Annotation Schemes for Academic Literature

Several annotation schemes have been proposed for academic literature. The annotation schemes are either designed for full texts or citation sentences only. Regarding full texts level, Hao et al. (2020) proposed an annotation scheme that included six main categories and 17 sub-categories for future work sentences. D'Souza &Auer (2020) described ten core information units for organizing academic contributions data in a knowledge graph, including ResearchProblem, Approach, Objective, ExperimentalSetup, Results, Tasks, Experiments, AblationAnalysis, Baselines, and Code. As for the citation sentence level, Teufel et al. (2006) proposed an annotation scheme with four categories and 12 fine-grained categories for citation function. The annotation experiment was performed on 320 conference articles and the agreement calculated with Kappa was used to measure the reliability. Differently, Angrosh et al. (2012) presented a citation-centric annotation scheme for academic literature. It included six categories for citation sentences and five categories for non-citation sentences. A pilot study was carried out using 11 annotators and nine articles. Agreement calculated with Krippendorff's Alpha was used to measure the reliability. The above research provides us insight into how to construct a fine-grained annotation scheme for research contribution sentences and evaluate the reliability of our scheme.

Annotation Scheme for Research Contribution

With the increasing of submissions, it is more and more challenging for reviewers to review a manuscript. On the other hand, users might spend much time reading but hardly figuring out valuable information from the paper. Therefore, highlighting the main contributions when submitting a manuscript becoming a requirement for many conferences and journals. A research contribution can be reflected from different aspects, such as creating a new dataset, proposing a new theory or framework, designing a new model, etc. Studies have discussed the fundamental concepts of academic literature, which are essential for identifying the type of research contributions. Q. Zadeh & Handschuh (2014) defined seven core conceptual classes for Computational Linguistics publications: Technology and Method; Tool and Library; Language Resource; Language Resource Product; Models; Measures and Measurements; and Other. D'Souza & Auer (2020) defined ten core concepts for research contributions for NLP publications: Research Problem, Approach, Objective, Experimental Setup, Results, Tasks, Experiments, Ablation Analysis, Baselines, and Code. The annotation scheme proposed for future work sentences in Hao et al. (2020) included six categories and 17 sub-categories: Method (Model, Algorithm, Feature, Other), Resources (Optimize resources, Expand resources, Change resource type, Other), Evaluation (Evaluate current work, improve evaluation means, expand evaluation areas, Other), Application (Applied for other tasks, Expand application areas), Problem, Other.

Our scheme (shown in Table 1) is a combination of the scheme in Hao et al. (2020), D'Souza & Auer (2020), and Q. Zadeh & Handschuh (2014), which we finalize after an analysis of a corpus of academic literature in computational linguistics. We try to redefine the categories to be adapted for research contributions and reasonably reliably annotatable. Our categories are as follows: one category is Dataset Creation. In the computational linguistics field, creating a new dataset is a common research contribution (Fisas et al., 2016; Hao et al.,2020) because other researchers for similar studies can reuse the new dataset. The second category is Theory Proposal. As we know, science is knowledge represented as a collection of "theories" derived using the scientific method (Somekh & Lewin, 2005). Theories provide explanations of natural or social behavior, event, or phenomenon (Somekh & Lewin, 2005). Proposing a theory is considered one of the essential contributions of academic research. The next four categories are Model Construction, Model Optimization, New Algorithm or Method or Technology, and Algorithm or Method or Technology Optimization. Different from the annotation scheme in Hao et al. (2020), we separate the Method and Model since they are different concepts, especially in computational linguistics, according to Q. Zadeh & Handschuh (2014). Methods, algorithms, and technologies are designed, developed, and employed to accomplish a specific task to fulfill a practical purpose. Simultaneously, models represent what is learned by an algorithm based on the data (Q. Zadeh & Handschuh, 2014). Both models and methods can be constructed from scratch or optimized based on the existing models and methods. Therefore, we distinguish research contributions from model construction, model optimization, method construction, and method optimization. As for the last three categories, including Performance Evaluation, Resources, and Application, we reuse and adapt from Hao et al. (2020).

Table 1. Our annotation scheme for research contributions.

Category	*Description*	*Example*
Dataset Creation	Build a new dataset	We propose to build multi-task datasets for the News and Tweets do-mains, by unifying the a forementioned task-independent datasets.
Theory Proposal	Propose a new theory to solve existing problems or for improvisations	We suggest viewing learning event embedding as a multi-relational problem, which allows us to capture different aspects of event pairs.
Model construction	Construct a model	We propose to generate comments with a graph-to-sequence model that models the input news as a topic interaction graph.
Model Optimization	Propose strategies to increase the efficiency of existing model	We propose an approach to improving the robustness of NMT models, which consists of two parts: (1) attack the translation model with xxx; (2) defend the translation model with xxx.
New Algorithm or Method or Technology	Develop a new method or algorithm or technology	We present a new method for sentiment lexicon induction that is designed to be applicable to the entire range of typological diversity of the world's languages.
Algorithm or Method or Technology Optimization	Optimize the existing method or algorithm or technology	Our submission combined techniques including utilization of a synthetic corpus, domain adaptation, and a placeholder mechanism, which significantly improved over the previous baseline.
Performance Evaluation	Evaluate the performance of the new or existing implementation	We evaluate a broad variety of neural models on the new dataset, establishing strong baselines that surpass previous feature-based models in three tasks.
Resources	Expand/change the types of resources	We provide a resource to be distributed for research purposes in the BioNLP community.
Applications	Apply the proposed model or theory to other tasks	Our model can also be applied to the cross-domain named entity recognition task, and it achieves better adaptation performance than other existing baselines.

Data

The data we use comes from ACL Anthology (https://www.aclweb.org/anthology/venues/acl/). We collect 3,293 articles from the proceedings of the Annual Meeting of the Association for Computational Linguistics, out of which 674 are from 2018, 1393 are from 2019, and 1226 are from 2020. The articles are in pdf format. We manually identify the sentences which indicate the research contributions. Specifically, we conduct a pre-investigation of the original corpus to summarize the patterns of research contribution sentences, then formulate the labeling specifications. For explicit research contribution sentences, we can easily identify by following the contribution block indicators, for example, 'Our contributions are summarized as follows', 'The major contributions of this paper are', or similar statements. As for implicit contribution sentences, we find that their locations in the paper are usually the last paragraph or the second last paragraph in the introduction section. We then figure out several verbs or verb phrases that indicate the research contributions, such as the present, introduce, compare, design, apply, develop, etc. By following the above strategy, we collect 3,104 research contribution sentences in total.

Annotation Experiment and Results

To evaluate the reliability of the research contribution annotation scheme discussed before and create a dataset for automatic research contribution classification, we conduct the annotation experiment with six annotators who are designers of the scheme and very familiar with the annotation guideline. They also have a background in NLP and machine learning, which can ensure annotation quality.

Annotation Results

The six students are divided into pairs for the annotation; in other words, each sentence will be annotated by two annotators. During the annotation, the annotators independently annotated the same number of sentences with the proposed scheme. We measure the agreement in Kappa, which ranges between -1 and 1. Generally, Kappa's of 0.8 is considered stable, and Kappa's of 0.69 as marginally stable (Carletta, 1996). We reached an inter-annotator agreement of K = 0.89. We consider the agreement quite good, considering the number of categories. For sentences that are annotated with different categories by the two annotators, a third annotator will perform the annotation, and a majority vote will be used to decide the final category.

Statistical Analysis of the Annotated Dataset

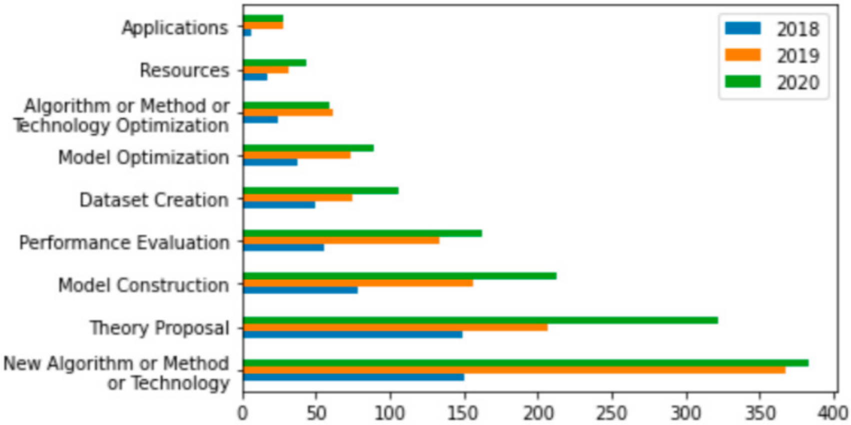

Figure 1: The distribution of research contributions in each category over years

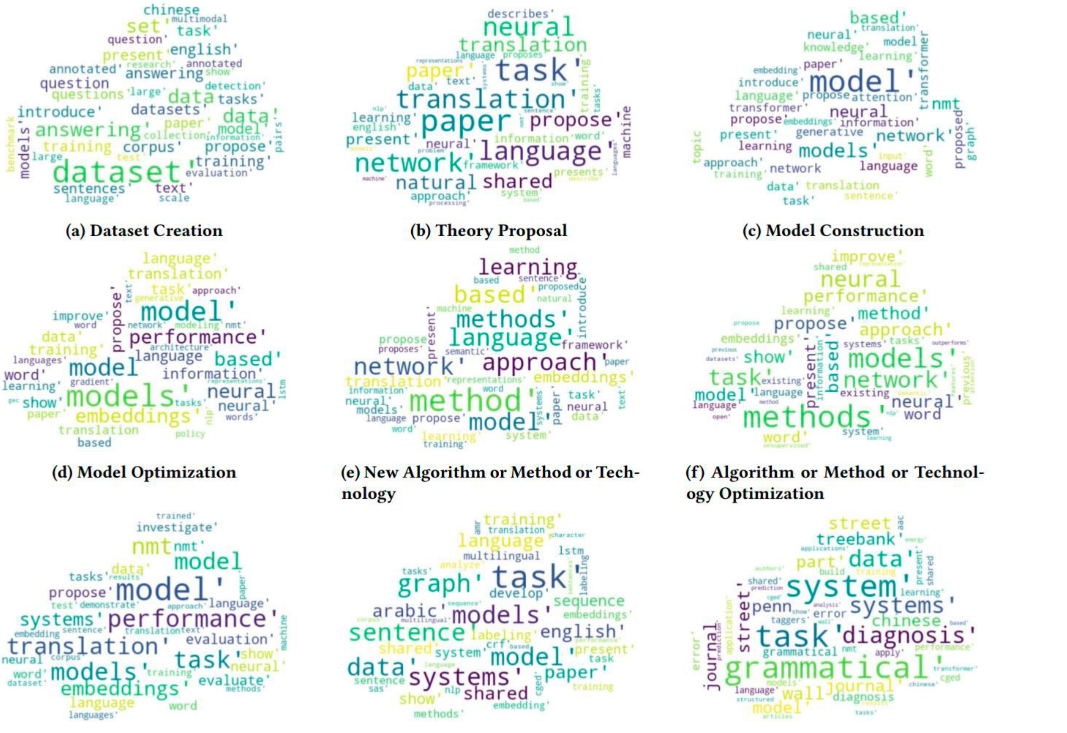
The relative frequency of each category for each year observed in the annotation results is shown in Figure 1. The distribution is very skewed, with 27.1% of the research contributions of the category New Algorithm or Method or Technology. Interestingly, the relatively high frequency of the New Algorithm or Method or Technology, Theory Proposal, Model Construction, Performance Evaluation categories with 76.6% in total. As we have known, the four categories are more substantial contributions than the rest five categories in computational linguistics—this concordance with the current research directions and concentrations on high-quality computer science conferences (https://mohammadkhalifa.github.io/2020/07/30/ACL2020-highlights.html). With the dramatic increase of submissions, top conferences require submissions to demonstrate stronger contributions for being accepted. As for the distribution of research contributions over the years, we find similar patterns.

Keyword Analysis on Each Category

We analyze the content of all research contribution sentences using YAKE! (Campos et al., 2020), to extract the keywords. YAKE! is the state-of-the-art tool for keyword extraction. It defines a set of features (casing, position, frequency, relatedness to context, and dispersion of a specific term), capturing keyword characteristics that are heuristically combined to assign a single score to every keyword (Campos et al., 2020). We extract the top 40 keywords (as listed in Figure 2) for the contribution sentences in each category and the keywords are limited to two grams.



(a) Dataset Creation

(b) Theory Proposal

(c) Model Construction

(d) Model Optimization

(e) New Algorithm or Method or Technology

(f) Algorithm or Method or Technology Optimization

(g) Performance Evaluation

(h) Resources

(i) Applications

Figure 2: The word cloud of the research contribution sentences in each category (top 40 keywords)

As shown in Figure 2, the keyword distribution reflects the most important contributions in each category and the verbs used to present the research contributions in each category. For example, in the category Dataset Creation, it is obvious that the keywords "data", "dataset", "corpus", "xxx dataset" are at the top of the list. Verbs such as "present" and "introduce" are frequently used to introduce a new dataset. Similarly, in the Model Construction and Model Optimization categories, keywords such as "model", "neural network model", "language model" are prevalent. However, the keyword "improve" appears in the Model Optimization category but does not appear in the Model Construction because "improve" indicates that academic literature contributes by optimizing previous models rather than introduce a new model. A more detailed study of the keywords may be helpful for automatic research contribution classification in the future.

Summary and Future Work

In this paper, we have described a fine-grained annotation scheme for research contribution in academic literature. Our annotation scheme concentrates on identifying different types of research contributions, which can help researchers understand the core content of a paper and the innovation growth of science. We report positive results in terms of the inter-annotator agreement in the annotation experiment. In addition, we conduct statistical analysis and keywords analysis on the constructed research contribution corpus.

We are currently investigating how well our scheme will work on academic literature from a different discipline, namely chemistry. Based on the investigation results, we would be able to optimize the categories so that the annotation scheme can be more widely used. Work on applying semi-automatic approaches to argument the amount of labeled data for automatic research contribution classification is another concentration. Besides, it would be interesting to compare the distribution of research contributions in each category in different fields.

Acknowledgement

The authors would like to thank Aakansha Tallapally, Durga Bhavana Yerrabelli, Nikitha Malladi, and Riyaz Ahmad Shaik for participating the annotation experiment.

Abstract

Prior research agrees that the success of digital products depends on their radical and incremental innovation. Despite the existence of various innovation measures in the literature, it is unclear how to measure the innovation output of digital products. This paper applies content analysis and text mining methods to analyze 39,153 update documents of mobile apps and estimate their radical and incremental innovation. Bidirectional Encoder Representations from Transformers (BERT) was adopted to classify the innovation output into nine categories (e.g. functional, business, and visual updates) based on comparing the classification performance of various models. According to the radical and incremental innovation level, the apps updates can be clustered into four levels, ranging from low to high. Shopping, travel, and finance apps rank highly on the radical innovation level, and the three categories share a similar innovation pattern. In contrast, game apps implement the strategy of radical innovation in their updates. This paper contributes to extending text analysis to measure the innovation output of mobile apps.

Introduction

In recent years, digital products have played a dominant role in economic development. Millions of entrepreneurs have engaged in developing mobile apps and providing digital services via their products. The rapid development of mobile commerce has brought the mobile apps market into a prosperous era. According to Statista's report, Google Play has 2.87 million apps and the Apple App Store released 1.96 million apps in the third quarter of 2020. On the one hand, the mobile phone is continuing to grow, and coverage of all netizens has basically been achieved. The huge scale of mobile phone netizens provides a solid foundation for various apps to open up the market. On the other hand, smart technology development and the widening of 5G apps have enabled a wider range of scenarios for mobile apps and have spawned more subdivided vertical categories of mobile application products.

Although mobile apps have broad prospects, their market is no longer “a blue ocean.” The Matthew effect can be observed in the fierce competition of mobile apps. In other words, those apps which have first mover advantage accumulate more advantages over time, while those which begin with a disadvantage have a lower and lower probability of succeeding (George & Ferraro, 2016). At present, mobile apps with a high degree of interest are mostly divided among Internet giants, especially Facebook, Google, and Apple. Thus, the essential question for developers is how to gain a competitive advantage in the fiercely competitive market.

One critical solution is innovation, which enables mobile apps to acquire new users or maintain survival. On the one hand, innovation can open new markets for apps and give the apps irreplaceable competitiveness (Zhou, Song, & Wang, 2018). On the other hand, innovation requires the app to quickly respond to the refinement and changes in user needs (Comino, Manenti, & Mariuzzo, 2019). Generally, innovation includes implementing a new or improved product or process that differs significantly from the unit's previous products or processes (OECD & Eurostat, 2018) and commercialization of innovation (Boer & During, 2001; Dewangan & Godse, 2014). Edison et al. (2013) proposed that innovation is divided into four categories: product innovation, process innovation, market innovation and organization innovation. Specifically, product innovation involves creation and introduction of new (technological new or significantly improved) products (Geiger & Cashen, 2002; OECD & Eurostat, 2018), which mainly refers to creating processes from scratch.

However, there is a huge difference between digital product, e.g., mobile apps, and physical products. Apps continuously evolve through updates during their life cycle (Zhou, Song, & Wang, 2018). Most apps gradually gain user recognition and competitive advantages through continuous innovation iterations. Some popular apps see updates as frequently as weekly; others release once or twice per month. Thus, the innovation of an app is not only a process from 0 to 1, but more importantly, a process from 1 to infinity (Nelson, 2009). Knowing how innovative the app is, is critical in achieving a competitive advantage in the market.

This study aims to propose a method to measure the innovation output of mobile apps in third-party mobile apps stores. Specifically, update documents of mobile apps serve as a unique data source to measure the innovation. The update document is the demonstration that depicts the revised activities that the developers have created in the new version of the apps. For example, the developers are required to list "What's New" for app updates in the Apple App Store and Google Play. Analyzing these update documents helps to identify the innovation output of the apps.

To accomplish this, we first divided app innovations into radical and incremental innovations based on innovation theory and developed a classification system. Next, we developed content analysis and machine learning methods in sequence to identify each update point from the update document and accordingly obtained the scores of each app in the dimensions of radical innovation and incremental updates. Moreover, clustering and other methods were utilized to analyze the measurement results in-depth.

Theoretical Underpinnings

Innovation of apps

An update (or upgrade) is the behavior whereby software replaces an installed version of a product with a newer version of the same product (Min Khoo & Robey, 2007). A newly updated version may include many new features or a revised appearance. For instance, the 10.2.3 version of Alipay includes two update points, namely optimizing the scan function and adding a "traffic" entry on the homepage. In this study, every update point is regarded as one output of innovation of the app. Previous explorations into the update of apps have been mainly based on three dimensions: degree of the update, update frequency, and update type.

Considering the degree of innovation, Christensen (1989) took the lead in defining disruptive technological innovation and incremental technological innovation. Incremental innovation, also named continuous innovation, means that this type of technology enables products or services to improve existing performance in accordance with those aspects that most users in major markets have always valued (Christensen, 2013). Correspondingly, disruptive innovation or radical innovation refers to radically new products that involve dramatic leaps in terms of customer familiarity and use (Christensen, 2013; Veryzer Jr, 1998). There is a consensus among scholars that both types of innovation have a significant impact on the market performance of new products. Incremental innovation can quickly respond to the refinement and changes of user needs, and maintain its unique differences among competitors (De Brentani, 2001), whereas, radical innovation is likely to bring major competitiveness and open up emerging markets (Hang, Neo, & Chai, 2006).

Apps are iteratively updated products, and the concept of radical innovation is not fully applicable to them. Nevertheless, adding a new business function to the front end of the app through the homogenization and re-programmability of digital technologies can introduce a new category of product or service, which is, to some extent, equal to the introduction of new stand-alone products due to changes in the core components. Based on this view, Tian et al. (2020) defined updates that add new features or functionalities to an existing app as app innovation and updates that improve existing supporting functions as incremental updates.

Many previous studies have proven that frequent updates make for better market applicability. Marvin et al. (2016) conducted a study on the update frequency and unveiled that the identified positive effect on frequent updates can be elicited only with functional feature updates and not with technical non-feature updates. In other words, the type of update has a moderating effect on the positive impact of update frequency (Fleischmann et al., 2016).

The classification of app update types is quite diversified, and there is no unified classification system yet. By manually analyzing the texts in the "What's New" section, Stuart Mellroy and his partners labelled 852 different updates in five categories: new content, new feature, improvement, bugfix, and permission changes (McIlroy, Ali, & Hassan, 2016). Furthermore, changes in the mobile platform will lead to a new type of update to the apps (Soh & Grover, 2020), which provides better compatibility with the platform. Actually, app updates are not limited to product innovation. The innovation of business strategies is also a critical means for many apps to optimize marketing performance (especially for e-commerce apps); hence commercial updates have been involved in the classification system by some researchers as well (Tian et al., 2020).

Metrics for app innovation

Metrics for innovation have become a hotspot in the field of innovation research (Dziallas & Blind, 2019). Innovation penetrates into multiple processes such as corporate management, manufacturing, and marketing. Consequently, the innovation indicators are varied. These can be divided into five main categories: determinants of innovation, inputs of innovation, outputs of innovation, the performance of innovation, and activities of innovation (Edison et al., 2013). Edison, Ali, and Torkar (2013) utilized a complete literature review integrated with questionnaires and interviews with practitioners in the software industry to systematically summarize the existing measurement systems into the following modes: R&D-based measures, revenue-based measures, IPR-based measures, count-based measures, as well as process, investment-based and survey measures. R&D-based measures are used for innovation inputs, while revenue-based measures are used for innovation performance. And it is not hard to understand the process, investment-based and survey measures work for estimating organizations' innovative capabilities. IPR-based measures are the major way to measure innovation output. Patent counts, citation-based volumes and patent density are the most widely used metrics. Nonetheless, "patent only covers a certain type of innovation" (Evangelista, Sandven, Sirilli, & Smith, 1998). Considering the high frequency and multiple types of iterative innovation of apps, IPR-based measures tend to ignore a great deal of non-patented inventions and innovations (Kleinknecht, Van Montfort, & Brouwer, 2002). Therefore, IPR-based measures are obviously not the best choices for innovation of apps.

In summary, update count seems to be the most effective metric in measuring apps innovation. However, count-based measures also have significant flaws in that they treat the quality and degree of all innovation outputs the same. In order to overcome this defect, this study applies the theory of radical innovation and incremental innovation to the measurement system (Qiao et al., 2018).

Based on the above theory, we established a new update classification system to assist in distinguishing the degree of innovation by referring to previous studies and analyzing a large number of update documents. More specifically, we defined nine types of updates as follows: functional updates, business updates, visual updates, visual improvements, existing functional improvements, systematic improvements, bug fixes, adaptability adjustment for platform, together with new content and activities. Functional, business, and visual updates are always accompanied by guidance steps within the app for enabling users to adapt. From the perspective of user familiarity, they have made major changes. Therefore, we classify them as radical innovations, while the remaining six types are considered as incremental innovation. In addition, it should be noted that in the ninth category "new content and activities," both the addition of regular activities and the addition of homogeneous content are predictable to users. That is why we categorized it as incremental innovation.

Table 1. Update classification system and related illustrations

Categories	*Subcategories*	*Code*	*Definitions*
Radical Innovation	1. Functional updates	FU	Addition of new features, new systems, new gameplays.
	2. Business updates	BU	Addition of new sales strategies and business expansion, for example, releasing a specific version opens the shopping festival when the platform provides a certain amount of shopping subsidies.
	3. Visual updates	VU	Changes of the overall design style of the app and revisions of the main interface.
Incremental Innovation	4. Visual improvements	VI	Minor changes to the interface and visual optimization, for example, the position of the icons, the addition of new entrances, and optimized special effects.
	5. Existing functions improvements	FI	Improvement of specific functions and gameplays, for example, adjusting the parameter of existing props and skills.
	6. Systematical improvements	SI	Improvement for the stability, security, fluency, size of installation package, or other systematic performance of the app.
	7. Bug fixes	BF	Changes for handling a programming bug/glitch.
	8. Adaptability adjustment for iOS system	IOSA	Improvement of compatibility with newly upgraded iOS systems.
	9. New content and activities	NCA	Addition of regular non-commercial activities and homogenized content, for example, the addition of new characters, new tasks, or new expression stickers.

Data

Information about 4,560 apps from Apple IOS China was gathered and organized. Some apps were dropped from the analysis as they received very few reviews and gained limited attention from users. Finally, we screened 39,153 pieces of update documents from 2,645 apps from

Apple IOS China. Each had effective update documents and at least ten reviews posted by users from January 1, 2019 to December 31, 2019.

As previously mentioned, before formal analysis, update documents should be divided into update points. For the sake of readability and structure, developers usually describe an update point in one line in the update document. Consequently, we separated the update texts by line breaks and treated each line of a text as a potential update point. Furthermore, some apps repeated previous updates in the latest version of the update document. We removed all of the duplicate content by identifying the keywords "recent updates." Finally, a total of 144,783 pieces of text were obtained.

Table 2. Comparison of update texts before and after preprocessing

When sending "live video," you can search for a song as background music.	1	When sending "live video," you can search for a song as background music.
You can post a private message in the "live video" of your friends.	2	You can post a private message in the "live video" of your friends.
Recent updates: Fixes and improvements to some known issues.		

Methodology

The analysis includes three steps: content analysis and coding, text mining and automatic classification, and update-based measuring. Content analysis is a semi-quantitative research method, which is widely applied to the study of update documents of apps (Vaismoradi & Snelgrove, 2019). However, since its work is mainly done manually, this method is only suitable for a small number of samples (Tian et al., 2020). Considering there are over one hundred thousand pieces of texts to be dealt with, utilizing machine learning methods for text mining has become an inevitable option. Therefore, we first built the training data set with content analysis and utilized it as the input data to discipline the classifier. After that, we counted the number of updates of each category of each app and scored them in the dimensions of incremental innovation and radical innovation.

Step 1: Labelling update points by content analysis

The coding scheme was established according to Table 1. It is worth noting that some invalid texts are inevitably recognized as update points during data preprocessing, such as welcome messages, thank yous, event previews, update previews, activity descriptions, function descriptions, developer’s contact information and information for which it is impossible to automatically determine whether it is an update point. These have been placed into another category, “NA,” which means not an update point in this procedure. To summarize, the complete coding scheme includes three primary codes: radical innovation, incremental innovation and not an update, as well as ten secondary codes.

Approximately 10% of the samples, namely 14,450 pieces of text, were randomly extracted for manual coding. One team member created the coding scheme, and the other two were assigned to code the text separately. After three rounds of coding, the Scottrade index of the two coders reached 0.764. Finally, the remaining borderline and difficult cases were resolved by the first author.

Step 2: Automatically labelling update points by text mining

In order to determine the best classification method, a variety of machine learning models were applied to classify the sample set, including FastText, TextCNN, TextRNN, TextRNN-Attention, TextRCNN, DPCNN, Transformer, and BERT. There are some differences in the implementation of these algorithms. To be more exact, the first seven algorithms all require word2vec to convert text data into word vectors in advance, whereas BERT's unit of analysis is not a word but short text. This is the reason we used the pre-training model of Amazon AWS when applying BERT algorithms. In the training process, we adopted a five-fold, cross-validation method, taking 20% of the data as the test set and 80% of the data as the training set, repeated five times. Ultimately, the BERT model performed best, with an accuracy rate of 81.71%, while the accuracy rates of other models were all lower than 76%. As a result, the BERT model was selected as the final classifier.

Table 3. Seven kinds of text classification algorithms and their classification accuracy

Model	*Accuracy*
FastText	75.54%
TextCNN	73.24%
TextRNN	68.05%
TextRNN-Attention	73.07%
TextRCNN	74.89%
DPCNN	69.91%
Transformer	73.82%
BERT	81.71%

After completing the classification, we extracted 100 results from each category of the final results to test the usability of the constructed classifier. The recall rate and precision rate of each classification exceeded 80%, which meets the accuracy requirements and proves the reliability of the classification results.

Table 4. Sampling results of the classifier constructed by the BERT

Classification	*Recall*	*Precision*
Not updates	0.88	0.93
Functional updates	0.86	0.91
Business updates	0.97	0.99
Visual updates	0.84	0.98
Visual improvements	0.96	0.81
Existing functions improvements	0.93	0.86
Systematical improvements	0.93	0.97
Bug Fixes	0.97	0.99
Adaptability adjustment for iOS system	0.99	0.97
New content and activities	0.92	0.89

Step 3: Measuring the innovation output of apps

Every update point is measured on the nine categories with the classification algorithm (i.e., BERT). For example, if a specific update point represents the content of functional updates, the functional update dimension is measured as one. Next, this value considers the radical innovation dimension. Each app is measured in the two dimensions of incremental innovation and radical innovation by aggregating their values on the nine categories.

Findings

In the section, we combined the app types, innovation types, and degree of innovation with various visualization methods to demonstrate and explore the app's lack of innovation in depth.

Gradient distribution of the scores of app innovation

As previously indicated, app innovation output has obvious polarization. Nearly 10% of apps scored 0 in radical innovation in 2019. To the contrary, 35 apps performed very well in this aspect, with a score of over 100. To present this phenomenon more intuitively, we clustered the evaluation results of innovation through the KMeans algorithm. After 13 iterations, the final clustering result is shown in Figure 1.

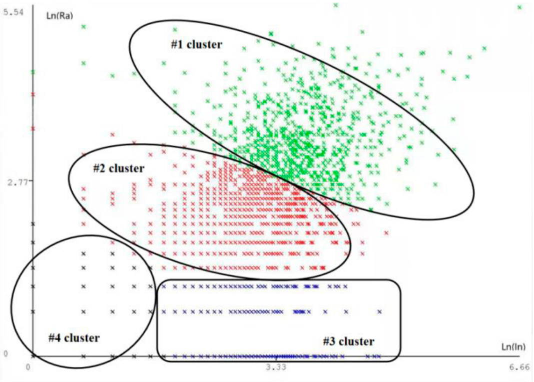

Figure 1. Clustering results of app innovation performance

As seen in Figure 1, the innovation performance of apps shows a gradient distribution. The #1 cluster accounts for 30% of the whole. Over 90% of apps in this cluster have excellent performance in both incremental innovation and radical innovation. They are most likely to be in the exploratory or growth period in the life cycle of software. For apps in the growth stage, speedy acquisition of new users through radical updates is the top priority. Meanwhile, it is necessary to quickly release incrementally updated versions based on user feedback to increase user retention. The #2 cluster is also the gathering place for killer apps such as Alipay and Taobao. These apps already have a stable stock of users, and there is room for growth in the number of users. The #3 cluster only consists of 19% apps; however, their characteristics are clear at a glance. They concentrate on developing incremental innovation, in most cases, because the users' groups are basically fixed, or they have technological innovations that are difficult for competitors to imitate. Apps in the #4 cluster are more cautious about innovation. Relatively speaking, these apps were rarely updated in 2019 and almost never ranked high in the IOS Hotlist. Nevertheless, WeChat, which is the most well-received instant messaging app in China, surprisingly belongs to the #4 cluster. There is no doubt that WeChat has become an essential app for almost everyone in China. For such a unique app, the risk of innovating (e.g., increase of input costs, users' dissatisfaction with the update) probably far outweighs the benefits.

Types and innovation modes of apps

Apps in the same field tend to imitate the successful ones to maintain functional equivalence (Wang, Li, & Singh, 2018), and their update modes usually maintain a certain degree of consistency in the sample of this study. Therefore, we calculated the average value of innovation performance for each type of app to observe their update patterns.

According to Figure 2, the radical innovation scores of the three types of apps, shopping, travel, and finance, are among the top three. As for the radical innovation dimension, game apps outshine others. By contrast, their radical innovation is mediocre. The scores of newspaper and magazine apps in these two dimensions are the lowest, but there are only four of them in our sample. Thus, it does not rule out the result of sample bias.

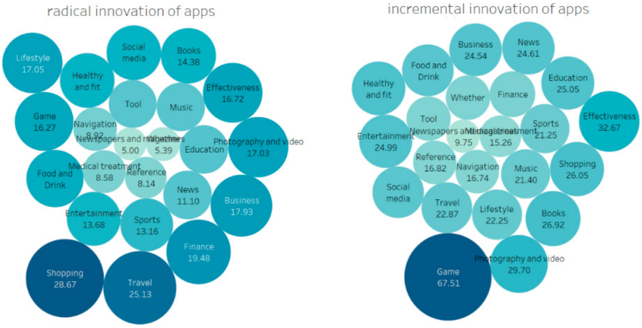

Figure 2. The average value of the scores of various apps in the radical innovation (left) and incremental innovation (right) dimensions

The game industry has always been an important branch of the mobile application industry. The majority of global app downloads in 2017 came from non-game apps. However, in terms of revenue, whether it is iOS or Android, game apps accounted for more than three-fourths of the earnings, and they are always the money-spinners.[1] In the iOS app store, games even have a special column.

The most obvious feature of game apps compared to other apps is that the new versions contain a lot of update points. For example, in the war strategy mobile game, The Clash of Kings, about 20 update points will be added for each update. Among the updates, it is not difficult to see that incremental innovation in content and activities is most essential, accounting for over 40% of daily updates. Holding periodic seasonal events and adding new characters, costumes, and props are the main ways for mobile games to keep users enthusiastic and make profits, rather than business updates. In addition, the properties of new characters and props are often modified based on user feedback, which is the primary content of existing function improvements.

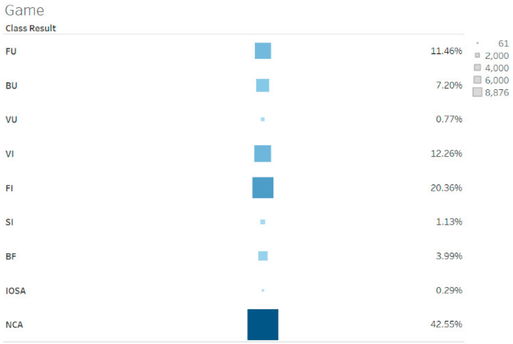

Figure 3. The proportion of various types of game app updates

[1] https://www.meetsocial.cn/information/78.html

Another interesting finding is that the update patterns of shopping, travel, and finance apps are extremely similar as shown in Figure 4. All of them did well in the dimension of radical innovation. Improvements to existing features are the dominating way they innovate incrementally, which accounts for approximately 20%. In addition, they also take notice of visual innovation and improvement. Compared with mobile games, user familiarity with the interface operation is not necessarily required. Therefore, they are more likely to revamp the UI to enhance the users' feeling of freshness and to better showcase the products or service. Among the three, shopping apps are most likely to think highly of commercial updates. Certainly, this is associated with the nature of the transaction of shopping. Travel and finance apps offer more digital content and functional service.

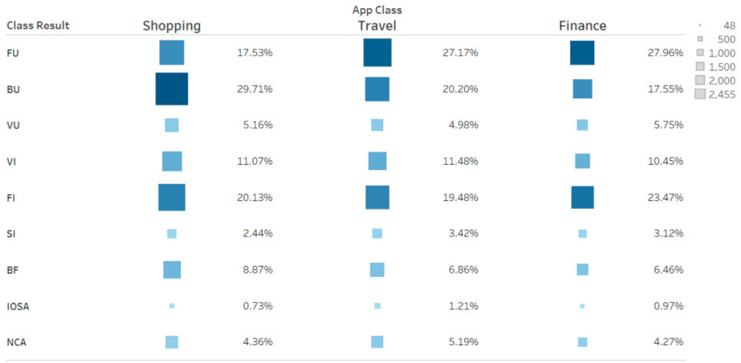

Figure 4. Proportion of various types of shopping (left), travel (middle), finance (right) app updates

Conclusion

To summarize, we have developed a measurement method for the innovation output of mobile apps, which can analyze tens of thousands (or even more) update documents and accurately identify the degree and type of updates. In addition, we applied this approach to conduct empirical research on 2,645 Chinese apps and found that the performance of the innovation output of apps is mainly divided into four levels. We also conducted an in-depth analysis of the update mode of some categories of apps.

Acknowledgements

Thanks are due to Xiaoke Zhang and Zhewen Liang for their great assistance with gathering the data of the apps. The funding from the National Natural Science Foundation of China under Grant 72072087 is also gratefully acknowledged.

Abstract

In the nineties of the last century, researchers have applied several indicators to study reference literature of scientific articles. Glänzel & Schoepflin (1999) was the first time to capture and understand the subject characteristics in terms of structure and ageing of cited literature in the sciences and social sciences. Following and extending the pioneer study two decades ago, the present study focuses on how to build efficient instruments for the measurement of relevant aspects related to the 'hardness' of science. Apart from the observed general shift towards the use of more recent and indexed literature, the need of more than one single indicator is also detected in this study.

Introduction

Researchers' selection of references is influenced by social context which help reflect the sanctioned level by the community. These recognitions imply not only research track but also reference patterns specially associated with specific communication patterns across subject fields expressing their publication behaviour and co-authorship patterns, ageing of information in the mirror of diachronous and synchronous processes and as well as the "hardness" of science. The "hardness" of sciences revealing the degree of impersonality in the relationships of field members (Norman, 1967), is an indicator detecting different levels of publication patterns between the sciences and social sciences. The term "hardness" implies the strength of empirical evidence due to the laboratory experimental approach. Although its literal meaning may not be perfectly righteous, we remain this term in this study to reflect the original source and historical background for distinguishing the different patterns between the two types of sciences. Measures for the hardness degree based on the argument that "hard" sciences focusing on natural objects and phenomena while "soft" sciences focusing on human behaviours and activities (Norman, 1967) were proposed and applied by Price (1970), Moed (1989) and Fanelli & Glänzel (2013) in the context of references. According to Moed (1989, p. 474), the Price index which can help detect the hardness of sciences is "the percentage of references in the scientific literature to 0 to 4 years old other publications." Larivière, Archambault & Gingras (2008) found that Price Index values are decreasing since the mid-1950s and decreasing with the mean reference age. It is also confirmed on other studies that the Price Index is a decreasing function of the average and median reference age (Glänzel & Schoepflin, 1995; Egghe, 1997). Several studies reveal the characteristics of references and explore the information contained in references to detect borders between different sciences by the way scientists refer to their literature. For example, Glänzel & Schoepflin (1999) found that the percentage of references to serials is a sensitive measure of the communication behaviour between the sciences and the social sciences. It was reported in their study that about 80% of all science journals cite more than 70% of references to serials, while all social science journals refer to less than 70% references in serials. They also focused on differences in the ageing of journal literature in science and the social sciences. Interestingly, the characteristics of fields in the social sciences were found drifted towards those of the sciences, as Schubert & Maczelka (1993) pointed out that the research field of scientometrics had a clear move from those referencing characteristics of the ‘soft’ sciences towards those of the 'harder' sciences during the 80’s.

Given that the patterns of academic publishing reform during the past decades especially under the wave of Web 2.0, the characteristics of reference behaviour may be transformed as well and thus worth being traced after such a long period. In this study we will investigate reference patterns and the “hardness” of science measured by related indicators such as Price Index, reference age, and share of periodicals in references.

Furthermore, the granularity of the underlying subject delineation also plays a crucial part in the discriminative power of bibliometric indicators derived from publication and citation processes. Subjects fields defined with lower resolution tend to become more heterogeneous, the inflationary trends in scientists’ publication and citation behaviour as early noticed and discussed by Persson et al. (2006) further contributes to possible biases in bibliometric indicators at higher aggregation levels and requires proper normalization to keep their validity. These “inflationary trends” also foster the concentration on the most recent literature in the reference lists as being in line with literature growth and the intensification of network density (cf. Cozzens, 1985; Persson et al., 2004).

In addition, Moed (1989) concluded that “indicators reflect at least partly the size of the scientific activity in the subfield or topic”. That is why the measurement of research performance at lower aggregation levels could be distorted by indicators determined at higher levels of aggregation. This finally led him to breakdown the Price Index, usually calculated for the subfields or journals, to the level of individual papers.

In this context, it is also worthwhile to mention that a more recent study by Zhang & Glänzel (2017) already dealt with evolutionary aspects of literature ageing at the large scale. They compared the situation in 1992 (which by and large corresponds to the data used by Glänzel & Schoepflin, 1999) with that in 2014 and confirmed a growing trend in favour of citing older documents (cf. Verstak et al., 2014; Martin–Martin et al., 2016), which is partly due to Google Scholar search services and the digitalisation and electronic storage of scientific publications resulting in accessibility improvements to scholarly knowledge. Thus, the general decrease of the Price Index in all fields was accompanied by the growing mean age of references in practically all fields of the sciences including the social sciences.

In contrast to the study by Zhang and Glänzel, we base our present analysis on the article level to allow for the breakdown to subjects at any aggregation level and thus to avoid fuzziness caused, for instance, by field heterogeneity and journal multidisciplinarity.

The objective of the present study is threefold:

1. In how far have patterns changed in the time elapsed since the publication of the study by Glänzel & Schoepflin (1999)?
2. Do the findings regarding ageing-related and reference-structure indices by Glänzel and Schoepflin still hold for an efficient distinction between ‘softness’ and ‘hardness’?
3. Can we propose a new, multidimensional view on subject-related information use?

In order to avoid any effect of distortions caused by the particular choice of subject granularity, all indicators will strictly be calculated for individual papers and then aggregated within their disciplines. This makes it possible to apply the indicators also to multidisplinary journals, cognitively heterogeneous disciplines or even to use them in an interdisciplinary context.

Methodology

The hardness of a field can be measured by different indicators such as the Price index, the percentage of references to periodicals, the mean references age, the mean reference rate, relations among authors, epistemic networks, and the number of books in the subject borrowed from libraries (McGrath, 1978; Schubert & Maczelka, 1993; Wouters & Leydesdorff, 1994; Schoepflin & Glänzel, 2001). In this study the indicators applied to identify the hardness of publications are the mean reference count, the mean reference age, the percentage of WoS indexed references as a proxy for the share of references in serials, and the Price index. Only references with valid reference year and published after the year 1200 were analysed.

Data sources and data processing

The complete 2019 content of the WoS, including SCIE (Science Citation Index Expanded), SSCI (Social Sciences Citation Index), A&HCI (Arts and Humanities Citation Index), BKCI-S (Book Citation Index– Science), and BKCI-SSH (Book Citation Index– Social Sciences & Humanities) have been processed as source documents. Only the citable document type 'Article' and 'Review' which have more than 9 references each paper or book chapter were analysed in this study. In order to ensure compatibility and comparability with previous data as the possibility to look at evolutionary aspects we have restricted the selection of topics related with those used in previous studies. Fourteen out of 153 research areas[1] mapped by 254 Web of Science subject categories were selected to compare the reference patterns across four broad categories: Life Sciences & Biomedicine, Physical Sciences, Social Sciences, and Technology. The details of samples are listed in Table 1. The amount of book chapters in each area is insignificant to influence the result largely, therefore in this study the sample group is not further distinguished by publication type but includes all types of publication.

Table 1. Number of samples in the 14 analysed research areas

Subject Category	Research Area	Abbreviation	Nr. of items (Nr. of book chapters included)
Social Sciences	Archaeology	Arc	3,336 (150)
	Business & Economics	Bus	47,865 (2240)
	Psychology	Psy	50,843 (688)
	Sociology	Soc	8,212 (824)
Technology	Metallurgy & Metallurgical Engineering	Eng	20,493 (56)
	Information Science & Library Science	Inf	4,689 (166)
	Instruments & Instrumentation	Ins	21,406 (24)
	Transportation	Tra	8,658 (151)
Physical Sciences	Astronomy & Astrophysics	Ast	20,595 (144)
	Mathematics	Mat	62,410 (342)
	Polymer Science	Pol	24,167 (393)
Life Sciences & Biomedicine	Cardiovascular System & Cardiology	Car	29,904 (130)
	Immunology	Imm	26,470 (228)
	Research & Experimental Medicine	Med	31,278 (433)

Results

The results of all the indicators in selected research areas are shown in Table 2. The distinct characteristics can be identified across fields. For example, papers in research areas of the social sciences own relatively more reference counts, longer reference age, and lower Price index than other fields; by contrast, areas in life sciences have extremely high ratio of WoS indexed references. Figure 1 illustrates these differences across fields obviously. Areas in technology

[1] https://images.webofknowledge.com/images/help/WOS/hp_research_areas_easca.html

and life sciences & biomedicine have generally around 35% percent of references published within 5 years, while the Price indices of areas in social sciences are around 20% only. Mathematics is very different from other areas in physical sciences, owning a quite low ratio of recent references which is of the same magnitude as social sciences. In the social sciences, economics and psychology have distinct high ratios of WoS references as shown in Figure 1. They are closer to information science and mathematics, but still much less than those areas of medicine, engineering, physics, or chemistry.

Figure 2 shows that in general papers in technology field cite lowest numbers of reference, and papers in technology and life sciences have longer reference age. The latter tendency responds the patterns of Price index revealed in Figure 1. Most of areas show their reference behaviours in line with other areas of the same broader field, except for mathematics which is a unique subject citing very few references and most of them are relatively older and non-indexed publications. This may imply that mathematics is better to be excluded from the discussion of applying referencing behaviours to distinguish the field differences or the hardness of science.

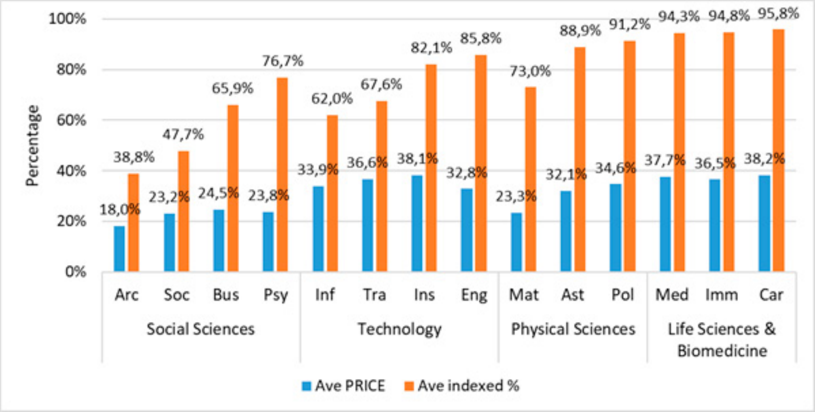

Figure 1. Average Price Index and average share of WoS references of papers published in 2019 in 14 research areas

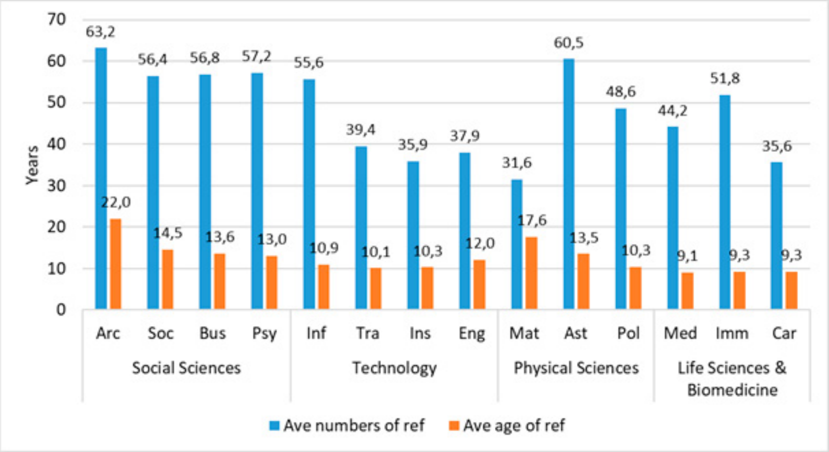

Figure 2. Average count and age of references of papers published in 2019 in 14 research areas

Glänzel & Schoepflin (1999) have used several indicators to study reference literature of scientific articles in the sciences and social sciences to capture and understand the subject characteristics in terms of structure and ageing of cited literature. In particular, they used the number of references, the share of references in serials, the mean reference age. The latter indicator was used to substitute the Price Index as the authors had found a strong (of course negative) correlation between these two indicators (Glänzel & Schoepflin, 1995). They concluded that the share of references in serials proved an efficient indicator of hardness with strong discriminative power. They also found a week correlation between the ageing and the reference-structure based indicators. The objective of the present study is not to redo the previous work by Glänzel and Schoepflin and to compare the results, or to simply add an evolutionary view, but to come to conclusions on how to build efficient instruments for the measurement of relevant aspects related to the 'hardness' of science. The strong correlations, on the one hand, and the almost uncorrelatedness between the considered indicators found by Glänzel and Schoepflin, on the other hand, already suggested that one single measure would certainly not suffice to reflect subject-characteristic reference patterns.

Table 2. Reference statistics of papers published in 2019 in 14 research areas

Broad category	Research areas	Nr. of samples	Mean nr. of refs	Mean Price Index	Mean % of WoS refs	Mean ref. age
Social Sciences	Arc	3,336	63.19	18.0%	38.8	21.98
	Bus	47,865	56.83	24.5%	65.9	13.59
	Psy	50,843	57.17	23.8%	76.7	13.05
	Soc	8,212	56.42	23.2%	47.7	14.51
Technology	Eng	20,493	37.94	32.8%	85.8	12.05
	Inf	4,689	55.63	33.9%	62.0	10.91
	Ins	21,406	35.94	38.1%	82.1	10.29
	Tra	8,658	39.45	36.6%	67.6	10.09
Physical Sciences	Ast	20,595	60.51	32.1%	88.9	13.52
	Mat	62,410	31.57	23.3%	73.0	17.59
	Pol	24,167	48.58	34.6%	91.2	10.35
Life Sciences & Biomedicine	Car	29,904	35.58	38.2%	95.8	9.30
	Imm	26,470	51.81	36.5%	94.8	9.27
	Med	31,278	44.16	37.7%	94.3	9.11

Table 2 gives the indicator values for 14 selected Web of Science research areas that have been chosen to connect results to those of the earlier Glänzel-Schoepflin studies. In all comparable research areas, we experience an increase of the reference age, which is in line with the observations by Zhang and Glänzel. Mathematics shows a strong growth in obsolescence (from 11.3 to 17.6, while the change remains rather limited with respect to the G&S study of 1999 (e.g., from 7.9 to 9.1 in research & experimental medicine, from 12.5 to 14.5 in sociology and from 9.1 to 10.9 in information & library science). This is accompanied by a growth of the share of database-indexed references, of course not typically for the life sciences, where the share was already close to or above 95% two decades ago. The comparison of the two indicators lets us already assume that both cannot clearly and most notably not simultaneously be associated with concepts like 'hardness'. The deviating values of the indicator pairs in all broad categories except the life sciences may illustrate that. Mathematics may serve as the most extreme example.

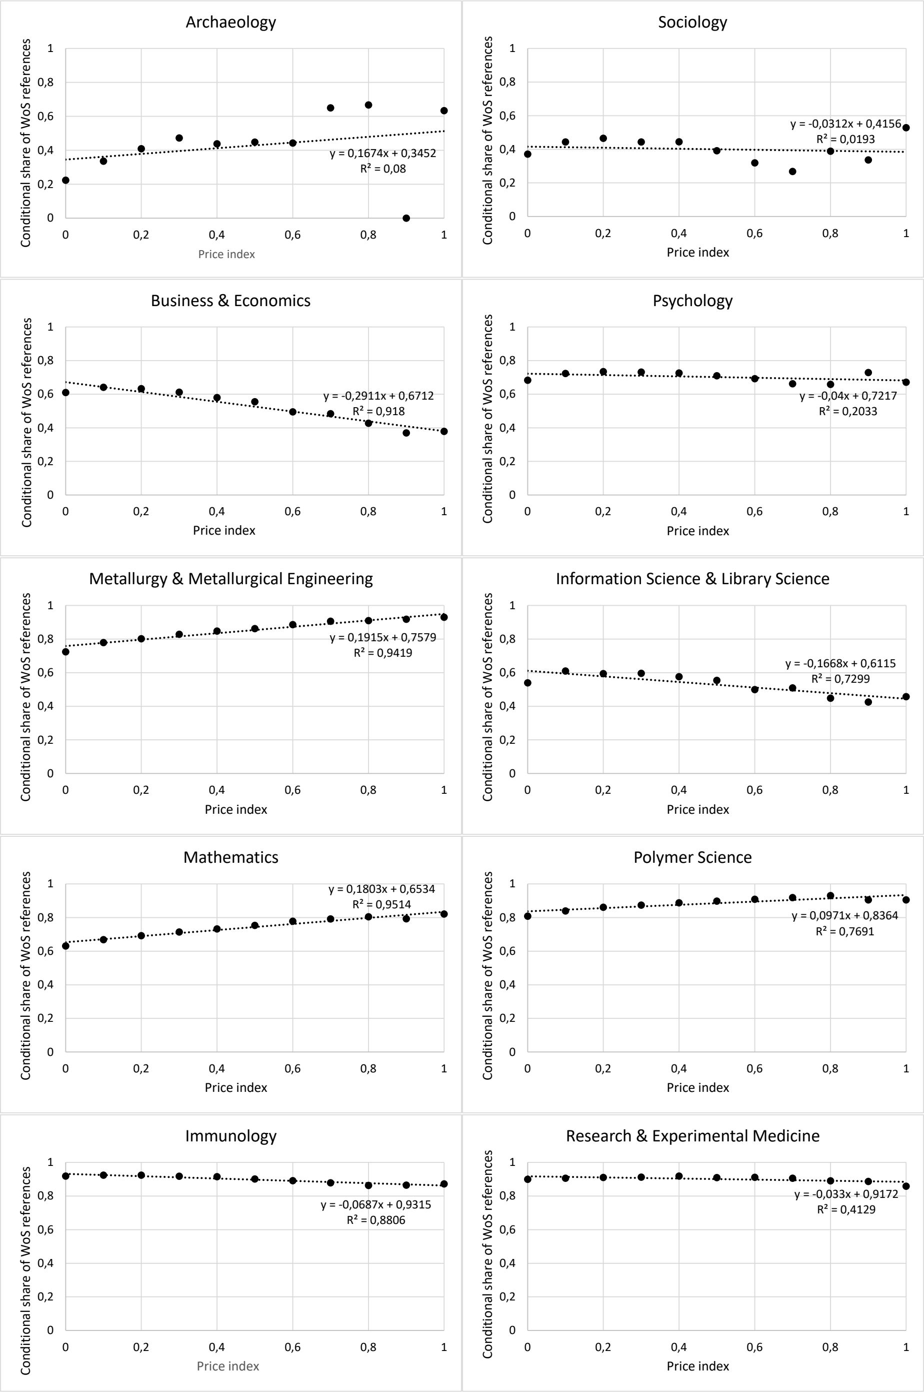

Figure 3. Scatter plots of conditional share of indexed references vs. Price Index in 10 selected research areas

The field is known for the slow ageing (researchers who have ever published or reviewed papers in this field understand why), but is, in turn, much relying on references to journals. Sociology with similar ageing characteristics originate information mainly from not indexed sources. In principle, none of the two indicators alone can express what we expect as a measure of hardness. We deepen this finding by regression analysis, showing the plots of the share of WoS-indexed references vs. Price Index in Figure 3.

We have chosen 10 out of the 14 research areas to ensure the legibility of charts, and calculated the conditional expectations based on the shares of WoS indexed and recent references (<5 years old), i.e., the Price Index. Instead of a direct linear regression analysis, we analyse another type of relationship (cf. Glänzel, 2010; Chi & Glänzel, 2018), namely by directly analysing the plot of π vs. the conditional expectation $E(\sigma|\pi)$, where σ represents the share of WoS indexed references and π stands for Price Index. This method has already successfully been applied by the authors in several contexts, among others for the correlation between usage and citation statistics (see Chi & Glänzel, 2018). There are two possible extreme cases: $E(\sigma|\pi) = E(\sigma) =$ constant means uncorrelatedness. The other extreme is the identity $\sigma = \pi$, with the trivial solution $E(\sigma|\pi) = \sigma$. However, because of the properties of conditional expectations there exists always a function f, such that $E(\sigma|\pi) = f(\sigma)$.

These plots are shown in Figure 3 where horizontal lines represent the extreme case of uncorrelatedness. In the selected fields in the life sciences, the two variables proved to be almost uncorrelated $E(\sigma|\pi) \approx \sigma$, where the slope is close to zero and the constant corresponds to the share of WoS indexed references. We just mention in passing that the most striking situation was found in research & experimental medicine, where the slope amounted to 0.005. In the life sciences, the natural sciences (except mathematics) and technology (except information science) the slopes are close to zero in general (also in the research areas not plotted here) and $E(\sigma)$ gives the expected share in these cases. This amounts to 0.9 or higher in the life sciences. A similar situation can be observed in the social sciences for sociology and psychology, where the slopes are close to zero but the $E(\sigma)$ amounts to 0.42and 0.72, respectively. We also mention that in instruments & instrumentation and transportation (not shown in Figure 4) with slopes close to zero, the expected shares of σ are 0.75 and 0.60, respectively.

By contrast, there are slight but distinct correlations between the two variables π and σ. These can be in part positive (e.g., for archaeology, metallurgy and mathematics) as well as negative (e.g., for business & economics and information & library science). In these cases, ageing as expressed by recentness of cited literature. Thus, for instance, in mathematics grows the share of WoS references with the share of recent references (and thus with assumingly decreasing age of sited literature), while in business & economics one can observe the opposite effect.

While, in the previous subsections, we have focused on selected research areas as defined by Clarivate Analytics, in this subsection we further lift up our perspective to observe the reference patterns across broad categories. The 14 research areas were applied to measure the general characteristics of their corresponding field. Figure 4, which gives the distribution of indicator values over individual papers in each major category, shows the basic statistics in terms of the two main indicators, share of indexed references and share of recent references (i.e. Price Index). In both graphs, the difference between life sciences and social sciences is obvious, especially for the share of indexed references. In the graph of Price Index, papers in technology have larger values than physical sciences and social sciences, although they have similar values of share of indexed references as physical science and much smaller values than life sciences. This finding emphasises the immediacy of references in the field of technology, and also, reveals the different function of the two indices distinguishing the major fields. For applied sciences such as technology, the Price index is more sensitive to detect its need of information immediacy, which is the most distinction from physical sciences. This finding suggests once again that the two indicators reflect essentially two different aspects of hardness.

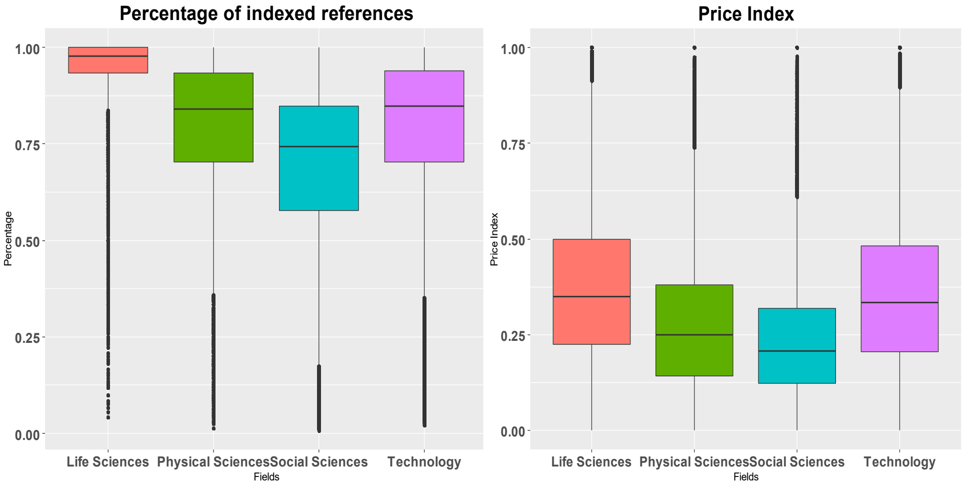

Figure 4. Box charts of share of indexed references and Price index in four broad categories

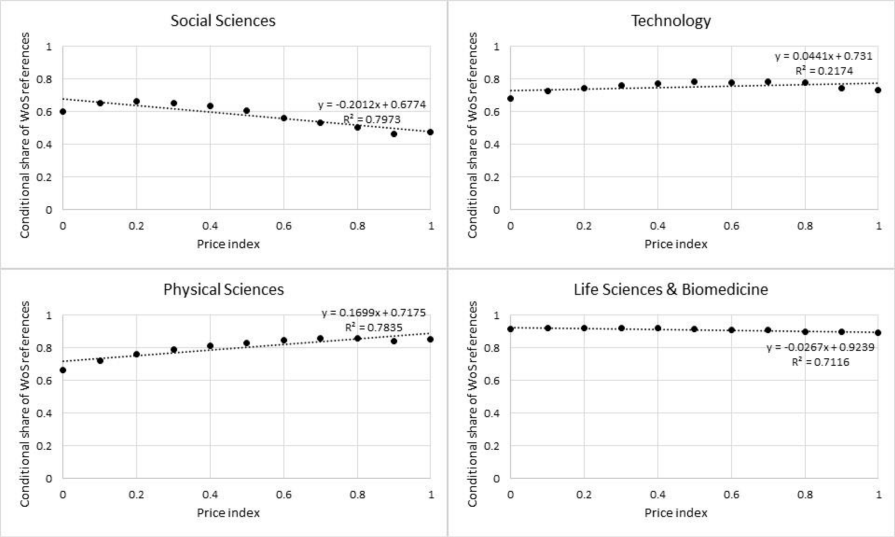

Figure 5. Scatter plots of conditional share of indexed references vs. Price Index in four broad categories

Following the analysis of the conditional expectations based on the shares of WoS indexed references and Price index, Figure 5 presents the plots in the four main fields. Similar to the findings based on individual research areas, mentioned in last section, we found a close-to-zero slop pattern in the life sciences, the natural sciences and technology. The life sciences own the highest expected share E(σ) (of 0.90), while technology and the natural sciences have similar share (of 0.70). Compared to these hard sciences, social sciences have the lowest share (of 0.67). In terms of the correlations between the two variables π and σ, social sciences and physical sciences have totally opposite consequent. The share of WoS indexed references grows with the share of recent references in physical sciences but decreases in the social sciences at the same ratio and condition.

Conclusions

This study, which was based on selected research areas and the four broad categories according to Clarivate Analytics Web of Science Core Collection, has brought three important answers to the questions addressed in the introduction. The evolution reflected by changing indicator values that could be observed is not unambiguous. There is certainly kind of shift towards "hardness" accompanied, even influenced but not necessarily caused by changing scholarly communication patterns. This shift is, on one hand, manifested by more frequently publishing in periodicals or serials with expectation of representing high standards, that is, preferably publishing documents that are indexed in the large multidisplinary bibliographic databases, and, on the other hand, by citing more recent literature, which is at least in part a (by-)effect of the global growth of literature (e.g., Cozzens, 1985; Persson et al., 2004; Larivière, Archambault & Gingras, 2008). A contrary effect certainly lies in electronic data storage and the improvement of search engines resulting in the accessibility of older and digitalised literature sources (see Verstak et al., 2014; Martin–Martin et al., 2016; Zhang & Glänzel, 2017). Consequently, the interpretation of the Price Index as the indicator of "hardness" of science, even in the context of ageing of scientific literature may need some adjustment. As to the second research question, the share of references in serials (or in indexed literature) being a structure-related indicator has considerably changed over time. In order to gain a more nuanced picture of "hardness", one would need more than one single indicator. The application of an indicator pair, one reflecting ageing, and the other one structural aspects, notably if built on individual documents, were able to capture the complex phenomena sketched by the above-mentioned studies and our present paper. This answers the third question.

Abstract

The evolution of the patterns of collaborative strategies plays an important role in the social construction of science to design efficient research policies and to support the production of knowledge. As international research landscape is clearly undergoing continued structural change, we aim to analyze dynamics in collaboration strategies/patterns at the global and disciplinary level, and to investigate whether countries are collaborating more diversely within their region compared to outside their own region using different approaches. We found that internationalization in science is growing in all disciplines. The number of countries in the global network establishes stronger partnerships, forming tightly knit groups and spreading influence more widely among countries with a preference to collaborate within the region instead of collaborating with out-region countries. We believe that these results, though preliminary, have significant implications for the design of programmes and alliances.

Introduction

Science is being characterized by the exponential growth in publications and the rise of team science scholars. This trend of growth in the size of research teams have an effect on evaluative assessment, which are becoming more significant in all subject fields (Bozeman & Boardman 2014; Wuchty, Jones, & Uzzi, 2007). Individual and institutional research assessments supported by metrics have a powerful "pull" effect on scientists competing intensely within an economy of reputation seeking to maximize their own research output and impact (Hennemann & Liefner, 2015). At the same time the evolution of the patterns of collaborative strategies, especially international collaboration, plays an important role in the social construction of science to design efficient research policies and to support the production of knowledge (Coccia & Wang, 2016). The availability of local skills and capacities are central to the development trajectories of regions incorporating science, technology, and innovation in their national development agendas for economic growth (UNESCO, 2015).

It has been argued that "the best science comes from international collaboration" and "scientific research is entering a new age, driven by international collaborations" (Adams, 2013, p. 557). As scientific collaboration networks are expanding and characterizing the social construction of science (Adams, 2012), the growth of international collaboration has been studied to investigate collaboration at different levels and to inform scientific policy makers who evaluate the scientific output of their countries. Scientific policy makers in developed countries are definitely aware of the importance and benefits of research collaboration, with many countries providing specific funding to support large-scale collaborative research projects (Corley, Boardman, & Bozeman, 2006). The study of collaborative strategies in science might provide detailed patterns and inform science policy makers. However, little has been known about how collaborative strategies at the global and disciplinary level have evolved in the last decade.

The growth of international collaboration has been analyzed at the global, regional, and disciplinary level in previous studies. Wagner and Leydesdorff (2005), for instance, found that the principle of the preferential attachment might explain that countries with more collaboration are able to attract more collaboration. Indeed, a few countries dominate the knowledge flows at the global level, even when the global network has widened to include a much greater number of countries (Leydesdorff et al., 2013). At the regional level, the growth of international collaboration moves science system away from institutional collaboration, with stable and strong national collaboration. For example, the growth of publications in major European systems is almost entirely attributable to internationally co-authored papers. This growth is not only a function of state and EU promotion and funding but also reflects individual scientist's pursuit of reputation and resources (Kwiek, 2020). The globalization of science does not seem to have evolved uniformly across all countries and regions, as historical, geographical, and economic factors play a key role (Chinchilla et al., 2019; Geuna, 2015; Sherngell, 2013). Knowledge and capabilities have been conceptualized as geographically sticky, since tacit knowledge and abilities are a result of a workforce and not easily transportable. Research collaboration with scientists from other regions could allow countries to upgrade their academic capacity and respond to unique societal and economic challenges more readily (Fitzgerald et al., 2021; Frenken & Boschma, 2007; Hidalgo et al., 2007).

Yet, this existing body of research usually focuses on more advanced countries−many countries fall outside this taxonomy and are therefore understudied. To better understand the dynamics of the global system of science, we must move to a more comprehensive analysis. As international research landscape is clearly undergoing continued structural change with new leaders (in term of size) emerging from all corners of the globe (Fitzgerald et al., 2021), we aim to analyze how this shift in the geographical spread and economic capacities of countries has shaped a reconfiguration of the global collaboration network. Besides, as it is supposed that the corresponding authorship has a distinctive value in the byline of publications (Bu et al., 2019; Huang et al., 2011), we want to study different roles in the integration of new countries in the global network, namely leading or supporting collaborators' role.

Research objectives

There are two research objectives of this paper: On the one hand, we aim to identify dynamics in collaboration strategies/patterns at the global level and disciplinary level; on the other hand, we expect to investigate whether countries are collaborating more diversely within their region compared to outside their own region.

Data and methods

Data were retrieved from the in-house version of the Web of Science (WoS) maintained at CWTS of Leiden University for articles, reviews, and letters. Each publication in the dataset is clustered as five disciplines according to the algorithm of Waltman and Van Eck (2012). These disciplines are SSH (Social sciences and humanities), BIO (Biomedical and health sciences), PHY (Physical sciences and engineering), LIF (Life and earth sciences), and MAT (Mathematics and computer science). National/Regional-level collaborations were collected from 12,187,856 distinct publications retrieved for the

2008-2017 period, yielding connections among 216 countries[1]. Among these documents, 3,114,463 were internationally co-authored; this is 25.5% of the total. Document metadata was used to extract author affiliation data for each document. These data allowed for the construction of networks on the bases of collaboration (i.e., co-authorship between countries on a given document). We study three overlapping temporal periods (2008-2011, 2011-2014, and 2014-2017, respectively) to avoid fluctuations in countries with a very limited amount of data records.

We enrich bibliographical metadata by adding information of research and development expenditure (% of GDP)[2] and researchers in R&D (per million people)[3]. As expenditures take time in translating into outcomes, infrastructures, workforce, etc., we calculate the mean average of the previous 4-year-long period for each period under analysis. For example, for the period 2008-2011, we consider expenditures in 2005-2008, and for the period 2014-2017, we consider expenditures in 2011-2014. We analyzed affiliated document using full counting methods for all papers and for leading papers. For each country analyzed, papers were grouped into three mutually exclusive categories, based on the institutional addresses of the authors, named collaborative strategies: 1) papers that only have a single institution (no inter-institutional collaboration), 2) papers that have at least two institutions from the same country (domestic collaboration), and 3) papers that have at least two institutions from at least two different countries (international collaboration).

For the constructed collaboration network, we are particularly interested in these measurements:

- The number of edges: It denotes the number of ties between countries.
- Network density: It allows us to determine the degree of cohesion that exists among the nodes, revealing whether the network has a thick or thin consistency and the extent of connectivity among nations (Wasserman & Faust, 1999).
- The average degree of nodes: It measures the spread of influence across the networks (Hanneman & Riddle, 2005).
- Size of k-core: A k-core is the maximal subgraph in which each node has at least k connections to other nodes in the subgraph, despite how many links we have outside the subgraph. With this method, the densely connected area can be identified and in order to be included in the k-core, a node must have at least k links to other nodes in the k-core, regardless of how many other nodes they are connected to outside the k-core (Kong et al., 2019).

Besides, we also expect to examine whether countries are collaborating more diversely within their region compared to outside their own region. To this end, we employ the Shannon's entropy by regions. Specifically, we follow Fitzgerald et al. (2021) and calculate three measurements:

- Within-region entropy: $CE_{in}(i,t) = -\frac{1}{log(N^{(t)}-1)}\sum_{j\in J_u}\frac{n_{ij}^{(t)}}{\sum_{j\neq i}n_{ij}^{(t)}}\cdot log(\frac{n_{ij}^{(t)}}{\sum_{j\neq i}n_{ij}^{(t)}})$, where $N^{(t)}$ represents the number of countries in our dataset in the given period t,

[1] Some of the 216 countries are not real "countries". Rather, some are regions/territories. Yet, for the sake of simplicity, we use "country" in the following sections in this paper.

[2] Gross domestic expenditures on research and development (R&D), expressed as a percent of GDP. They include both capital and current expenditures in the four main sectors: Business enterprise, Government, Higher education, and Private non-profit. R&D covers basic research, applied research, and experimental development.

[3] The number of researchers engaged in R&D, expressed as per million. Researchers are professionals who conduct research and improve or develop concepts, theories, model techniques instrumentation, software of operational methods. R&D covers basic research, applied research, and experimental development.

$n_{ij}^{(t)}$ the number of collaborations between countries i and j in time period t, J_u the set of countries in the region of country i.

- Outside-region entropy: $CE_{out}(i,t) = -\frac{1}{log(N^{(t)}-1)} \sum_{j \in J_o} \frac{n_{ij}^{(t)}}{\sum_{j \neq i} n_{ij}^{(t)}} \cdot log(\frac{n_{ij}^{(t)}}{\sum_{j \neq i} n_{ij}^{(t)}})$, where J_o the set of countries outside the region of country i.
- The proportion of within-region entropy (as a measurement to understand the dynamics of inter- and intra-region collaboration diversity): $C(i,t) = \frac{CE_{in}(i,t)}{CE_{in}(i,t)+CE_{out}(i,t)}$.

We also expect to see how the expenditures on R&D of a country affects its performance on international collaboration and within-region collaboration. To this end, we implement two distinct regression models. In the models, we adopt the proportion of internationally collaborative publications and the proportion of within-region Shannon's entropy as the dependent variable, respectively. For the independent variables, we consider the average R&D investment proportion (among all its GDP between 2008 and 2017) and the number of researchers per one million population in the country. For both models, we use the income level of countries as a control variable in both models.

Yet, we found that the distribution of within-region Shannon's entropy is highly skewed. To this end, we cannot adopt the raw variable to a regular regression model. Instead, we use the percentile (rank) of this variable in the model in practice. Moreover, for a specific country, if any of the values of two independent variables is missing, we remove this country from our regression analyses. This results in 109 countries/regions remained.

Results

Overview

Table 1 provides an overview of data for the three periods. All indicators show a growth on international collaboration. The number of internationally collaborative papers has grown at a high rate (71.8%) than the total number of papers (53.4%). At individual level, the number of authors involved in internationally collaborative papers has risen by 81.3% much faster than the number of unique authors at the global level (66.55%). Besides, almost all countries have participated in the global international network as leading or supporting collaborators.

Table 1. Basic statistics of research collaboration by 4-year periods.

ALL	2008-2011	2011-2014	2014-2017	Growth rate
Number of papers	3846013	4879242	5898173	53.36
% international collaboration	23.6	25.2	26.5	12.05
% domestic collaboration	35.2	36.5	36.7	4.11
% single-authored papers	40.7	38.0	36.7	-9.96
Number of authors	6352677	8371230	10580467	66.55
% international collaboration	32.7	34.2	35.6	8.86
% domestic collaboration	50.7	51.8	52.4	3.37
% single-authored paper	46.6	43.5	40.1	-14.08
Number of countries	211	218	227	7.58
% of leading countries	98.1	96.3	95.6	-2.56

At the disciplinary level, Figure 1 shows that the percentage of internationally collaborative papers has increased around 12% in all disciplines. BIO and LIF present the highest values of growth in contrast with SSH that decrease 2.34%. In domestically collaborative papers, SSH also present a decline followed away from MAT (22.5% and 5.5%, respectively) in favor of increasing proportionally in single-authored papers (26.5% and 0.54%, respectively). The rest of disciplines present difference patterns, decreasing the percentage of single-authored papers in favor of international and domestic papers. Similar patterns are observed in the number of authors involved in distinct collaborative partnerships (Figure 2).

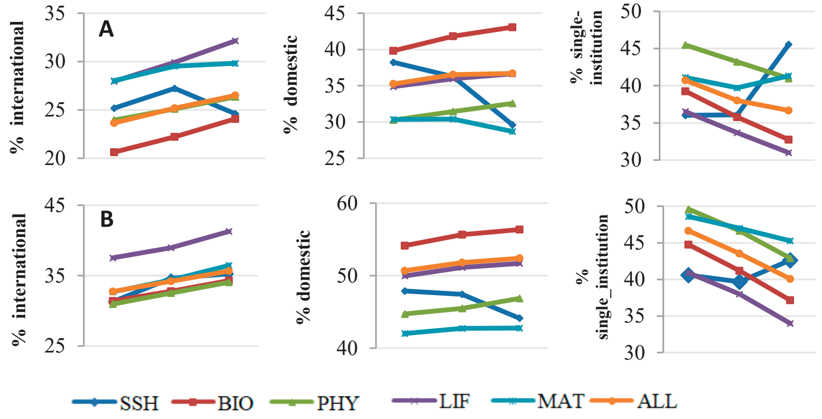

Figure 1. Evolution of the percentages of papers (A) and authors (B) by collaboration types at the global and disciplinary levels. Temporal periods: 2008-2011, 2011-2014, and 2014-2017.

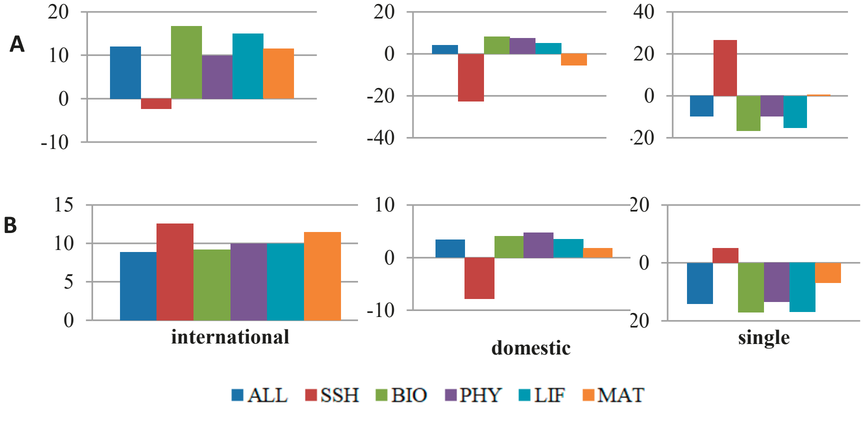

Figure 2. Growth rate of the number of papers (A) and authors (B) by collaborative types at the global and disciplinary levels.

The number of authors involved in at least one internationally collaborative paper increase significantly especially in SSH and MAT (12.6% and 11.5%, respectively). Considering authors that have been involved in at least one domestic paper, all disciplines show an increase except for SSH (-7.8%), which is the only discipline where the number of authors involved in at least one single-authored paper has risen (5%). Finally, considering the number of countries that at least have been involved in international collaboration as corresponding author, we can observe a descend especially strong in LIF and BIO and only PHY increase the number of countries acting as corresponding authors in international collaboration. These findings are in consonance with trends observed in previous studies (Coccia & Wang, 2017; Leydesdorff & Wagner 2008; Wagner, Park, & Leydesdorff, 2015).

Network analysis

We conducted network analyses to examine whether the network changed as the number of papers increased. Network measures are shown in two levels of aggregation: global and disciplinary level. Table 2 displays a set of basic structural indicators to analyze the structural properties of the global collaboration network. The number of countries linked to other countries has growth in the past decade (8%). According to the UNESCO[4], there are 193 country members and 11 Associate members. Our findings show that almost all nations and territories have researchers participating in international collaborative networks.

The size of the *k*-core component grew from 99 to 113 countries in a 10-year period. The average degree increases 34%. The average distance across the network is lower than two—a very low number considering the global network as a whole—and it is decreasing in the years examined. Diameter measures the longest distance between a pair of countries. In our study, the diameter is equal to 3 which mean that the distance from one side of the network to the other is small and the network is tightly linked together. Average clustering coefficient is high, which reinforces that the global network is forming tightly knit groups. To a certain extent, the global network is characterized by a high level of clustering and a small average number of steps between countries, which fits with the model of ‘small world (Watts & Strogatz 1998). All these indicators suggest that the network became denser, and that influence and power (in terms of collaboration flows control) were spread more widely among countries at the global level.

Table 2. Network statistics for the global network science.

	2008-2011	2011-2014	2014-2017	Growth rate
Number of nodes	210	217	227	8.10
Number of edges	8319	10031	12071	45.10
Density	0.38	0.43	0.47	24.14
Average degree	79.23	92.45	106.35	34.23
Average shortest path	1.63	1.58	1.54	-5.84
Diameter	3	3	3	0.00
Average clustering coefficient	0.79	0.80	0.81	2.83
Betweenness	0.003	0.003	0.002	-21.50
Size of *k*-core component	99	103	113	14.14

At the disciplinary level, Figure 1 shows the growth rate for each indicator over the period studied. We can observe that SSH registers the higher increase in the number of nodes (countries) in international collaboration followed by MAT and LIF. That means that these disciplines are becoming more opened to collaborative partnerships, especially in the case of SSH and MAT. By the other hand, the low increase of PHY and BIO might be explained by the cumulative/historic participation of science. Indeed, these fields are traditionally the most collaborative in research and they are characterized by a high participation of institutions around the world (Glänzel & Schubert 2004; Abramo,

[4] UNESCO https://en.unesco.org/countries/member-states

D'Angelo, & Murgia, 2013). In all indicators, we can observe a trend already discussed in previous research. The growth of internationally collaborative papers shows that new members (countries) are entering into the global network and ties among countries are increasing (edges). Greater density of the network and the decrease of betweenness measures suggest that fewer of the communications pass through the leading countries. According to Wagner et al. (2015), this may mean reducing influence for advanced countries, and shifting of power to some "peripheral countries".

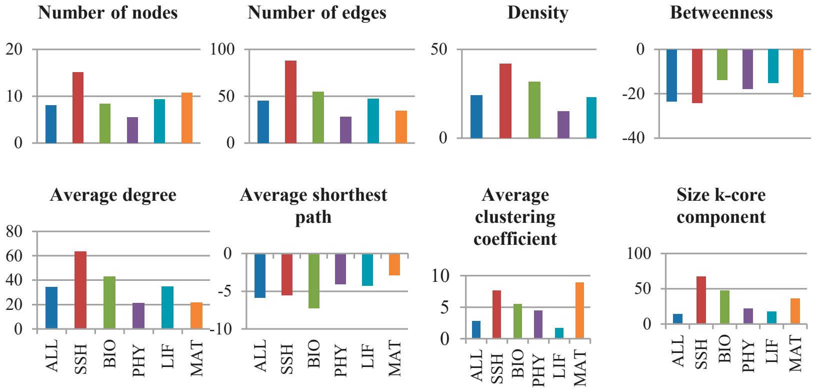

Figure 3. Network statistics by disciplines in the global network.

Collaboration diversity at the geographical level

So far, we have seen as the internationally collaborative papers are still growing in the last decade and that the network is becoming denser and more connected at the global and disciplinary level. The next step in our research is focused on regional level. We want to know how this internationalization is distributed at the geographical level, how it evolves over time and what the main strategies for building ties with partners inside or outside the region at the international level are.

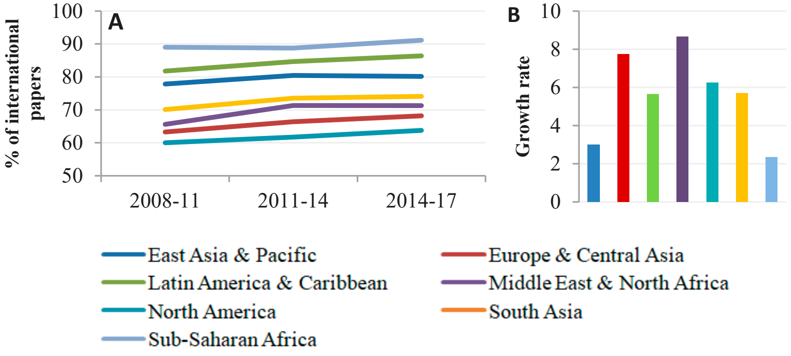

Figure 5. Percentage of papers by collaborative types and geographical regions.

Figure 5A shows the percentage of papers in international collaboration by regions. All regions tend to increase their international participation. Sub-Saharan Africa region shows the highest values in international collaboration followed by Latin America and

Caribbean. However, the regions that experienced the highest increases in their international presence are Middle East & North Africa and Europe (Figure 5B).

With country-level data in hand, it is possible to examine regional trends in global science over time to view whether large shifts occur in scientific output and knowledge absorptive capacity over geographic spaces (Wagner, 2018). The heterogeneity of countries in each group in terms of different levels of development and scientific production might affect these results. Then we expect to quantify how countries have changed (or not) their patterns of international collaboration measuring a countries' diversity of links to collaboration patterns both within their own region and with countries in other regions. As in Fitzgerald et al. (2021), we use the Shannon entropy of the distribution of collaboration partners for each country. The indicator provides values between zero and one. Values closer to one refer to countries that are collaborating evenly with many countries and values closer to zero refers to countries are collaborating with few countries. For each region, we plot the average proportion of within-region entropy (as a share of total entropy) for each region Figure 6. We observe that Europe & Central Asia shows the highest values of entropy, which means that countries from this region have increase their focus on diverse within-region collaboration. South Asia and North America present a lower diversity of partners. That might be explained by the number of countries in these regions. South Africa and North America are formed by 8 and 3 countries respectively in comparison with the rest of regions. Overall we observed a general declined over time of this tendency except for Sub-Saharan Africa. Countries from this region are intensely collaborating among them.

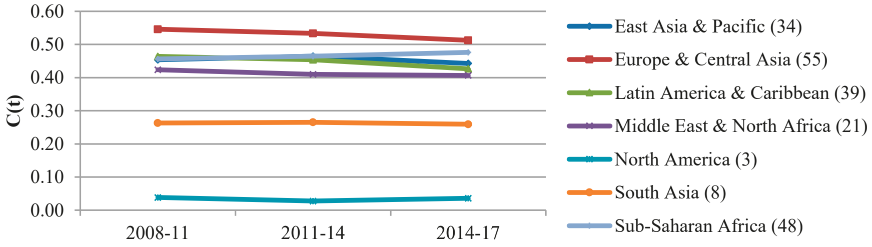

Figure 6. Within-region entropy (as a share of total entropy) results.

We plot collaboration entropy metrics within and outside of the region for each country by the final time period, with points scaled by the percentage of international collaboration. For example, in Figure 7, we can see that the South Asian countries strongly favor diverse partnerships outside their region; thus, they tend to collaborate more often with countries outside the region. Results show that almost all their production is carried out with international partners except for India, the country with the highest number of publications in the region, with the lowest percentages of internationally collaborative papers and the highest values of within-region collaboration diversity along with Maldives. We might suggest that growth of international publications in these countries is attributable to partnerships outside the region (Figure 7A). Figures 7B and 7C present the evolution over time of these two distinct strategies. We can see changes in some countries intended to opening up with their inter and intra-regional neighbors (for example, Maldives). On the other hand, there are countries that decreases intra-regional collaboration and either remain steady or decrease their inter-regional collaboration (for example, India and Pakistan respectively).

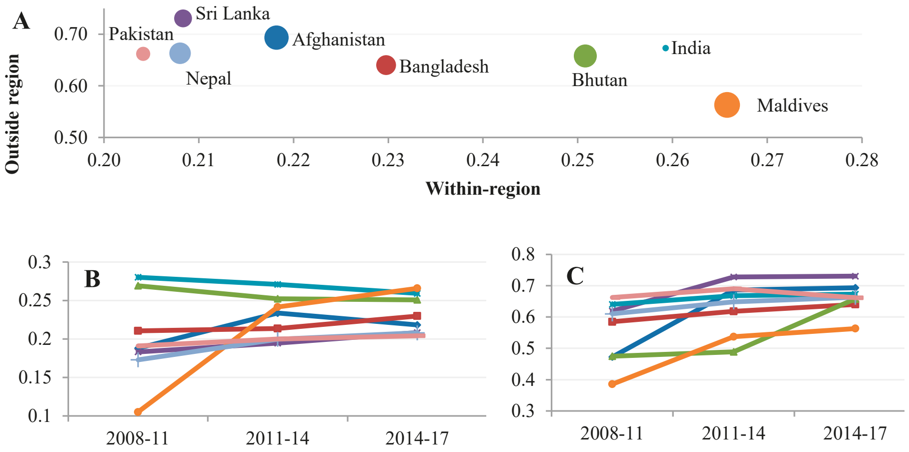

Figure 7. Inter and intra-region collaboration diversity for the South Asian countries (A); evolution over time of within-region collaborations (B) and outside region collaborations (C).

Regression analysis

Table 3 shows the regression result for the proportion of internationally collaborative publications. We see that when the number of researchers per million people and the income level is fixed, the proportion of internationally collaborative publications is negatively and significantly correlated with R&D expenditures. Yet, the number of researchers shows a positive relation with internationally collaborative paper count. Specifically, when other variables are equal, the proportion of internationally collaborative publications will increase 0.4% when there is one more researcher in every one million population.

Table 3. Regression results for the proportion of internationally collaborative publications (R Square=0.35, F=18.53, Sig.=0.00).

	Coefficient	Std.	t	P>|t|	[95% Conf. Interval]	
Intercept	98.767	5.307	18.611	0.000	88.245	109.290
R&D	-12.07	3.613	-3.341	0.001	-19.235	-4.907
Researchers	0.004	0.002	2.573	0.011	0.001	0.008

Note: "R&D" = Proportion R&D expenditures in the country's GDP. "Researchers" = Number of researchers per million population. The same below in Table 4.

Table 4. Regression results for the proportion of within-region entropy (R Square=0.05, F=4.84, Sig.=0.00).

	Coefficient	Std.	t	P>|t|	[95% Conf. Interval]	
Intercept	58.429	9.877	5.916	0.000	38.846	78.013
R&D	-13.434	6.724	-1.998	0.048	-26.767	-0.100
Researchers	0.011	0.003	3.370	0.001	0.004	0.017

Table 4 shows the regression model result for the within-region entropy. We observe that when other variables keep unchanged, the rank of within-region entropy for a country will decrease 12.3% (=13.434 / 109 [=number of countries in the regression model]) if the country increases 1% more GDP on R&D. Such an effect is significant on the 0.05 level. We also find a positive relation between the number of researchers per million population and the rank of within-region entropy for countries as well.

Discussion and conclusions

The evolution of the patterns of collaborative strategies, especially international collaboration, plays an important role in the social construction of science to design efficient research policies and to support the production of knowledge (Coccia & Wang, 2016). This study has shown the main collaborative strategies focusing on the growth of international collaboration over time at global, disciplinary and regional levels using different approaches. International collaboration in science is growing in all disciplines while the share of single-institutions papers is on the decline, which is in consonance with previous studies (Abt, 2007; Larivière et al., 2015). In terms of network analysis, the number of countries participating in the global network has growth establishing stronger partnerships, spreading influence and power more widely among countries and forming tightly knit groups. These findings are in accordance with previous studies showing that, between 1900 and 2005, the number of countries increased from 172 to 194, which represents a growth close to 13%. As long as new countries enter in the global network, this growth is decreasing and suggests that the network is not recreating political structures (Chinchilla et al., 2018; Wagner & Leydesdorff, 2005; Wagner, Park, & Leydesdorff, 2015). Our contribution here lies on the updating of temporal periods of international collaboration compared with other collaborative strategies.

Science policymakers care about the locations of national players as well as the outcomes of research, even when international collaboration seems to respond to the dynamics created by the self-interests of individual scientists rather than to other structural, institutional, or political factors (Wagner & Leydesdorff, 2005). In this study, we use the Shannon entropy as a way to determine the preference of countries to collaborate with other countries within or outside their regions showing that within-region collaboration has increased over time relative to international collaboration. We believe that these results, though preliminary, can shed light on the potential strategic programs or alliances. For example, in the cases that the diversity of collaborators increases more within regions than outside regions, a stronger regional clustering and more institutional cohesion inside the region should be observed. This is the case of Sub-Saharan countries where diversity within regions when compared to diversity between regions is increasingly higher, and the total strength of international collaborations relative to external collaborations also increases. It suggests the formation of localized regional collaboration networks. On the other hand, regions, e.g., Europe, with a high level of within-region partners seems to change the pattern over time, suggesting an opening up of global collaboration networks. However, the heterogeneity or not uniformity in scientific relationships of countries must be considered into each region

This internationalization presents policy challenges and opportunities. As internationalization of science affects the research performance of countries and, in certain degree, depends on the attractiveness of a partner in the global network, different strategies could be used to attract internal or external partners at convenience at different levels. At the individual level, the choice among forms of collaboration can be influenced by incentives and considerations concerning the organizational research system. For example, a scientist could be encouraged to privilege within-region collaborations because these will favor creation of team spirit within the workplace. In other cases, mechanisms for career advancement that reward external collaboration could encourage partnerships with regional and extra-regional colleagues (Abramo, D'Angelo, & Murgia, 2013; Acedo et al., 2006; Wagner & Leydesdorff, 2005). At the national and regional level, the forms and sources of research financing can influence the types of collaboration chosen. For example, it could encourage local- and intra-region- level collaborations, while supra-national financing and in certain cases, the incentive systems to individual organizations, can favor collaborations at the international level (Hoekman et al., 2010). A smart balance must be found between the necessary reinforcement of internal coherence, mainly around the project of collectively "discovering" the relevant specialization, and the challenge of positioning local research in the global world of science. In fact there is no contradiction if the territorial strategy is well defined (Benaim, Herauld, & Mérindol, 2016). In addition, it raises many interesting yet far-reaching questions, such as: which collaborators countries are drivers in fostering and enhancing smart specialization, clusters of innovation, absorptive capacities? Such questions deserve further investigation and suppose future research.

The current study has some limitations. First, scientific capacities of countries are driven by a combination of factors. We consider some of them, such as the income level, expenditures in R&D, and researchers. However, it is necessary to keep analyzing other factors (e.g., scientific capacities, power relationships) affecting international collaborations to better understand conditions and possibilities of the fewer developing countries to access to the global scientific network. Second, as scientific system of science is growing; the scale of bibliographical databases has grown, too, with new journals added in the collection. That means that comparisons over time might differ from current results. Third, in network analysis, the current paper does not consider whether peripheral countries are consolidating positions in the regional and global network. We plan to further study roles of countries (closeness, betweenness, etc.), in the regional and global network. Besides, as the vast differences in volume of production and scientific capacity by country complicate analyses of collaboration, we plan to analyze the temporal evolution of the exchange of knowledge between countries and the relative importance of specific countries in building ties across borders by applying similarity measures (e.g., Affinity Index, Probabilistic Affinity Index (Chinchilla-Rodríguez et al., 2021)) and combining regression analysis with other indicators. The ultimate goal is to help policy-makers in planning research agendas and collaborative alliances.

Abstract

We analyse the extent to which countries' research priorities align with their performance in the UN Sustainable Development Goals (SDGs). Our central assumption is that a misalignment between the investment in research areas and the socio-economic challenges may reduce the effectiveness of the investments in research to address those challenges. We develop a new method to identify research that is related to an SDG by examining which research areas in WoS have more publications that contain text that is related to SDG policy outlets. Then we propose a new method that combines all SDG indicators available, to measure the performance of countries in certain SDGs in relation to the top performers. Overall, we find that the SDGs' research priorities in which researchers in low and middle-income countries publish most in international journals, are not necessarily the research areas where those countries perform worst when analysing SDG indicators. SDG2 (Zero hunger) and SDG3 (Good health and well-being) are exceptions where we can find a degree of alignment, but in other challenges such as SDG12 (Responsible consumption and production) and SDG13 (Climate action), higher income countries perform worst and are not specialised in those research areas.

Motivation

Scientific research is a critical ingredient to develop knowledge-based economies, where knowledge drives productivity, social wellbeing and the achievement of socio-economic needs. Without scientific capacity, the skills and capabilities available in a country are constrained, and therefore, the ability to absorb, adapt and develop new ideas and technologies is limited.

Simultaneously, there is an increasing demand for science and research funding to be better aligned with socio-economic needs (Ciarli and Ràfols, 2019; Sarewitz and Pielke Jr., 2007). In this context, research should not be limited to frontier technologies, but the priority should be to contribute to solving our major collective challenges, that usually are more problematic in low- and middle-income contexts.

An important approach to understanding how countries and regions are making progress in solving societal challenges is to map efforts in relation to the targets and indicators set out in the seventeen 2030 Sustainable Development Goals (SDGs). These SDGs recognise that ending poverty and other deprivations must go hand-in-hand with strategies that improve health and education, reduce inequality, and spur economic growth – all while tackling climate change and working to preserve our oceans and forests.

However, from the science side, the process by which scientific endeavours influence achievements in SDGs (as well as other 'Grand' or societal challenges) is complex, distributed in space and time, and the links are usually indirect. Still, it is crucial to identify how certain research may be associated with individual objectives. Since funding resources are scarce and research funders need to make choices about the types of research they support, it is crucial to develop frameworks (as well as tools, datasets and methods) that allow for making informed choices and prioritising some research agendas over others.

In this paper, we use the SDGs to investigate the research priorities of the research systems in most countries in the World versus the main challenges they face. Our central assumption is that a misalignment between the investment in research areas and the socio-economic challenges, may reduce the effectiveness of the investments in research to address those goals, and we intend to bring prioritisation and directionality to the debate about science policy investment.

Results can help local policy makers and international donors in two crucial ways: first, to influence/support prioritisation in relatively neglected research areas, when such underinvestment may harm the achievement of socio-economic goals. Second, to have a better understanding (and more productive discussions with relevant stakeholders) of the research being prioritised, capabilities created in the country, and what reasons might have led to the absence of research in areas that are crucial to advance relevant socio-economic outcomes.

Data and Methods

We created an indicator of revealed research priorities of countries in a certain SDG[1] based on Web of Science (WoS) publication data, and an indicator of revealed socio-economic challenges of a particular country in a certain SDG based on a combination of indicators associated to the SDGs. Below we describe how we calculate the indicators that allow analysing these two dimensions.

Revealed research priorities by country in each SDG

Scientific publications were assigned to a specific SDG using a 2-step method developed by the authors. First, we build a query with a set of terms (or combinations of terms) that are strongly associated to a specific SDG. Second, we use those SDG related queries to search publications in WoS research areas that are generated by citation relations between all WoS publications in 2015-2019. Since these research areas are obtained from a publication-level clustering algorithm based on direct backwards and forward citations, the advantage of this approach is that these clusters can be seen as a community of papers that address (or are related to) a specific area/field. In comparison, a query-based approach is only able to identify individual publications. Our approach allows to include relevant publications that do not explicitly use a specific SDG query term in their abstract/title, because they use a slightly different language, or focus on an issue that was not explicitly mentioned in SDG policy reports and publications. For instance, with reference to health and well-being (SDG3), policy documents may refer to some tropical diseases, but not all of them. Our approach allows to expand the initial set of publications to other publications that are closely related. Since research is cumulative and the communities/groups of researchers are the ones able to solve a certain challenge (instead of a specific paper), we believe this approach is more adequate for our research question.

The methodology used to obtain a final list of keywords per SDG consists of a series of steps. In the first step, we selected texts from various sources that contained descriptions of specific SDGs. Instead of relying only on official UN sources to identify relevant terms, we chose to search a wide array of policy reports, grey literature, scientific publications, web forums and official UN sources. In this way, we aim to capture a broader understanding of SDGs that is shared in different types of publications and authors. We then extracted relevant fragments

[1] We decided to only include 16 (1 to 16) out of the 17 SDGs, because SDG17 deals with “Strengthening global partnerships and enhancing the means of implementing the Goals” which is very difficult to operationalise in terms of defining a query of terms strongly associated to that goal.

from these texts, which referred to a particular SDG and met a certain criterion.[2] This step allowed us to exclude text content that is not SDG specific and text that is about more than one SDG. Once selected, we partitioned the text referring to an SDG in different entries, respecting the authors' different ideas. Afterwards, we selected relevant keywords within these pieces of text using a combination of Textrank and Vosviewer algorithms. Finally, we carried out a manual selection of the keywords extracted through these filters and shared these lists with other team members and experts to check for missing or irrelevant terms.

After validating all 16 SDG queries, we applied those queries to the CWTS WoS dataset, in a sub selection of publications from 2015-2019, to search clusters of publications (research areas) strongly associated with each other by their backward and forward references. We use a classification system generated by Waltman and Van Eck (2012) at CWTS that separates all WoS in 4013 micro-clusters of publications. The algorithmically created clusters at this level prove to be an optimal granularity for normalisation (Ruiz & Waltman, 2015) and to be described by automatic labels and hence the preferred level to be used in our study. Then we run our 16 SDG queries in all publications of those clusters, to check which of the research areas have a high share of publications which include our SDG related text in their abstracts and titles. We then associated with a certain SDG all publications that belong to a cluster that has a relatively high share of publications with a certain SDG query term. Given that different SDGs required different parameters (shares), together with other team members and experts, we decided to define two thresholds for each SDG to allow for robustness checks later on:

1. Min threshold (Loose): the share of seed publications (containing the SDG keywords) over all publications in the research area that identifies a relevant number of research areas related to the SDG, among some non-relevant areas, based on information contained in the cluster labels[3] (micro and meso clusters) and in a sample of top publications (not containing the SDG keywords) against the SDGs targets.
2. Max threshold (Strict): the share of seed publications (containing the SDG keywords) over all publication in the research area that identifies only research areas that are strictly related to the SDG, based on information contained in the cluster labels (micro and meso clusters) and in a sample of top publications (not containing the SDG keywords) against the SDGs targets.

After this first initial analysis of what clusters are associated to what SDGs, we compared our results with the results obtained using the publicly available queries from the SIRIS approach.[4] By checking the differences between "loaded" clusters using the two approaches, and analysing the labels of those clusters, this comparison allowed us to improve our:

- Recall (type II error, false negative), namely clusters that should be associated with a certain SDG but are not with our current approach (queries).
- Precision (type I error, false positives), namely publications clusters that are currently being associated with a certain SDG but shouldn't.

After comparing our results using the two approaches and changing some of our terms to improve recall and precision, we recalculate the min-max thresholds and use the final set of

[2] These fragments must contain text referring specifically to at least one SDG. The text must refer to problems associated to the SDG(s), making a clear connection between the problems and Goal(s) (e.g. using the term "Sustainable Development Goal" in their analysis of the problem). References to "sustainability" alone were not considered sufficient for the document to be included. References to issues associated to the SDGs (e.g. poverty or hunger) but with no explicit mention of the SDGs were also not considered sufficient for the document to be included.

[3] The analysis of most frequent keywords from relevant clusters in both approaches was crucial to check differences and understand which terms retrieve which clusters.

[4] http://science4sdgs.sirisacademic.com/

research areas per SDG to do our country analysis. In this paper, results correspond to our Max thresholds only for simplicity. We ran a sensitivity analysis between Min and Max thresholds and the correlation of results between the two is extremely high. Each SDG specific thresholds can be provided upon request, and the platform[5] that we use to understand which publication researcher areas are associated with an SDG is openly available (Rafols et al., 2021)
The metrics for comparisons between countries are created based on address criteria, using fractional-counting method (counts are weighted by number of authors' countries and we only consider independent countries that have more than 500 publications in 2015-2019). Revealed research priorities of countries by SDG are calculated using a comparative specialisation index (Balassa, 1965) that allows to check if a country's research is more or less specialised in a certain SDG than the world average (Ciarli and Ràfols, 2019). Later we normalise this estimate of research specialisation between -1 and 1 (1 = High specialisation; -1 = Low specialisation) to be able to compare it with the revealed challenges.

Revealed challenges by country in each SDG

To analyse the performance of countries in different SDGs, we build an index per SDG that combines data from two different sources: i) UN SDG database; ii) SDG Index. We check which indicators have fewer missing values for all countries and years of interest and build a unique dataset with 80 different indicators. After compiling this dataset of indicators per SDG, we run a principal component analysis per SDG to obtain a single score by country/SDG for which data is available.[6] We followed the next steps:

- For the selected indicators, we calculate the logarithm of those that are not percentages or indexes (e.g. per capita)
- Then, we do a linear transformation, by converting each indicator/country to a score between 1 (Best) and 0 (Worst):

$$n_{cti} = \frac{Worst_{ti} - x_{cti}}{Worst_{ti} - Best_{ti}} \quad \text{c (country), t (period), i (indicator)}$$

- We reverse some variables for consistency, forcing higher values to represent better results.
- For each variable, we calculate the relative distance ($d_{cti} = p95_{ti} - n_{cti}$) of each indicator/country to the frontier of that indicator (top5% - percentile 95), and we changed all values below zero to zero. After this transformation, higher values represent worst results with respect to the SDG targets (higher challenges relative to countries at the frontier).
- We calculate z-scores for each relative distance to the frontier (top5%).

$$z_{cti} = \frac{d_{cti} - \mu}{\sigma} \quad \mu\text{(average)}, \sigma\text{(std. deviation)}$$

- We compute a principal component analysis (PCA) (Jackson, 1991) for each SDG with more than one indicator available, and we forced the PCA to estimate only one component per SDG (eigenvalues and eigenvectors can be provided upon request).
- We predict the scores of all SDGs for all countries and we normalised the results between -1 (High performance) and 1 (1 = Low performance).

[5] https://public.tableau.com/profile/ed.noyons#!/vizhome/UKStringsSDGtocommunities/Dashboard1

[6] In this version we present results for the period 2008-2017, which is when we are able to get more data points for most countries/years. In the conference we are planning to present results also for time dynamics between two separate periods (2008-2012 and 2013-2017).

Countries with low performance in a specific SDG can be seen as those furthest away from the "frontier" in that specific SDG, meaning that those countries have a higher socio-economic challenge in that SDG. Countries with high performance are those at the "frontier" that are the best performers in that specific SDG.

Preliminary results

We start by analysing descriptively how many publications per SDG exist in the World, according to our approach, and how certain income country groups perform a larger share of SDG research than others. In the second part, we graphically analyse the relation between SDG research priorities and SDG challenges for all countries for which data is available.
According to our approach (using both the strict and loose threshold), during 2015-2019, the research in WoS that is related to at least one SDG is between 30% (strict threshold) and 50% (loose threshold). The remaining research can be seen as research not directly related to the SDGs' targets, indicators and objectives.

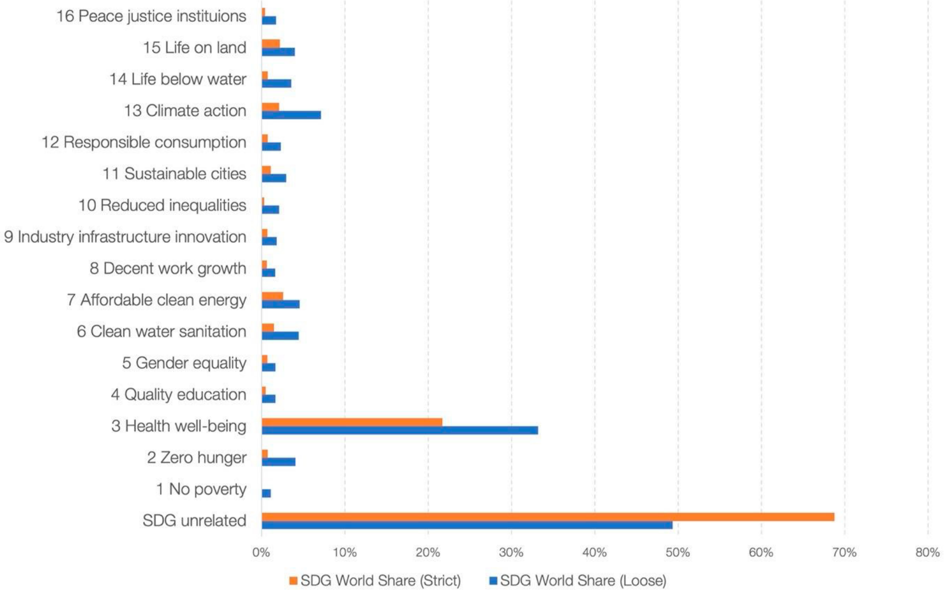

Figure 1. Share of publications associated to an SDG between 2015 and 2019 in the World.
Source: WoS

In Fig. 1, we observe that SDG3 (Good health and well-being) is the SDG with higher share of research associated to it. At the other spectrum, we find that SDG1 (No poverty) is the SDG with lower share of research associated to it. It is important to note that research related to a specific SDG can be about numerous issues. For example, in SDG3 (Good health and well-being) we find a lot of research related to cancer, cardiovascular diseases, infectious diseases but also some research related to social sciences (e.g. mental health) and ambient air pollution. Therefore, it might be the case that within a SDG there might be specific misalignments of research priorities versus societal challenges if, for example, most of the research in SDG3 is related to diseases that are not the ones that generate more burden globally (Confraria and Wang, 2020; Evans et al., 2014; Yegros et al., 2019). Another aspect worth noting in Fig.1 is results depend greatly on the threshold used. For example, the amount of research related to SDG1 while using the loose threshold is more than 15 times higher than while using the strict threshold. In SDGs 3 (Good health and well-being), 7 (Affordable and Clean Energy) and 15 (Life on Land) the differences are not that large (< 2 times). This finding relates to the idea that there is a variety of understandings regarding the connection between research and SDGs, and this might change across SDGs (Armitage et al., 2020).

In the next analysis we will only present results using the loose threshold to allow a broader understanding of what is SDG related research. One aspect worth analysing is if the distribution of SDG related research differs across country income groups. It might be the case that some country groups are more specialised in specific SDG related research than others. In order to have a general overlook at these differences, in Fig. 2 and Fig. 3 we calculated how much SDG related research is done by researchers in countries belonging to different World Bank income groups (high, upper-middle, lower-middle and low income).

As expected, the vast majority of research is done by high and upper-middle income countries (>90%) which represent around 56% of World population during the same period. The 29 low-income countries in our set, participate in a residual share of research across SDGs, although they seem to be relatively specialised in it. Their percentage is slightly higher in SDG1 (No Poverty), SDG2 (Zero Hunger), SDG5 (Gender Equality) and SDG3 (Good health and well-being) which represents more than 50% of all the research done in the region. Regarding our 104 middle-income countries (upper and lower), they seem to be less specialised than the other regions in research related to SDGs in general, but are relatively specialised in SDG6 (Clean Water and Sanitation) and SDG7 (Affordable and Clean Energy), and less specialised in SDG5 (Gender Equality), SDG10 (Reduced Inequalities) and SDG16 (Peace, Justice and Institutions). Please note that this middle-income group includes large countries such as China, India, Brazil and Russia that during the same period comprise around 75 to 80% of World population. The other 72 high-income countries produce the majority (>50%) of research in all SDGs, but seem to be particularly specialised in SDG16 (Peace, Justice and Institutions), SDG10 (Reduced Inequalities), SDG5 (Gender Equality) and SDG4 (Quality Education).

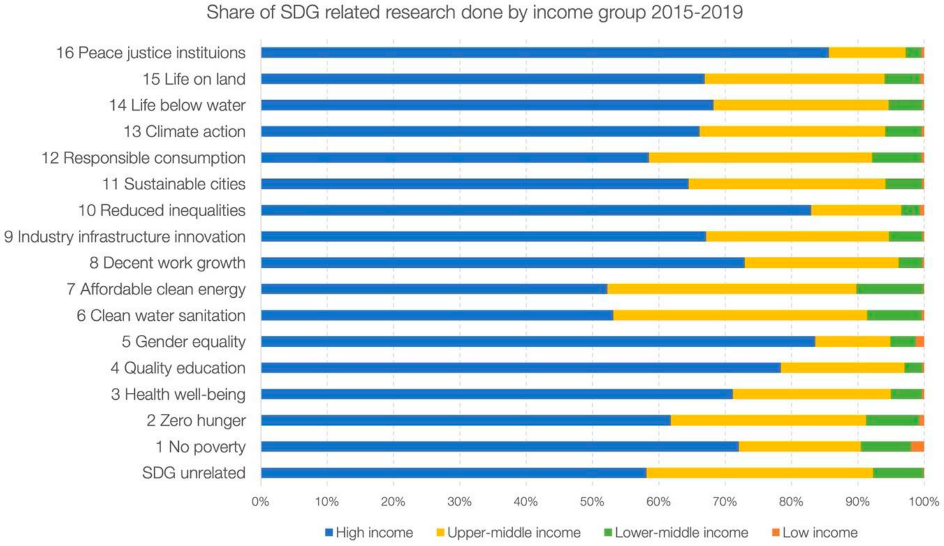

Figure 2. Share of publications associated to an SDG by income group between 2015 and 2019

Source: WoS

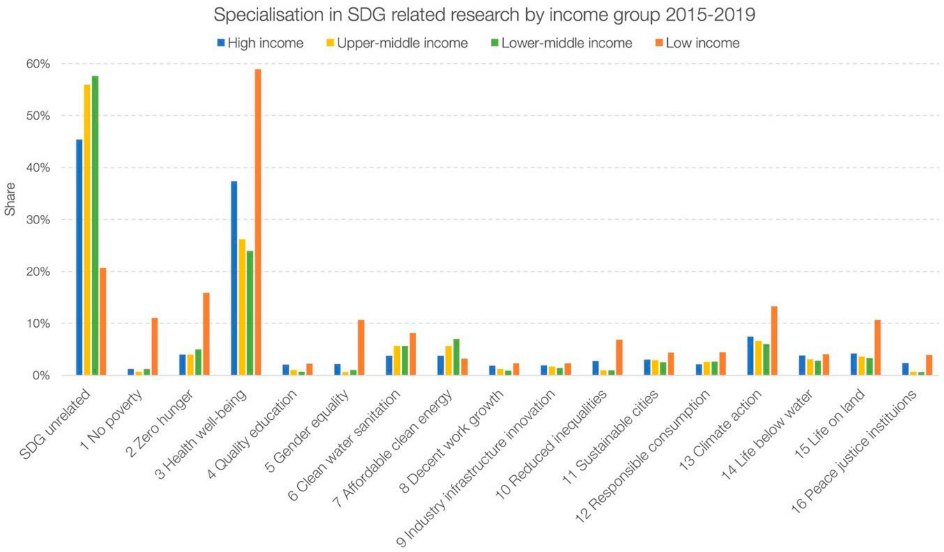

Figure 3. Revealed SDG research priorities by income group between 2015 and 2019
Source: WoS

Having analysed the research priorities in all countries across SDGs, our next step is to estimate which are the SDGs that are more problematic in each country (and country groups). Following the method illustrated in Section 2.2 for each SDG we created an index between -1 (the country is among the best performers in the world - top5%) and 1 (the country is the worst performer in the world).

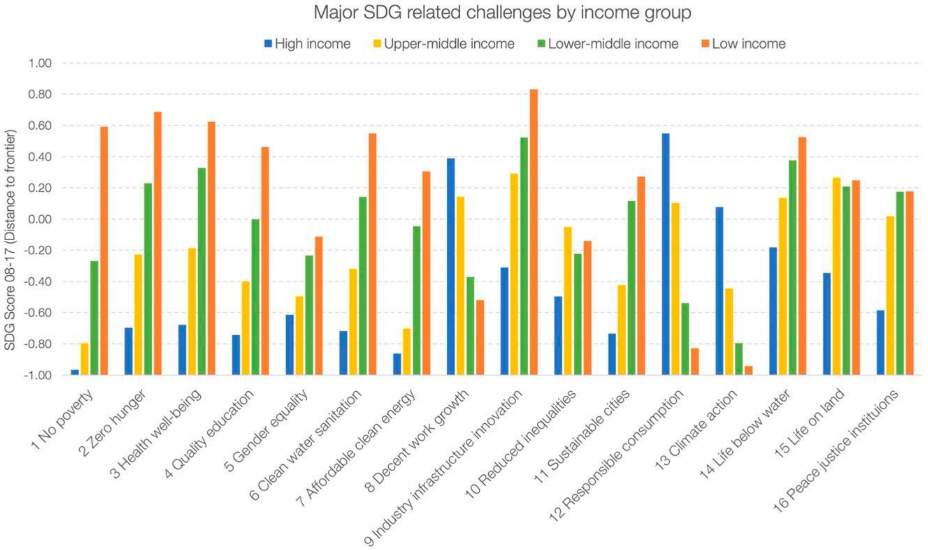

Figure 4. Revealed SDG challenges by income group between 2008 and 2017
Source: Own calculation based on UN, SDG Index and World Bank data.

Fig. 4 summarises our findings per country income group. Overall, as expected, low-income countries perform worst (further away from the frontier) in most SDGs. The exceptions are SDG12 (Responsible Consumption and Production) and SDG13 (Climate action) in which higher income countries are further away from the frontier (top 5% performers). These differences relate, for example, to the high level of domestic material consumption and waste per capita (SDG12), and high levels CO2 emissions per capita (SDG13) generated by higher income groups. Another interesting finding is that in SDGs 8 (Decent work and economic growth), 10 (Reduces inequalities) the differences between income groups are not substantial. The next question we explore is whether the SDG research specialisation of all countries, for which there is data, is related to the major challenges they face using the SDG Indicators. We use an indicator of SDG revealed research priorities discussed in section 3.1 (1 = highly specialised in research related to an SDG; -1 = no research performed related to an SDG) and an indicator of relative SDG challenge discussed in 3.2 (1 = Major challenge, country furthest away from the "frontier" in this SDG; -1 = country at the "frontier" in this SDG). Using these two dimensions we plot the scores of all countries in a specific SDG. Our major findings are the following and also derive from a pairwise correlation table in the appendix (Table A.1.):

- Linear positive correlations were found between research priorities versus countries challenges in SDG2 (Zero hunger)[7], SDG3 (Good health and well-being)[8] and SDG6 (Clean water and sanitation)[9], meaning that the countries that are further away from the frontier in these two SDGs, are the ones that are relatively more specialized in research related to these SDGs. In SDG2 and 3, these were expected findings given the long-term research specialisation that lower income countries have on Health and Agricultural Sciences (UNESCO, 2015).
- A positive but non-linear (log) correlation was also found in SDG1 (No Poverty), meaning that most countries in our sample don't suffer problems related to poverty, but the ones that do, seem to be relatively specialised in poverty related research.
- A negative correlation was found between research priorities versus countries challenges, to a certain extent in SDG4 (Quality Education), SDG7 (Affordable and Clean Energy), SDG12 (Responsible Consumption and Production), SDG13 (Climate Action). This means that the countries that are further away from the frontier in the indicators that compose these SDGs are the ones that have lower research specialisation in these SDGs.

Overall, we couldn't find a specific alignment/misalignment pattern between SDG research priorities and SDG challenges across countries. In some SDGs (1, 2, 3 and 6) there is a certain degree of alignment probably related to international research funding patterns in lower income countries (Confraria and Wang, 2020), that support research that is relevant to the major challenges in those countries. In other SDGs (e.g. 12, 13) high-income countries are, on average, further away from the frontier and they are not relatively specialised in the corresponding SDG research as the other countries.

The previous analysis gives us a broad picture, at SDG level, about levels of alignment between SDG challenges and SDG revealed research priorities in all countries. The next question we explore is whether the SDG research specialisation of specific countries is related to the major

[7] Targets related to levels of hunger, malnutrition, agricultural productivity, sustainable food production systems, genetic diversity of seeds, etc.

[8] Targets related to levels of maternal mortality, neonatal mortality, health access, disease burden, end of epidemics, etc.

[9] Targets related to wáter use efficiency, population using basic sanitation services and drinking water services, proportion of population practicing open defecation, etc.

problems they face using the SDG Indicators. Answering this question might provide guidance to rebalance research priorities towards topics closer to countries' major challenges.
As an example, we perform this analysis for three countries belonging to three different income groups (Ethiopia – Low income, India – Medium income, Germany – High income).
Our major findings in Fig. A.1. (in Appendix) are the following:

- Ethiopia shows a partial alignment. It faces significant challenges in several SDGs: SDG1 (No poverty), SDG2 (Zero hunger), SDG 3 (Good health and well-being), SDG4 (Quality education), SDG6 (Clean water and sanitation), SDG7 (Affordable and clean energy), SDG9 (Industry, infrastructure and innovation) and SDG15 (Life on land). But Ethiopia's researchers are also relatively specialised in research related to most of those SDGs. The exceptions are SDG4 (Quality education) and SDG7 (Affordable and clean energy), which are SDGs where Ethiopia has a high burden in relation to other countries.
- Our analysis shows that India faces significant challenges in SDG2 (Zero hunger), SDG 3 (Good health and well-being), SDG 5 (Gender equality), SDG6 (Clean water and sanitation), SDG11 (Sustainable cities), SDG14 (Life below water) and SDG15 (Life on land). In terms of research priorities India is relatively specialised in research related to SDG6 (Clean water and Sanitation), SDG7 (Affordable Clean Energy) and SDG12 (Responsible consumption and production). Major challenges in India such as SDG14 and SDG15 doesn't seem to receive a lot of attention in terms of relative research priorities.
- Germany seems perform worst in SDG12 (Responsible consumption and production) and SDG13 (Climate action) as most high-income countries, and their research specialisation seems to be in line with the World's average (0).

Overall, we find that higher-income countries are closer to the frontier in most SDGs (SDG 12 and 13 are exceptions) and have SDG research specialisation patterns closer to the world average. Lower-income countries present higher volatility in terms of SDG research priorities and SDG challenges.

Discussion

This paper provides a new way of exploring the extent to which countries' research priorities align to their major SDG areas of challenge. Our motivation is that there is an increasing demand for science and research funding to be better aligned with socio-economic needs, but there are very few robust methods (and datasets) that help policy makers to understand these relations. We develop an approach based on citation relations that define research areas allowing us to understand if a country is generating research (based on WoS data) relevant to their societal challenges (based on SDG indicators). We found that around two thirds of research that is done in the World in 2015-2019 is unrelated to the issues addressed in the SDGs. However, when we look at the research specialisation of specific countries by income group, we find that, on average, lower-income countries seem to perform more research on SDG issues in relative terms.
Our findings also indicate that there is a positive relation between SDG achievements by country and SDG research specialisation in specific SDGs such as SDG2 (Zero hunger) and SDG3 (Good health and well-being), meaning a certain degree of alignment between research priorities and SDG achievements across countries in these SDGs areas. However, it is essential to emphasise that these two SDGs are quite broad, and one could argue that certain types of research within those SDGs should be prioritised instead of others (Confraria and Wang, 2020; Yegros et al., 2019).

We instead found a negative relationship between research prioritisation and SDG challenges for SDG4 (Quality Education), SDG7 (Affordable and Clean Energy), SDG12 (Responsible Consumption and Production) and SDG13 (Climate Action). In the cases of SDG12 and SDG13, the countries that perform worst are high-income countries that seem to have unsustainable consumption/production patterns and contribute more to climate change. However, the countries that seem to be relatively specialised in these themes seem to be lower income countries. As for SDG 4 and 7, on average, lower-income countries seem to be the ones that face major challenges in these dimensions, being also the ones that are less specialised in research that is related to those challenges. Such misalignment between the investment in research areas and the socio-economic challenges in these SDGs/countries may reduce the possibilities of improvements in those challenges in those countries, as these countries need to rely on research capabilities developed elsewhere, where the issues faced may be different.

Lastly, this study has several limitations related to the accuracy of our estimates of SDG research priorities of countries and SDG challenges faced by them. Yet, one thing we would like to emphasise, that is particularly important for future research, is related to the marginal impact of increasing research investments in areas related to a certain SDG on the improvement of that SDG. This impact may not be the same for all SDGs. For example, local research in health (SDG3) may lead to significant improvements in the health outcomes of a country. In contrast, more local research on Poverty (SDG1) may not lead to similar marginal improvements. Future research should look carefully at this issue and consider spillovers between SDGs and positive and negative interactions between them. These may guide research prioritisation and building of research capabilities to address different challenges.

Dissension or consensus? Management and Business Research in Latin America and the Caribbean

Julián D. Cortés

julian.cortess@urosario.edu.co
Universidad del Rosario, Colombia
Fudan University, China

Abstract

This study presents longitudinal evidence on the dissension of Management and Business Research (MBR) in Latin America and the Caribbean (LAC). It looks after intellectual bridges linking clusters among such dissension. It was implemented a coword network analysis to a sample of 12,000+ articles published by authors from LAC during 1998-2017. Structural network scores showed an increasing number of keywords and mean degree but decreasing modularity and density. The intellectual bridges were those of the cluster formed by disciplines/fields that tend toward consensus (e.g., *mathematical models*) and not by core MBR subjects (e.g., *strategic planning*).

Introduction

The Winchester Mystery House has been used as an analogy for Management and Business related Research (MBR) —a purposeless although expensive entity (Davis, 2015). The hypothesis of the Hierarchy of Sciences states that while some sciences/disciplines studying simple phenomena (i.e., cells' functioning) will tend toward consensus, others studying complex phenomena (i.e., human collective behavior) will tend toward dissension (Fanelli & Glänzel, 2013). Thus, the latter path should be shaping MBR. Bottom line, dissension fragments research findings to advance on —a significant downsize effect for regions with scarce R&D resources such as Latin America and the Caribbean (LAC) (Cortés-Sánchez, 2019).

This study aims two-fold: i) to explore such dissension in MBR in LAC; ii) and to identify potential *intellectual bridges* to pooling efforts and multiply impact. I implemented the coword analysis (Callon et al., 1983). Such a science mapping (SM) technique enables stakeholders to map individual/institutional/national research and knowledge competencies (Shiffrin & Börner, 2004). Findings would be of interest to researchers in MBR, business schools, and funders by presenting the first comprehensive regional study for MBR to identify research clusters, topics as intellectual bridges between disciplines, and their evolution since 1998.

Methodology

This study modeled four coword networks for the periods 1998-2002, 2003-2007, 2008-2012, and 2013-2017. Dissension paths were explored by computing and comparing macro, meso, and micro structural network scores. Dataset and high-resolution figures are available in open access for replication and further use (Baker & Penny, 2016): http://bit.ly/2QyDJNP

Data

Bibliographic data was sourced from Scopus due to its journal coverage and LAC authors' involvement (Mongeon & Paul-Hus, 2016). The query searched for articles published from 1998 to 2017 by at least one author affiliated with any LAC institution in SCImago's *business, management, and accounting* subject area (SCImago, 2020). The final sample consisted of 12,149 articles after removing a journal with predatory features (Cortés-Sánchez, 2019) and articles with missing data. Table 1 presents the bibliometric descriptives for the top-10 LAC countries by output.

Methods and software

Coword analysis enables putting together the conceptual structure based on the co-occurrence of articles keywords (Callon et al., 1983). *KeyWords Plus* method generates key-terms based on the articles' title and the references cited appearing more than twice (Clarivate Analytics, n.d.). A link connects two keywords (i.e., nodes) if both appear in the same research article (i.e., edge). The scores computed for the coword networks were: i) macro: density, mean degree, modularity; ii) meso: number of clusters; iii) and micro: betweenness (Scott & Carrington, 2014). Density is the proportion of links in a network relative to the total number of links possible. The mean degree is the average number of links per node in the network. Modularity express a networks' strength of cluster division. Increasing values indicate the existence of a community-like structure. Clustering analysis identifies highly interconnected nodes to uncover known communities. Betweenness unveils a node's capacity in mediating the flow of information in a network. Increasing values indicate a higher betweenness. Bibliometrix (Aria & Cuccurullo, 2017) and Gephi (Bastian et al., 2009) were used for networks' layout and scores' computation.

Results and discussion

Figure 1 summarizes the macro, meso, and micro scores for each network. The period 2008-2012 stands out as the network with the highest increase in the number of nodes (198%), mean degree (55%), and clusters (39%). Density and modularity, however, diminished by 50% and 2%, respectively. The networks' density and modularity had decreased throughout 1998-2017 despite the mean degree's uninterrupted growth. The number of clusters peaked in 2008-2012 (39) and reached the lowest point in 2013-2017 (22).

Ronda and Guerras (2012) found that density and clusterability, a modularity proxy, have increased between 1962-2008 for the *strategic management* coword network. That seems plausible for an MBR sub-field. Using bibliographic coupling, Fanelli and Glänzel (2013) computed a mean degree and modularity for the field of *business and economics* of 27.3 and 0.5, respectively, which were similar to the mean degree of 2008-2012 (29.6) and the modularity of 2013-2017 (0.53). The caveat is that bibliographic coupling networks are different from co-word analysis, the latter similar to that of cocitations (Yan & Ding, 2012).

Figure 2 presents the four coword networks. Nodes' size is proportional to their betweenness. Nodes with labels are: i) those among the top-10 betweenness; ii) those that increased their position among the top-20 betweenness compared to the previous period (light-green colored); and iii) those that decreased their position among the top-20 betweenness compared to the previous period (red-colored). Clusters colored in burgundy and pine-green are the first and second-largest ones, respectively. I tagged clusters manually following a discernible thread among highly connected keywords. The two most crowded clusters for each period were:

i) 1998-2002: *mathematical models, computer simulation, and algorithms* (18% nodes), and *science, technology and innovation* (STi) (10%);

ii) 2003-2007: *LAC issues* (15%), and *strategic management for sustainable development* (15%);

iii) 2008-2012: *STi in LAC* (10%), and *mathematical models, computer simulation, and algorithms* (9%); and

iv) 2013-2017: *strategic management for sustainable development* (22%); and *logistics* (14%).

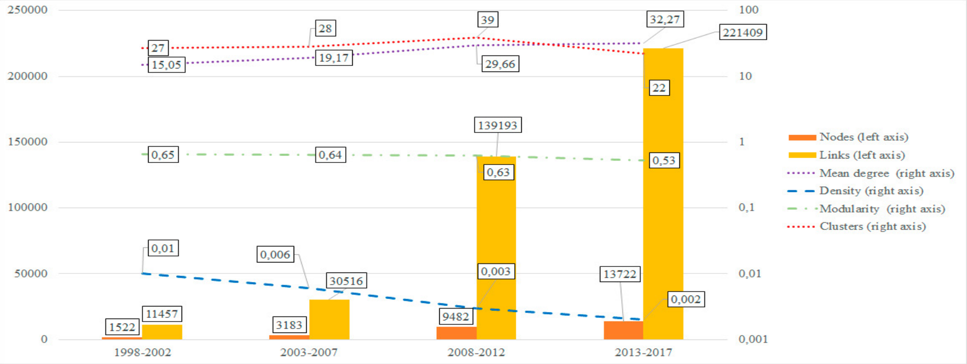

Figure 1 Nodes, links, density, modularity, and clusters of coword networks 1998-2017. Source: elaborated by the author based on Scopus (2020).

Table 2 (Appendix) presents the top-20 keywords by period according to their betweenness. Topics comprised of *mathematical models, computer simulation*, and *algorithms* cluster show consistent appearance among the four periods. *Sustainable development* and *environmental impact* related issues also showed consistent appearances. In contrast, MBR core topics, such as *strategic planning*, *quality control*, or *marketing*, showed either intermittent appearances or a downward trend.

Crowded clusters mixed between each other (e.g., STi *plus* LAC issues ⇒ STI in LAC) and specific keywords persisted (e.g., mathematical *models, computer simulation, and algorithms*; or *strategic management for sustainable development*). Contrasting those findings with the persistence and higher betweenness of the *mathematical models,* it unveils the broader applications of such methods for MBR and other disciplines (e.g., from supply chain management to e-commerce and genetics), even more than influential methods in MBR such as *case study* (actually, copied from medical sciences) (Eisenhardt, 1989). Furthermore, global solution-oriented agreements such as the Sustainable Development Goals produced inflections in the research output and permeated MBR in LAC and other developing regions (Cortés-Sánchez et al., 2020).

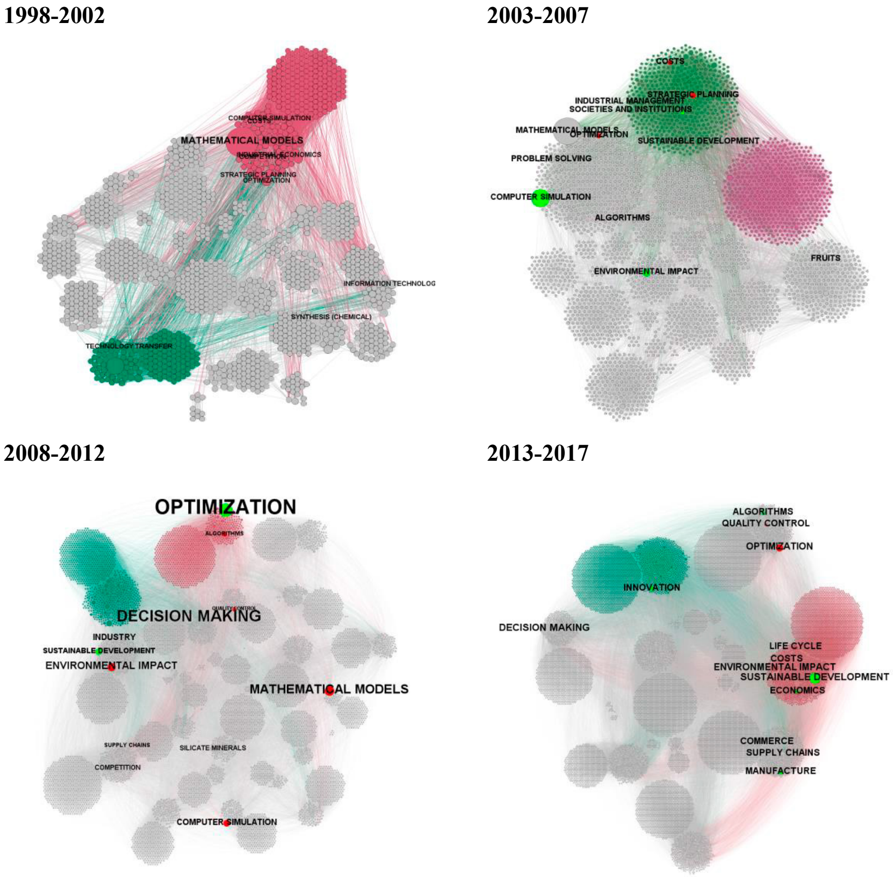

Figure 2 Coword networks 1998-2017. Layout: circle park (hierarchy 1: modularity class; hierarchy 2: betweenness). Source: elaborated by the author based on Scopus (2020) and computed with bibliometrix (2017) for R and Gephi (2009).

Conclusion

This study presented longitudinal evidence on the increasing dissension path of MBR in LAC. Also, it presented the mixture and persistence of crowded clusters and intellectual bridges. Such bridges were not from MBR but different disciplines moving toward consensus (e.g., mathematics or physics). Further research could implement non-redundant SM techniques such as social (i.e., coauthorships) or information (i.e., bibliographic coupling) based networks, discuss the advantage and obstacles of open vs. closed network structures, and source data from broader and inclusive bibliographic databases (e.g., Google Scholar or Dimensions).

Abstract

Books and evaluations thereof are essential components of the research system. Despite existing efforts to use citation-based metrics to evaluate books, we argue that a more effective book evaluation system should focus on the entire lifecycle of book publication, not just the final products. Building on this idea, we here present the preliminary results of an ongoing project aimed at establishing such a system. As the first step of this project, we analysed ISBNs used for book outputs submitted to two national research evaluation systems, the UK Research Excellence Framework 2014 and the formal Lithuanian research assessment for 2004–2016. By conducting this analysis, we investigate whether and how ISBNs might be used as a reliable identifier in collecting bibliographic data, which will then serve as the foundation of the new book evaluation system. We describe our approach to ISBN collection, processing and analysis, and discuss the suitability of ISBNs for our purposes. Notably, we found ISBNs a handy indicator, given their relevant ubiquity in the book-centric bibliographic universe. However, processing ISBNs from existing systems is very time-consuming and requires extensive manual effort, which calls for a better book bibliographic data infrastructure.

Introduction

The evaluation of books is critical to the research assessment system because books are an important type of research output (Giménez-Toledo, Mañana-Rodríguez, & Tejada-Artigas, 2015; Kulczycki et al., 2018; Zuccala & Robinson-García, 2019). Usually, book evaluation is carried out by experts, who either assess book publishers or review individual books (Giménez-Toledo et al., 2019). However, ambiguous rules in book publishers' rankings (Dagienė, 2020) and institutional competition for funding have led to gaming the system (Aagaard, 2015; Mouritzen & Opstrup, 2020; Rowlands & Wright, 2019). Several studies have suggested that book metrics can help counteract a certain degree of academic bias in book assessment (Faggiolani & Solimine, 2018; Williams, Basso, Galleron, & Lippiello, 2018).

Quantitative indicators for books have been gaining momentum in recent years. Various approaches have been taken to investigate these metrics; most focus on the ex-post assessment of books and their impact (Liu, Ding, & Gu, 2017; Torres-Salinas, Robinson-Garcia, & Gorraiz, 2017; White & Zuccala, 2018; Zhou & Zhang, 2020). Thus far, it seems that only evaluation labels proposed for identifying peer-reviewed publications (Kulczycki et al., 2019) provide an ex-ante solution for measuring book quality.

After investigating criteria, processes, and practices for assessing book publishers across countries, Dagienė (2020) suggested a new approach to book evaluation. This model accounts for the value that book producers add to a manuscript at different publishing stages (e.g., quality control, production, dissemination, archiving, and marketing)—assuming here that it is the stages that are deemed essential for effective scholarly communication (Publications Office of the European Union, 2019).

Different publishers do not contribute equally to each step of book production. For example, (1) not all publishers conduct peer review, so there is a need for unique labels (Kulczycki et al., 2019); (2) many publishers do not edit submitted manuscripts, which they deem the authors' responsibility; (3) some publishers do not consider long-term archiving necessary, and some publishers do not consider digital formats necessary at all. Still other essential parts of book production important for the future of scholarly communication (Kraker et al., 2016), such as open access or understandability, are not even considered in research evaluation.

Ideally, publishers need to offer information on their contribution in each step as part of the book metadata. The availability of such information would allow book outputs to be evaluated without relying on general book publisher information (such as editorial board members, peer-review procedures, and the publishing programme).

Moreover, since this new approach to book assessment works on the book (not publisher) level, we suppose that the ISBN Standard (already established in the book industry) will be the core of this approach. However, such a system's optimal implementation process still needs to be considered from many perspectives.

This research-in-progress paper addresses only one goal of the ongoing project, namely, assessment of the use of ISBNs as the primary book identifier for such a system. The broader aims of our project are: (1) to determine how much metadata about books is available in various sources; (2) to identify the publishers of books submitted by research institutions as their research outputs; and (3) to examine the extent to which these publishers have provided high-quality metadata at the level of individual publications.

In this paper, we pursued the following questions as initial steps in the above research agenda:
(1) How many books submitted to research evaluations have ISBNs that can be used to gather their metadata?
(2) What are the reasons for missing ISBNs?
(3) How can the use of ISBNs in research evaluations be improved?

This paper provides the results of our efforts to obtain book metadata based on the ISBNs collected in national research evaluation exercises. We also report issues in collecting and processing ISBN data.

Having a collection of valid ISBNs is an essential step towards constructing a book evaluation system that focuses on the individual components of the publication workflow and can be implemented automatically.

Research design

Many researchers have examined the sources of books' bibliographic data (Halevi, Nicolas, & Bar-Ilan, 2016; Torres-Salinas & Moed, 2009) or book metrics (White et al., 2009; Zhu, Yan, Peroni, & Che, 2020). Unfortunately, in the databases explored to date, it is impossible to obtain a comprehensive sample of books and publishers, so as to evaluate all possible variations of book outputs and their publishers at the country level. In this study, we used openly available data on books already submitted by academic institutions as part of national research evaluation exercises. Specifically, we used data from two evaluation systems that recognise books as institutional research outputs and empower experts to assess submitted books at the individual level. These are the UK Research Excellence Framework 2014 (REF 2014)[1] and the formal Lithuanian annual assessment, whose data span two databases ranging from 2004 to 2016 (Dagienė, 2020; Dagienė, Kriščiūnas, Tautkevičienė, & Maskeliūnas, 2019).

Bibliographic information on Lithuanian book outputs was derived from databases managed by the Lithuanian Research Council: (1) Dynamics of Lithuanian Research Potential[2] for outputs published 2004–2008 and (2) Reports on Scientific, Arts and other Relevant Activities of Research and Higher Education Institutions[3] for outputs published 2009–2016.

[1] Research Excellence Framework 2014. https://results.ref.ac.uk accessed 22 December 2020.

[3] Mokslo ir studijų institucijų mokslinės, meninės ir su jomis susijusios kitos veiklos ataskaita https://mokslas.lmt.lt/INSTITUCIJOS/ accessed 16 April 2020

From the REF website, we downloaded all book ISBNs, which were further validated and parsed using the *isbnlib*[4] Python package. We also used the plugin *isbnlib-worldcat* [5] to discover the numbers of books included in WorldCat and obtain their initial metadata.

The prefixes extracted from the ISBN codes identify the publishers. The *Global Register of Publishers (GRP)*[6], created by the International ISBN Agency, contains the country and the agency responsible for the ISBNs' registration as well as detailed information about the publisher: the exact name, current status (active/inactive), address, website, and administration's contact information (name, phone, fax, and email). However, in this study, we used only a portion of this available data to analyse patterns among publishers and their imprints/brands.

Searching for valid ISBNs and other attributes of book outputs

REF 2014 policies describe ISBNs as optional identifiers. Hence, institutions submitting bibliographic data for their book outputs choose to submit an ISBN (and, as various correct ways exist, choose the method for presenting the ISBN), or they skip this field when submitting the entry. However, in Lithuania, the formal research assessment regulations mandate ISBNs for any book output. Nevertheless, both British and Lithuanian records contained sufficient ISBNs to investigate the amount and quality of metadata available at the book level. Before using these acquired ISBNs to collect metadata, we first checked their validity. Table 1 shows the numbers of records collected as initial data (Stage 1) and those remaining after data cleaning (Stage 2). The methods and results of this process are presented next.

Cleaning and unifying ISBNs in the UK REF 2014 book output data

We validated all gathered ISBNs using the *isbnlib* Python package and manually searched for missing or incorrectly presented ISBNs in various online catalogues (Stage 2). Table 1 summarises the results of extracting unique and valid ISBNs from REF 2014 data.

Table 1. Numbers of records with ISBNs before and after cleaning (REF 2014)

Type of outputs in REF 2014	*Stage in data cleaning*	*Records in REF 2014*	*Unique entries*				*Linked only with ISSNs*	*Not applicable for ISBNs*	*Other reasons*
			total	*valid*	*not valid*	*missing*			
(A) Books	Stage 1	10,371	10,173	10,161	12	8		10	
	Stage 2		10,064	10,064	–	–	7	2	6
(B) Edited books	Stage 1	2,133	2,022	2,011	11	11		37	
	Stage 2		1,962	1,962	–	–	36	1	1
(C) Chapters in edited volumes	Stage 1	14,396	11,771	11,748	24	35	9	18	
	Stage 2		10,401	10,401	_	–	8	2	14

Since an ISBN was an optional, manually added data element, those ISBNs that were submitted at all varied greatly in presentation. Ten and thirteen-digit ISBNs of the same book (isbn10 or isbn13) were sometimes provided, dashes were included in some records and omitted in others, typographical errors appeared, and ISSNs were sometimes used instead of ISBNs. When we cleaned the records by removing unnecessary characters or spaces and converting isbn10 codes to isbn13, the list of unique ISBNs shortened.

[6] The Global Register of Publishers https://grp.isbn-international.org/ accessed 22 December 2020.

The figures in the initial REF 2014 data sets differ from the counts of valid ISBNs because different institutions submitted the same co-authored books. A major source of these differences is the edited volume resources. For example, some ISBNs (attributed to edited volumes) combined eight entries (chapters) of the same book in the initial dataset. After data cleaning and ISBN validation, it appeared that not eight, but 15 entries (chapters) belonged to the same ISBN (i.e., the same edited volume). In the end, the number of edited volumes shrank from 11,771 to 10,401.

Reasons for missing ISBNs in REF 2014

Our data cleaning process left 77 entries without ISBNs. We found three main reasons for this omission:

Series and journals with ISSNs. Most outputs in this category were submitted under *edited books* (Table 1, type B). These can be books or volumes in continuously published book series; alternatively, they can be 'special issues' in journals with their own ISSNs. For these resources, it is technically permissible for individual books to be assigned ISBNs in addition to ISSNs (*ISBN users' manual*, 2017). In analysing the data and searching for missing ISBNs, we have noticed that some academic publishers use this practice.

ISBNs are not applicable. This category consists of publications that are not eligible for ISBNs under the ISBN Standard. These outputs include exhibition catalogues (printed or issued online), dictionaries (continuously published online), teaching content (issued for educational purposes and not for sale), and personalised books not intended for general availability or purchase.

Other reasons. We used this last category to include outputs which could have had ISBNs but did not. While the exact reason for this omission was unknown for each case, we identified several different scenarios. First, some PDFs were made publicly available on institutional repositories as books without ISBNs. Authors could self-publish—an option recognised in the ISBN Users' Manual (2017, 3.16)—and thus order ISBNs for their own books. Second, several publishers in the REF 2014 sample were inconsistent in assigning ISBNs, providing codes for some books in their catalogues but not for others. We cannot find any explanation for this in the publishers' book catalogues or websites. Third, and most unusually, publications produced by Helle Panke lack ISBNs 'as the organisation does not wish to be bound to Germany's regulations concerning book pricing.'[7] The fourth scenario is that publishers printed poorly formed ISBNs on the books' copyright pages, and no other valid ISBNs were found for these books. Lastly, some invalid ISBNs appeared only in the REF 2014 records and institutional repositories; we could not find bibliographic information about either these books or their ISBN codes in any library or union catalogue.

The UK final dataset contains 22,427 valid ISBNs representing 26,823 book-related outputs submitted to REF 2014.

ISBNs in Lithuanian data on book outputs

The first dataset gathered from the Lithuanian Research Council databases included bibliographic information on 4,430 book outputs submitted from 2004 to 2016. Similar issues and scenarios arose during the cleaning of the Lithuanian data as had appeared with REF 2014 (Dagienė, 2020; Dagienė et al., 2019), and similar challenges were encountered regarding the validity of ISBN codes. The *isbnlib* package revealed 65 invalid ISBNs in the initial data set; we consulted the Lithuanian Academic Electronic Library[8] holdings and found valid codes for 44 (out of 65) missing ISBNs. However, we also found 21 invalid ISBNs included in some

[8] The Lithuanian Academic Electronic Library https://www.lvb.lt/ accessed 12 January 2021.

books' bibliographic records. After all, because we did not find any other ISBNs for 19 books, we excluded them from our final dataset of 4,074 records.

Discussion and conclusions

In this paper, we present the preliminary results of an ongoing project aimed at establishing a new approach to book evaluation. We found processing ISBNs from existing systems to be very time-consuming and require significant manual effort.

Examining submissions to two national research evaluation exercises (in the UK and Lithuania), we found that nearly all book outputs have ISBNs. This suggests that an ISBN is a suitable identifier for gathering the metadata needed to construct and demonstrate the approach proposed in our project.

Although almost all book outputs have ISBNs, our results show that many ISBNs in book evaluation systems or library catalogues have not been validated, which makes it more difficult for the data to be used or reused automatically. We found more than 1,500 entries with incorrect or missing ISBNs, which required tremendous data cleaning efforts. To address this matter, we recommend that book evaluation systems implement an automatic ISBN validation system at the submission stage, like that undertaken in the REF 2021 process[9]. Such a mechanism would benefit other book information systems, such as library catalogues and book output registration systems (e.g., institutional repositories or systems for administration of research assessment exercises). This change will improve our bibliographic universe by making higher-quality data available right at the outset of data collection. The work reported in this paper represents the first step towards this goal.

As the next step of our project, we are planning to use the collected ISBNs to gather metadata records for books in the book evaluation systems. These records will be used to construct a new book evaluation ecosystem focusing on how book publishers participate in the publication lifecycle, which will produce more meaningful results about the quality of books and their publishers.

Abstract

The main objective of this paper is to develop a knowledge base for the development of "good" evaluations of research practices. A good evaluation of research practices, intended as social practices à la MacIntyre, should take into account the stable motivations and the traits of the characters (i.e. the *virtues*) of researchers. The development of a questionnaire for the assessment of researchers' virtues is a challenging task. The use of ontologies and taxonomic knowledge, and the reasoning algorithms that can make inferences on the basis of such knowledge represents a way for testing the consistency of the information reported in the questionnaire and to analyze in a correct and coherent way the data gathered through it.

Introduction

We live in an evaluation society (Dahler-Larsen, 2011): evaluations, quantifications and assessments are everywhere and analyse, scrutinize and monitor all kind of aspects of scholarly activities. In addition, in recent decades, the rapid changes taking place in the production, communication and evaluation of research have been signs of an ongoing transformation. Largely, we are facing a transition from a traditional evaluation model, based on indicators (e.g. number of publications and citations) to a modern evaluation, characterized by a multiplicity of distinct, complementary and new dimensions including the so called *altmetrics*. This situation is led by the development and increasing availability of data and statistical and computerized techniques for their treatment, including among others the recent advancements in artificial intelligence and machine learning.

In this context, it becomes increasingly important to "evaluate evaluations", beyond the convenience calculations of the past (Larson and Berliner, 1983), looking for "good" evaluations. Although there is a proliferation of increasingly sophisticated quantitative methods to evaluate research, there is still a lack of clarity on how to understand and operationalize the notion of "good" evaluation of research practices. Researchers' motivations and their specific traits of character (i.e. researchers' *virtues*) have recently been recognized as important factors that must be considered to make a "good" evaluation (Daraio and Vaccari, 2020). Good evaluation takes into account the constitutive elements of *research practices*, intended as *social practices*, according to the MacIntyre view (MacIntyre, 1985; Murdoch, 1998). Following this line, good evaluation must consider researcher's virtues in the realization of the "internal goods" of the social practice they are involved in.

The main result of this recent study (Daraio and Vaccari, 2020) is the preliminary version of a questionnaire to assess the researcher's virtues, to be able to complement current research evaluations with additional elements referring to scholar's motivations and personal threats of character currently excluded by bibliometric indicators in use.

The main objective of this paper is to exploit the properties of ontology-based modelling to represent the domain of researchers' virtues in order to prepare a questionnaire to be administered to researchers. This approach will allow us 1) to check the consistency and the coherence of the questionnaire content and structure before its application (or use) and 2) to correctly and coherently interpret the data gathered through the questionnaire.

The paper unfolds as follows. The next section illustrates the main problems that have to be addressed for the assessment of researchers' virtues. The following section introduces the virtues of researchers as starting point for the semantic modelling of the domain and further elaborates on the questionnaire proposed in Daraio and Vaccari (2020). Section 4 outlines the ontology-based modelling. Section 5 summarizes existing literature on the topics and the last section concludes the paper.

Towards the assessment of researchers' virtues: challenges and first steps

The assessment of researchers' virtues is challenged by several pitfalls and problems. The first issue is related to the question of the measurement of virtues. Virtue, it has been argued, seems to consist of a special sensitivity that escapes empirical measurement (Murdoch, 1998). Recently, however, some scholars have tried to undermine this pessimist assumption by giving hope to those of us who seek to develop a model of evaluation of research including also a component based on the virtues. Snow (2014) has recently launched a promising line of research based on the elements of psychology that characterize the virtues. In its perspective *virtue* is composed of the following three elements:

1) *intelligence*, which highlights the fact that virtue proceeds from a set of cognitive and emotional mental states that enable us to be sensitive to some morally relevant features of the situations in which, really or imaginatively, we find ourselves (Snow, 2014, pp. 4-5). See also Snow (2010 and 2012);
2) *dispositionality*, refers to the fact that this state is a trait of the personality of the agent and is not an occasional element of his psychology;
3) *behaviour*, i.e. virtue typically manifests itself in the actions and other behavioural responses of the virtuous person (Snow, 2010, pp. 4-5).

Snow argues that each of these characteristics of virtue can be measured and she outlines a model that consists of three measurement criteria. First, the agent's performance must be taken into account, i.e. the presence of the virtue in question must be verified from the agent's ability to repeatedly perform a given behavioural pattern in the different situations that constitute, so to speak, the field of action of a specific virtue. Secondly, Snow believes it is crucial to take into account the reports that agents make of their emotional and cognitive life during the performance of actions that they consider virtuous. To facilitate this task, Snow believes it is desirable that, on the model of some US colleges, research institutions make available to their participants' special apps that can be downloaded on any electronic device, allowing them to collect the results of the self-observations of agents. Gathering the products of introspection, in addition to offering a useful material to those who are called to assess the presence of virtues in others, also allow agents to take into account the health of their virtues and measure any flexing or, on the contrary, increases in their readiness and effectiveness in responding to the pressures the world exerts on them. Finally, Snow argues that it is important to connect these data with those that impartial observers, in the figure of external evaluators, can collect in the course of annual surveys covering both the outputs of the research and the way in which the researcher dwells in different spheres of social interaction with other participants in the practice.

A further problem to be addressed is which questions to introduce in the questionnaires. These must be sufficiently diversified to allow the evaluators to answer not only the dry question about whether or not there is a virtue, but also to determine the *quantum* of it. Snow suggested four levels to be introduced in the questionnaires.

I. The first verifies the presence in the agent of receptivity to the *stimulus* that typically activates virtue.

II. The second examines its ability to recognize the virtue appropriate to the given circumstance.

III. The third verifies the most complex ability to generate a virtuous response.

IV. The fourth, finally, measures the ability of the agent to generate the virtuous response in a cross-cutting way to a plurality of situations.

Following the four levels questions introduced by Snow, it is possible to measure on a scale from 0 (minimum) to 4 (maximum) the researcher's mastery of virtue. This is done over a spectrum ranging from *(1)* the ability to understand the importance of the problem to which virtue constitutes an answer, to *(2)* the ability to recognize the virtue in question, to *(3)* the ability to express virtue occasionally, to *(4)* the ability to manifest it in all situations that constitute the scope of that virtue.

On top of these problems, the traditional problems related to the development of questionnaire and the collection of the necessary information through questionnaire and interview arise (Hochschild, 2009; Rabionet, 2011; Kvale, 2008 and Wolcott, 2008).

In this paper we suggest to exploit the advantages of an ontology-based modelling that we will illustrate after the next section, for overcoming the aforementioned problems.

3. Semantic modelling of the virtues of researchers

The starting point for the semantic modelling of the domain in exam are the virtues of researchers.

Let's start with a general characterization of the nature of virtue. Virtues are dispositions to believe, to feel emotions and act in certain ways that are activated when we perceive relevant characteristics in the world. A courageous person, for example, will face danger firmly when she believes that someone or something to which she attaches a value is at risk of being harmed. Similarly, a charitable person when she believes that someone is suffering will tend to sympathize with that suffering and, consequently, take care of it. Furthermore, an accurate person is one who does not accept any belief-shaped thing that enters his or her mind, but takes special care in forming his or her beliefs. Actions of these type will not be singular but will be stable and predictable: whenever she perceives certain relevant characteristics of a situation, the virtuous agent will tend to give the appropriate response to those characteristics. The possession of virtue moreover seems to be something that admits degrees of competence along a spectrum that goes from knowledge about what to do to a more complex one about why to do a certain thing. This element depends on two factors that concern our practice of attributing virtuous traits:

1) we sometimes attribute a virtue even when those who perform the corresponding action are not able to give an articulated justification of what they have done and/or their actions are not cross situationally consistent.
2) we believe that those who give an articulated justification of their virtuous actions, and tend to manifest the virtuous trait in a coherent plurality of situations, have a greater knowledge of virtue than those who do not. Unlike the former, these agents tend to know how to distinguish circumstances that require a virtuous response from similar ones that do not.

An entirely brave person, for example, will tend to discriminate between the real danger from a mere apparent threat and to avoid facing danger just for the sheer pleasure of the adrenaline that follows. It will also be able to recognize situations that require a courageous response and to be motivated accordingly in a variety of situations: not only those involving physical confrontation, but also those involving, for example, the defense of an unpopular idea or pursue a complex line of research never explored before. In a similar way, an entirely accurate person takes into account that research is both time- and resource-consuming and is able to put different investment policies in place depending on circumstances. These agents seem to possess greater knowledge of the virtue of those who simply act virtuously in a limited number of cases and lack the ability to formulate a justification for what they do. They are able to articulate the reasons in favour of virtuous behaviour in a plurality of contexts and use them to justify their conduct to themselves and others. For those who possess this knowledge virtue will not be a mere disposition to act, but a disposition to act infused by a reflective ability that involves the mastery of concepts. As with other character traits, finally, virtues are *profound qualities* that reveal what kind of person is the one who possesses them. The attribution of character traits is in fact a common practice that we use as much to get a general idea of someone we do not know well as, if we know him better, to predict what he will say or do or to explain why she has made certain choices in the past. Moving from the spectator's point of view to that of the agent, there are facts that are typically explained (retrospectively) by referring to motives that depend on general principles of our conduct that survive that individual case. Although not all of these principles are something we necessarily approve of, some of them are aspects of our character that are valued by ourselves and others and that we strive to maintain, creating opportunities to test them and reflect on how we express them in our behaviour. In these cases, virtue becomes a crucial element of our narrative and plays a normative role in our future choices.

In our research we are going to use two different types of virtues: the *intellectual* or *epistemic virtues* and the *virtues of character*. The former involve dispositions to exercise a set of capacities that relate to how we acquire our beliefs and communicate them to others. The latter, on the other hand, concern functional ways in which we enter into relationships with ourselves and interact with others by promoting our own and their good. The former are developed primarily through teaching by specialized staff (professors; research directors; etc.). The latter, on the other hand, require having entered into a non-emulative educational relationship with figures who have the role of educators in the community (parents, teachers, etc.).

Below we provide an open-ended list of the virtues that enable the constitution of a good research practice and constitute something that should be taken into account by those making comparative judgments about the relative value of different research practices in addition to existing and currently used individual bibliometric indicators. For an extensive discussion on these individual bibliometric indicators, see Schubert and Schubert (2019) and Wildgaard (2019). Schubert and Schubert (2019) offer an overview on h-index related indicators while Wildgaard (2019) presents a summary of existing author-level indicators of research production.

The virtues that enable the constitution of a good research practice include:

a) Intellectual virtues:

Accuracy: it is the disposition that consists in the care with which the individual researchers collect data that will constitute the pool of information shared in the research practice. Since collecting and evaluating information is time and resource consuming, the accurate researcher is one who implements several "policies of investigation" that are appropriate to the research circumstances (Williams, 2002).

Sincerity, Honesty: it is the disposition to tell the truth to others and, when this does not happen, it is the capacity to indicate good reasons why this did not happen where good refers to the fact that these reasons have a constitutive reference to the interests of other people (McIntyre 1985, Williams 2002).

Creativity: is the ability, which finds expression both in our social interactions with others and in the products of our research, to produce something that not only has value but is characterized by the elements of novelty and the capacity to arouse surprise in others (Swanton 2003, pp. 162, 165).

b) Virtues of character useful to oneself:

Humility: it is the ability to accept the authority of the standards related to the rules that define the practice. I have to recognize that other participants know rules and know how to apply them better than I do. I have to be willing to learn from these people and accept their criticism (MacIntyre 1985, p. 193).

Pride: it is evaluative attitudes towards ourselves (Ardal, 1966; Cohon, 2008; Taylor, 2015). Unlike other emotions, which simply motivate us to pursue or avoid objects, this traits of character fix our attention on persons, casting a positive or negative light on them. If I am proud of my child's success at school, my pride does not fix my attention on the 'merits of my child,' and still less on 'me in the role of father,' but on the whole of myself. As Cohon has rightly said, "when I feel pride, I am proud of something in particular [its cause] … But the attitude of pride is a pleasure or satisfaction not in that particular accomplishment or possession, but in myself in my entirety" (Cohon, 2008, p. 166). We believe that the pride associated with one's own achievements in research and the consequent approval of one's peers or superiors is a fundamental spring that drives researchers to perform at best in their area of research (Tangney, 1999).

Patience is the ability to curb one's own urge to complete a research in order to obtain as soon as possible the gratification of a positive result. To be able to wait and to be guided by a cautious skepticism that prompts us to control accurately the different steps of our investigation.

Prudence: is the capacity to sacrifice the satisfaction of less important pleasures closer in time than the satisfaction of more distant but more important pleasures. Where the degree of importance is defined with respect to the long-term objectives that characterize our lives (Parfit 1984).

Resilience: together with pride, this ability is indispensable to move forward in the research. It allows us to leave behind failures (paper rejected, unfunded projects, etc.) and to focus on future projects (Hormann, 2018).

c) Virtues of character useful to others

Courage is the capacity to risk damage or danger to oneself when individuals, values, goals that are crucial to the existence of the practice are at stake. Courage is therefore a way of showing that our attachment to these elements of the practice is genuine (MacIntyre, 1985, p. 192).

Empathy, Benevolence: in line with extensive literature, by this term we mean the human ability to feel the emotions and feelings of other people through a vicarious feeling that is similar to that of the person with whom we sympathize. We do not believe, however, that empathy in itself is a virtuous capacity in research practices. Since empathy is an instrument for reading the other's mind, it can also be used to manipulate other researchers in malicious ways. Empathy must be cultivated in such a way that it is rooted in the benevolent tendencies of human beings (Batson 2017, p. 2). In this way, empathy can allow the creation of a climate of *trust* between those who work within research institutions. Indeed, mutual trust is an indispensable component in these practices given the fundamental fact of the asymmetry of power that characterizes those interactions (Baier, 1991).

Integrity: is the willingness to behave in such a way that our actions are the outcome of our deepest values and commitments and that we tend to refuse making them hostages to imposed obligations or duties that we do not endorse on reflection.

Justice: following Aristotle (Aristotle 2014, Book V), we distinguish justice into two aspects. The first relates to the ability to promote the good of other researchers as members of our institution and research unit, that is, those to whom we are bound by ideal bonds and common respect for the rules that define our research community. The second is in turn divided into two spheres. The first concerns the ability to distribute the goods of research practice appropriately on the merits. The second, on the other hand, is the ability to compensate for or punish poor distributions or misconduct.

Practical wisdom: it is a kind of *super-virtue* essential to make each virtue effective. In line with Aristotle, we believe that this rational capacity enables the virtuous agent to acknowledge and respond properly to the items in the field of the research practice, choosing the appropriate means for their own ends (McDowell, 1979). Moreover, it also allows the different virtues within an individual's character to operate and develop harmoniously with each other.

A first attempt to develop a questionnaire for the evaluation of virtues in research practices has been done by Daraio and Vaccari (2020). Our Table 1 below, elaborating further Table 1 of Daraio and Vaccari (2020, p. 1067-1068), proposes some examples of questions to consider in evaluating the virtues of researchers.

Table 1. Examples of questions to include in the Questionnaire on Researchers' Virtues

a) Intellectual Virtues	**Questions**
Accuracy	- Do you thoroughly collect all the pieces of information that constitutes the body of knowledge on which the practice revolves? - Do you evaluate this disposition as instrumental or intrinsic? - Do you have a tendency to share data, results, methods, ideas, techniques, and tools used in the practice?
Sincerity, Honesty	- Do you think there are circumstances in which your colleagues can be manipulated? - Are you inclined to admit publicly when you make mistakes?
Creativity	- Are you able to explore and follow your own line of research? - Do you have the tendency to question your own ordinary experience and look with suspicion at what is the result of habit?
b) Virtues of character useful to oneself	**Questions**
Humility	- Are you incline to recognize that other researchers (participants to the practice) know rules and know how to apply them better than you do? - Are you to be willing to learn from these people and accept their criticism?
Pride	- Are you able to gain an impartial knowledge of one's own qualities? - Do you have the ability to feel fulfilment for academic success through demonstrating competence according to social standards and to draw strength from one's achievements? - Do you think you have a stable awareness of your own value that is not shaken by the successes of others? Do you have the capacity to enjoy and congratulate other people' accomplishments?

Patience	- Are you able to curb the rush to hastily complete a search to achieve the gratification that comes with a prima facie positive result? - Are you willing to be guided by a cautious scepticism that prompts you to control accurately the different steps of our investigation?
Prudence	- What do you think about people who tends to restraint of actions, inclinations, and impulses that are likely to upset others? - Do you tend to respect the fundamentals of the research practice within which one works?
Resilience	- Would you describe yourself as a person who leaves behind failures (paper rejected, unfunded projects, etc.) and to focus on future projects?
c) Virtues of character useful to others	**Questions**
Courage	- Are you willing to risk damage or danger to oneself when individuals, values, goals that are crucial to the practice are at stake? - Do you have a propensity to apply for highly competitive grants?
Empathy, Benevolence	- How do you feel about people who are sensitive to the suffering of their colleagues caused by failures or exclusions? - How do you feel about people who seeks feedback to improve interactions with others? - Do you think that preservation and promotion of the welfare of people with whom one is in frequent personal contact is important? - How would you describe collegial engagement?
Integrity	- Do you think that to hold beliefs that are consistent with actions has always a positive value?
Justice	- Does the practice of distributing funds, grants and awards according to merit always have a positive value? - Do you tend to think that the situations in which researchers work have commonalities that would allow for comparisons of their accomplishments?
Practical wisdom	- Would you describe yourself as someone who tends to choose the most effective means to achieve their ends? if not, why? - Have you ever been in a situation of conflict between things that have identical value to you? If so, what considerations do you turn to in an attempt to resolve the conflict?

Note: The content of this table is an elaboration of the content of Table 1 by Daraio and Vaccari (2020, pp. 1067-1068).

Designing an ontology for the modelling of researchers' virtues: Implementation aspects

Formally, an ontology in Description Logics is a knowledge base. It is a couple (pair) O=<TBox,ABox>, where TBox is the Terminological Box that represents the *intensional* level of the knowledge or the conceptual model of the portion of the reality of interest expressed in a formal way; and ABox is the Assertion Box that represents the *extensional* level of the knowledge or the concrete model of the portion of the reality expressed by means of assertions (instances).

The use of ontology-based modelling in our context allows us to implement *cognitive interviewing methodology* to address the challenges outlined in the previous section.

Cognitive interviewing is a psychologically oriented method for empirically studying the ways in which individuals mentally process and respond to survey questionnaires. Cognitive interviews can be conducted for the general purpose of enhancing the understanding of how respondents carry out the task of answering survey questions. However, the technique is more commonly conducted in an applied sense, for the purpose of pretesting questions and determining how they should be modified, prior to survey fielding, to make them more understandable or otherwise easier to answer. The notion that survey questions require thought on the part of respondents is not new and has long been a central premise of questionnaire design. However, cognitive interviewing formalizes this process and it has become an interdisciplinary field (for an overview, see Willis, 2004 and Miller et al., 2014).

An ontology-based semantic modelling approach offers several advantages, including:

i. a conceptual specification of the domain of interest, in terms of knowledge structures;

ii. the mapping of such knowledge structures to concrete data (the answers of the questionnaire);

iii. the reasoning over the abstract representation of the domain prior to the data collection;

iv. a flexible conceptual system that can be easily updated;

v. an open conceptual system that can be used as a common language for the research community.

The languages for representing ontologies and taxonomic knowledge, and the reasoning algorithms that can make inferences on the basis of such knowledge have been addressed by a large body of research in Artificial Intelligence and Knowledge Representation. Their formal characterisation is nowadays based on Description Logics (Baader et al., 2003), which provides a syntax for concept and role expressions and formal semantics to interpret them in a set theoretic framework. Concepts (i.e. classes) model sets of individuals and roles model binary relations. The representation of ontological knowledge is thus achieved by defining concepts and the properties (relations) that link them to other concepts in the domain of interest. The concepts are arranged in a hierarchical structure based on the subsumption relation (i.e. set containment). Along with the formal language, systems that allow to model and use ontologies are accompanied by various forms of syntactic representation, including graphical models. Protegé (Gašević et al., 2009) is a standard tool that builds its success, among other things, on the capability to handle multiple syntactic representations that allow the user to model the domain of interest using the most convenient notation, while grounding it to a well understood formal counterpart. Another key feature of Protegé is the decoupling of the representation from the reasoning tool that is adopted to make inferences. Protegé, for all the reasons explained above, will be used for the development of the ontology for the assessment of researchers' virtues.

Related works

While there is a rich literature and several approaches for extracting information through ontologies, for a review see Wimalasuriya and Dou (2010), the literature on ontological modelling in support of questionnaires development is scant. Notable exceptions include Sherimon et al. (2013 and 2014) where an ontology-based model for gathering the patient medical history based on dynamic questionnaire ontology is developed. The model is implemented and explained for diabetes domain by using Protegé. Another interesting contribution is Borodin and Zavyalova (2016), in which the authors focused on the problem of semantic representation of questionnaires. They constructed the generic ontological model of questionnaire, which provides a possibility of question structure description including complex questions with a set of answers of different kind and question order, including skipping and branching.

Surveys in fact, may be conducted to gather information through a printed questionnaire, over the telephone, by mail, in person or on the web, etc. and the structure of survey questionnaires and feedback if described in ontological terms provides an opportunity not only to structure the survey data but also to analyse the responses.

We contribute to enrich the limited existing literature, showing the potential of ontology based modelling for challenging and intriguing topics as the "good" evaluation of research practices, that relates the development of a questionnaire for the assessment of the motivations and the stable threats of characters (or virtues) of researchers.

Concluding remarks

This paper is realized within a challenging and interdisciplinary research project on "Evaluating Evaluations" with the financial support of Sapienza University of Rome. Based on the conceptual tools used by normative ethics, in particular from the perspective known as ethics of virtues, we have started to develop a questionnaire capable of revealing the presence and quantity of virtues in individual researchers. We believe that the use of ontology-based modelling in this context might enable us to further implement a cognitive interviewing methodology which may help us to address the many challenges of this research field.

Abstract

This paper analyses the open access (OA) output of Spanish public universities from 2011 to 2020. A bibliometric analysis was carried out using Clarivate Analytics' Web of Science Core Collection, and a set of bibliometric analyses was performed to provide an evidence-based response to the research questions (What are the most significant initiatives for promoting open access at higher education institutions at both the national level and the institutional level? What open access contribution are Spanish public universities making? What types of open access are used the most? How does OA affect the impact of scientific production? What type of open access increases impact? Is there a relationship between funded research and open access publications of results?). The bibliometric analyses looked at four dimensions: activity indicators, OA types, impact indicators and funding. The paper concludes that the institutional measures and actions fostering OA identified in universities' policies and mandates bear a correspondence with the bibliometric data. Spanish public universities have higher rates of OA publications, with a clear preference for Green Published and DOAJ Gold publications. OA publications are systematically more cited than non-OA publications (with Green Accepted in the lead), and there is a strong relationship among visibility, funding and open access.

Introduction

The early adoption of OA mandates in organizations such as the US National Institutes of Health and the UK Higher Education Funding Council (Van Noorden, 2014) has evolved steadily, spreading through both national and supra-national organizations. In 2020 the Registry of Open Access Repository Mandates and Policies records over one thousand OA mandates. Of key importance at the supra-national level, the launch of Plan S by Coalition S (an initiative backed by the European Commission, the European Research Council and the national research agencies and funders from twelve European countries) has triggered an intense debate on its practical implications and contributed to setting the OA policies at the centre of European research policy. Also at the supra-national level, the European Union's Horizon 2020 research grant scheme includes an explicit OA mandate. OA mandates and policies show a correlation between their intensity and their effects (Gargouri et al., 2012), and the economic implications are often non-trivial (Quadery et al., 2019).

The practical implementation of OA mandates was researched in depth by Larivière and Sugimoto (2018), who analysed more than 1.3 million papers reporting publicly funded research by a selection of US, UK and Canadian organizations. The authors identified important differences in OA percentages and OA types between funding programmes, agencies and fields of knowledge. De-castro and Franck (2019) conducted an in-depth analysis of the European Commission's pilot initiative to fund article processing charges (APCs) associated with finished projects financed under the 7th Framework Programme. They concluded that the transference of OA funding policies to specific institutions might have a positive effect on the overall efficiency of publicly assumed APCs.

In Spain the evolution of the rules and regulations affecting OA publications has one of its important landmarks in the 2011 Science, Technology and Innovation Law. The law's preamble establishes a favourable position toward open access policies as one of its 'measures for a science of the 21st century'. Section 37 of the law states that the personnel whose research activity is primarily funded by the national budget must post a publicly accessible digital version of the final contents published or accepted for publication by no later than 12 months after acceptance. In line with legislation, the main public research-funding instrument in Spain, the State RDI (Research, Development and Innovation) Plan, requires the open access publication of the findings of publicly funded research. In addition, in another a major milestone in the evolution of OA policies in Spain, the Spanish Conference of University Rectors, acting on their universities' behalf, has released a public commitment to open science. This includes a declaration supporting measures to foster the implementation of open science and containing several points directly related to open access and its management by Spanish universities.

The correspondence between policies and mandates and their practical implementation is key to understanding the effectiveness of the former and the real dimension of the latter. A detailed analysis of existing policies and the volume of OA publications and their types is the first step toward understanding the relationship between them and establishing a baseline for further cohort analyses.

Background

Interest in analysing open access is evident in numerous scientific publications that approach the subject from different perspectives. On the one hand, there are extensive discussions about the advantages and limitations of open publishing (Kurtz & Brody, 2006; Beall, 2012) and analyses of its scope and implications (Suber, 2003, 2005; Zuccala, 2009). The relationship among open access, visibility and increased citations has also been explored (Harnad & Brody, 2004; Eysenbach, 2006; Moed, 2007; Gargouri et al., 2010; Suber, 2012; Science-Metrix, 2018). The relationship between impact and open access type is a topic of constant interest as well (Perianes & Olmeda, 2019), with some studies focusing on the Green route (Gargouri et al., 2010; Harnad & Brody, 2004; Moed, 2007; Gumpenberger, Ovalle-Perandones & Gorraiz, 2013), while others consider the Gold route more promising (Jubb et al., 2011; Torres-Salinas et al., 2018). Another endeavour of particular interest is to identify the proportion of publications in open access in specific databases (Björk et al., 2010; FECYT, 2016), disciplines and countries (Gaugouri et al., 2012; Archambault, 2013).

Some open access policies' impact has been investigated in studies analysing the effect of the mandates of international RDI funding agencies (European Commission, 2016b) and national funding agencies, as in the case of Canada (Zhang & Watson, 2017) and Spain (Borrego, 2015). More-recent studies have analysed the relationship among open access, DOI and dissemination on social media, showing how different access modalities can contribute to the visibility of research results (Laakso et al., 2017; Pinowar et al., 2018; Science-Metrix, 2018; Borrego, 2017).

Given that higher education institutions are responsible for a major share of a country's total publication output, several authors have studied open access in universities. Studies such as that of the universities of Sweden (Fathli, 2011), Norway (Elbaek, 2014) and the Netherlands (Bosman and Kramer, 2018) have shown the diversity of case studies between countries and disciplines. Another recent study (De Filippo and Mañana, 2020), which analyses open access in the universities belonging to the YERUN network, demonstrates the importance of promotion policies in universities and how such policies affect research visibility.

Study contexts and objectives

As mentioned, there is a particular interest in mainstreaming open access in higher education institutions. Several studies have focused on aspects related to certain variables (percentage of available publications, types of policies implemented, impact and citation). In this research, however, we consider open access to be very much related to aspects such as regulations and

mandates, access to funding, the national and institutional context in which research is done, impact and visibility.
The study focuses on the case of Spanish universities. These institutions are of interest because, as stated before, an explicit national policy exists about the mandatory publication of all findings of publicly funded projects. Furthermore, Spanish research centres and higher education institutions have demonstrated high levels of availability in open access. The YERUN network study mentioned before (De Filippo & Mañana, 2020) shows that the four Spanish universities in the network have open access percentages that are up to 20 percentage points higher than the country's average. Another study on centres of excellence in Catalonia shows that nearly 70% of production is available by some means (Rovira et al., 2019).
One of the studies of the particular case of Spanish universities is Melero et al. (2018), which examines the degree of OA archiving of 28 Spanish universities between 2012 and 2014, finding an asymmetric distribution of articles deposited in repositories. Meanwhile, the 'Open Access Observatory', an information system developed by 11 Catalan universities, analyses the evolution of open access in Catalonia and shows a constant growth from 2011 to 2019 (Observatori de l' accés obert, 2020).

The authors of this paper are currently participating in a research project on the implementation of open science and open access in Spanish universities. This research is funded by the Spanish National Science and Technology Plan and will continue until 2023. In the light of the evidence and the importance that the Spanish government has given to open science practices, the main objectives of this study are twofold:

- To identify and analyse policies and mandates for the promotion and development of open access at the level of the Spanish Public University System (SPUS).
- To analyse practices related to open access to scientific publications, considering their evolution and main characteristics.
- To propose a typology of universities considering open access practices and their relationship with funded research and visibility.

The following research questions have been established:

Q1. What are the most significant initiatives for promoting open access at higher education institutions at both the national level and the institutional level?
Q2. What is public universities' contribution to the total number of open access Spanish publications?
Q3. What types of open access are used the most?
Q4. How does OA affect the impact of scientific production? What type of open access increases impact?
Q5. Is there a relationship between funded research and open access publications of results?

Source and methodology

Source

Two types of information sources were used:

- *Spanish national regulations.* Regulations and official websites were consulted to find out about aspects related to open access in higher education institutions in Spain.
- *International multidisciplinary bibliographic and bibliometric databases*. The publications by Spanish public universities included in the Clarivate Analytics Web of Science's Core Collection (Science Citation Index, Social Science Citation Index and Arts and Humanities Citation Index) for 2011-2020 were retrieved and analysed.

Methodology

The study was carried out in two phases:

- *Spanish national regulations*

  The main sources for the analysis of the milestones and evolution of OA in Spain were the articles reviewed in this document and the publicly available reports of official Spanish organizations such as ministries and universities. The *Melibea* database, which contains information on institutional OA policies and repositories for a number of Spanish universities (Acceso Abierto, 2018), was also queried to systematize the evolution of OA policies at the institutional level.
- *Bibliometric analysis*

  In this phase all scientific publications from Spain and all scientific publications from each Spanish public university were identified (through the 'organization enhanced' search).
  Publications of all document types and languages from 2011 to 2020 were recovered.
  After the documents were downloaded and cleaned up, the following bibliometric indicators were obtained.

  - Spanish publications in WoS per year (total and OA), growth rates
  - SPUS contribution (total and OA) to Spanish publications, growth rates
  - Percentage of OA publications per university
  - Type of OA in Spain and in each university
  - Citations/document in OA publications versus non-OA publications
  - Citations/document by open access type
  - Percentage of highly cited papers (HCPs) in total publications and OA publications
  - Percentage of OA in funded publication and non-funded publication (considering information given in funding acknowledgement fields). Funded publications are those resulting from a publicly or privately funded research project.

Open access documents were analysed according to the five types of OA provided in the WoS database.

1. **DOAJ Gold:** Articles published in journals listed in the Directory of Open Access Journals (DOAJ) as Gold in accordance with their licence type.
2. **Other Gold:** Other Gold OA articles identified as such by Impact Story or Unpaywall Database (Our Research). Most of the journals publishing this type of OA are hybrid journals.
3. **Bronze:** Free-to-read public access articles available at the publishers' website for which the specific licensing details are not clear
4. **Green Published:** Final published versions of articles hosted on an institutional or subject-based repository.
5. **Green Accepted:** Accepted manuscripts hosted on a repository (peer reviewed, but possibly not fully copyedited)

Case study description

Spain's university system contains 83 institutions, 50 of which are public, and 33, private (Ministry of Education, 2020). The latter group includes 16 Catholic universities, which are governed by specific legislation. Under Spanish law the purpose of all universities, be they public or private, is to provide a public service: higher education. This includes research, teaching and study.

Studies of the Spanish university system show that differentiation between types of institutions clearly identifies the existence of public and private 'subsystems' with very different characteristics and activity patterns. Public universities clearly outnumber private universities in terms of their absolute number of institutions, professors and students (Grau Vidal, 2012). Although the number of private institutions has climbed rapidly, due to their much smaller size private universities account for 10% of the academic staff and 12% of the students. Their contribution to research is much smaller still: 4% of the total scientific output. As shown by Casani et al. (2013), public universities produced 96% of the papers published in Web of Science (WoS) and received 99% of the citations. These data are clear indications of the scale and quality of the public sector. Moreover, its research is more visible, for Spain's public universities publish a larger percentage of their papers in Q1 journals than do the country's private universities.

On the basis of this evidence, this study focuses on the Spanish Public University System. The list of institutions included and their acronyms are shown in Appendix I.

Results

Spanish national regulations

Some Spanish institutions can be qualified as 'early adopters', such as the Universitat Oberta de Catalunya (UOC) and the Universidad Politécnica de Madrid (UPM). These universities developed OA regulations prior to the development of the official OA mandate (the 2011 Science, Technology and Innovation Law). The vast majority of institutions rolled out their OA regulations within five years after the law was enacted, while other organizations, such as the Spanish National Research Council (CSIC) and the Rectors' Conference (CRUE), implemented their standards or declarations of support only after developments and OA mandates were consolidated in other organizations (Figure 1).

Figure 1: Timeline of implementation of OA legislation in Spanish universities (section above year line) and main policy milestones (section below year line)

For the specifics of the university regulations in place, we used the Melibea database (available at https://www.accesoabierto.net/politicas/). It is a directory and estimator of policies in favour of open access to scientific production developed by the 'Acceso abierto a la ciencia' (Open Access to Science) Research Group (CSIC and University of Barcelona). Melibea contains an extensive review of 31 repositories and the OA policies of Spanish universities. Going by the 2018 data, 51.6% of these repositories do not specify which version of the publication should be deposited, 41.9% call for the version corrected by the authors to be deposited, and 6.45% call for the published version to be deposited. On the subject of when to deposit publications, 38.7% require immediate deposit after publication and 35.5% do not provide specifications. Fifty-eight percent require the journal to have an OA policy prior to deposit, while 42% make of this feature a recommendation. The wide variability in the procedures and requisites for the deposit of research publications in institutional repositories is clearly an area for improvement; notwithstanding the organizational freedom universities hold under Spanish laws and regulations, common policies for institutional repositories are desirable, as they would increase the interoperability of the various platforms and foster national accountability for OA repository deposits.

While analysis of existing OA policies and developments does provide information on the evolution, extent and implementation of open access, it needs to be complemented with its quantitative counterpart. Accordingly, we retrieved and analysed universities' scientific output in Web of Science, which currently provides detailed data on the OA status of each contribution. The results of this analysis are detailed in the following section.

Bibliometric analysis

Between 2011 and 2020, Spain published 768 863 documents in the Web of Science Core Collection, 38.55% of them in open access. While the country's total production grew by 44%, open publications increased by 123%, increasing their share from 28.6% in 2011 to 44.8% in 2020. Higher education institutions produced more than 80% of Spain's publications in the period we analysed, making them the country's main producer of scientific publications. Open access documents at universities showed growth at a rate of 135%, which is higher than the Spanish average although the average number of publications in OA by universities (35%) is slightly lower than the country's average (Table 1).

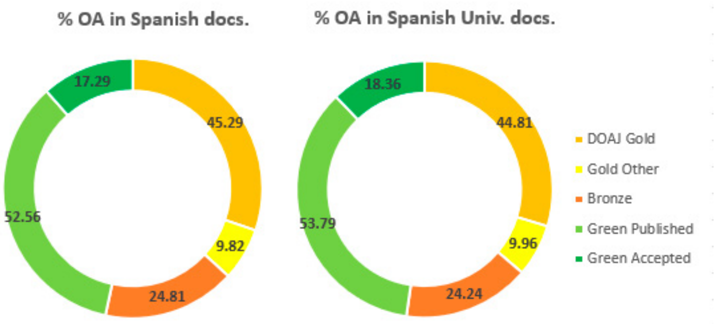

Figure 2. Distribution of publications by open access type (Web of Science, 2011-2020)

The most widely used types of access are Green Published and DOAJ Gold (Figure 2).
At the university level, the percentage of OA publication in the analysed decade ranges from 31% to 59%. Twenty-nine of the 50 public universities have percentages ranging between 30% and 40%, another 18 lie in the range from 40% to 50%, and only three exceed 50%. Looking at the most recent year only, the proportions increase significantly. Interestingly, open access rates are very high in HCPs, where three institutions publish over 80% of their output in OA (Figure 3).

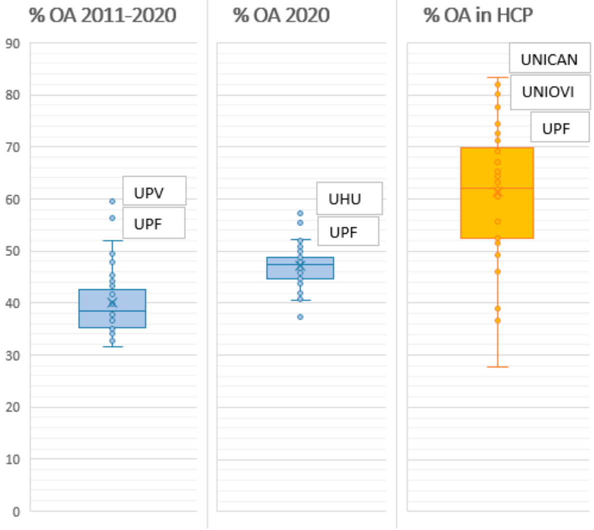

Figure 3. Distribution of open access (OA) publications at Spanish public universities

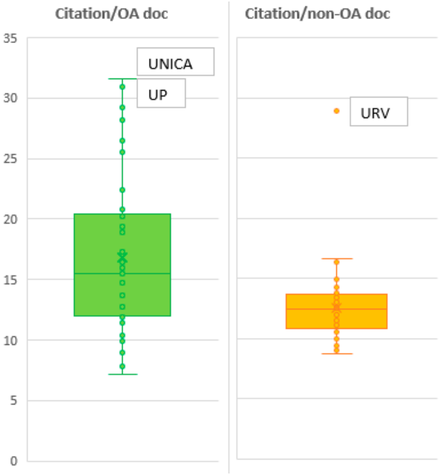

Figure 4. Distribution of impact (citations/doc) in OA and non-OA publications

Turning to the subject of publications' impact, open access documents received on average a higher number of citations; two universities have over 30 citations/document (Figure 4). We found that the two groups of publications (OA and non-OA) present statistically significant differences in their citations/document medians, U=639.5, Z=-3.755; p<.001, with a median of 15.51 for OA documents and a median of 12.41 for non-OA documents.

On comparison of open access documents' impact by access type, Green Accepted publications were found to receive on average more citations per document (Figure 5).

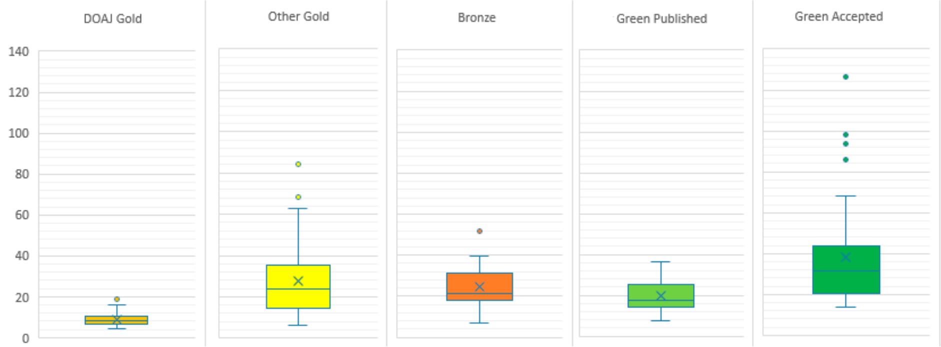

Figure 5. Distribution of impact (citations/doc) in publication by OA type

We also studied the percentages of OA publications in funded research and non-funded research. The two groups of publications (funded and non-funded) present statistically significant differences in their median percentages of OA publications, U=606.5, Z=-3.997; p<.001, with a median of 70% OA for funded documents and 65.22% OA for non-funded documents.

Discussion and conclusions

The landscape of OA rules in Spain is highly dynamic, with a wide range of directives codified into laws and regulations. The highest-ranked legislation addressing OA, the 2011 Science, Technology and Innovation Law, has not been followed up by specific regulations on the administrative consequences of noncompliance with its 37th article (which concerns open access). It has been implemented in a flexible framework, however, adapting its articles to the specific needs and requirements of various higher education, research-funding and research evaluation institutions.

The bibliometric analysis shows that the most widely used types of open access in Spain are Green and DOAJ Gold OA and that the growth rates for OA documents are greater for universities than for Spain as a whole. This could be partially explained by the existence of a wide variety of university regulations concerning OA publications and by the maintenance of a set of institutional repositories that provide researchers with the infrastructure required to deposit Green OA contributions.

The comparatively high percentages of OA documents among highly cited papers could be potentially explained by another variable: the non-independence between funding and OA percentages. Funding agencies' OA mandates seem to be an important factor, ceteris paribus, contributing to the statistically significant differences in OA proportions between funded research (which has higher OA proportions) and non-funded research. Although it cannot be deduced from the available data that HCPs are the result of funded research, if that were the case (which seems plausible if we assume that one of the expected results of most funded research is significant scientific impact), one potential explanation would be that HCPs are subject to funding entities' OA mandates. Self-selection bias, implying that most relevant papers of a given author are prioritized for OA publication, thus contributing to their 'citation advantage' is a plausible contributing factor in this case, although current data does not allow the authors calculating its relative contribution to high citation thresholds.

The citation advantage, an edge that has been extensively analysed in the bibliometric literature, is present in the case of the outputs studied. The differences in citations per document are statistically significant: OA documents receive a median of 15.51 citations per document, while non-OA receive 12.41. Within the various types of OA, Green Accepted presents the highest values. One factor that might help explain this observation is the existence of a variety of institutional repositories that could improve the accessibility of Green Accepted manuscripts.

Overall, the bibliometric data seem to be congruent with existing laws and regulations, although the specific paths that lead from official rules to specific, observable bibliometric phenomena are not completely clear. Further research might focus on such specific links between theory and praxis with the aim of identifying university types.

Acknowledgements

The results were found under 'Diagnosis of the OS in Spanish universities and instruments for its transformation and improvement (DOSSUET)', a project financed by the Spanish State Research Agency under the National RDI Plan's RETOS call.

This study was carried out with funds provided, also, by the Rámon y Cajal call (RYC2018-024894-I) from the Spanish Ministry of Science, Research and Universities.

Abstract

Excellent research is increasingly conducted within a complex web of interacting researchers, coming from different scientific and institutional backgrounds. The SFB Programme of the Austrian Science Fund aims to strengthen Austria as a location for high-level scientific research by supporting the establishment of sustainable, extremely productive and internationally visible research units. A theory-based evaluation was conducted following a mixed-methods approach to empirically examine the effects of the intervention on research excellence, patterns of collaboration and interdisciplinarity. The performed bibliometric analysis clearly shows that SFB succeeded in supporting exceptional research as evidenced by the outstanding publication and citation record of the funded projects. Moreover, the study reaffirms the SFBs' highly successful publication strategy as publications generally appear in high impact journals (with respect to their field) and receive more citations than expected for these journals. However, excellence in scientific outcomes is not paralleled by achievements in terms of interdisciplinarity and international collaboration. While the qualitative analysis emphasises the programme's perceived unique orientation towards promoting interdisciplinarity, interdisciplinarity is typically a result of very closely related (sub-) disciplines working in a sub-project. The evaluation resulted in a differentiated picture of the factors contributing to the objective of funding outstanding research.

Introduction

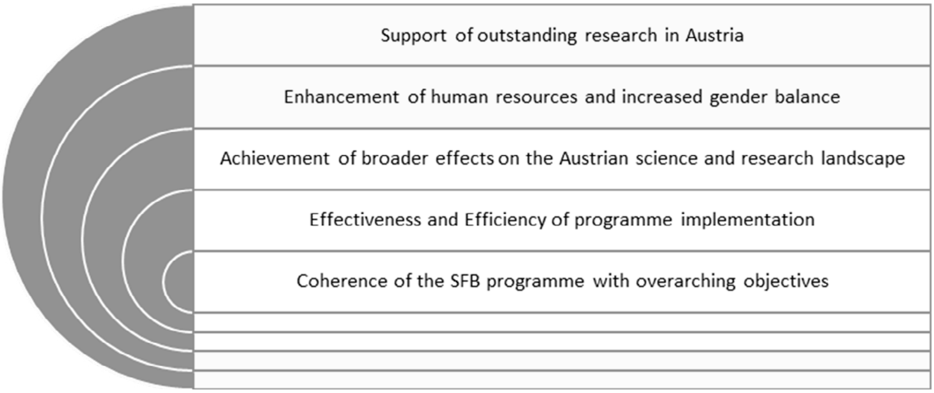
Particularly excellent research is increasingly conducted within a complex web of interacting researchers, coming from different scientific and institutional backgrounds (see, e.g., Powell and Grodal 2005, Scherngell 2013, among others). The growth of research collaboration as a phenomenon within the research system has attracted quite some attention in the academic literature but is also of major concern for research policymakers and funding organisations (see Scherngell 2013 for an overview). The potential benefits, costs and factors influencing the performance of research collaboration have been put under investigation, as research policymakers seek to design funding programmes that contribute to strengthening the competitiveness of national research and innovation systems for the benefits of society.

The SFB programme is the only network-based basic research programme in Austria. SFB aims to strengthen Austria as a location for high-level scientific research and enhance the competitiveness of the country's research and innovation system by supporting the establishment of sustainable, extremely productive and internationally visible research units, which are generally multi- or interdisciplinary and support institutions in developing strategic focus areas. Research networking programmes like the SFBs pick up these scientific insights and lay the foundation for nationally-funded research groups to address major scientific issues, to advance the frontiers of existing research and potentially pave the way for social and economic innovations. They seek to enhance 'research collaboration', which is a special form of collaboration, undertaken for research, where 'research' is implicitly seen as scientific research (Amabile et al., 2001, Katz & Martin, 1997).

In this article, we examine empirically the effects of the intervention on research excellence, patterns of collaboration and interdisciplinarity. Specifically, we address the question of identifying and measuring the contribution of the SFB Programme on outstanding research performance and the multi-/interdisciplinary character of the research networks. Thereby, we show that a mixed-method approach in evaluations, based upon a delineation of impact pathways allows combining different perspectives and increases research integrity.

Methodology

The article rests upon the findings of a comprehensive impact evaluation of the SFB programme, which was performed from 02/2019 until 02/2020 (Dinges et al. 2020) considering five evaluation dimensions (see Figure 1). The overall methodological approach to this evaluation study followed the principles of *theory-based evaluation* (Blamey and Mackenzie 2007, Carvalho and White 2004, Chen 1990, Mayne 2001) and *contribution analysis* (Mayne 2011, Mayne 2008). For gathering the relevant evidence, the study was informed by a mix of sources and recognised research methods (*mixed methods approach*).



Support of outstanding research in Austria
Enhancement of human resources and increased gender balance
Achievement of broader effects on the Austrian science and research landscape
Effectiveness and Efficiency of programme implementation
Coherence of the SFB programme with overarching objectives

Source: Dinges et al. (2020)

Figure 1: Main evaluation dimensions of the SFB Programme evaluation

The quantitative part of the analysis is based on various *bibliometric indicators*. In this programme-related study we were faced with special challenges linked to the specific task and the resulting research questions: In the first place, we mention the usual difficulty of attributing scientific publications correctly to the programme's outputs and impacts, and of comparing the results with those of individual projects and the national standards in the supported areas. After the appropriate framework for this was found, the challenges of using bibliometrics in this context had to be met. In particular, the evaluation needed to define how to identify and measure excellence, how to evaluate (international) collaboration and the extent of interdisciplinarity in the supported research since the programme aims to support outstanding research by creating long-term multi-/interdisciplinary and exceptionally productive research networks. Along with the data obtained from the SFB programme, we used bibliographic data on published results, control groups and the benchmark populations indexed in Clarivate Analytics Web of Science Core Collection (WoS).

The publication-activity and citation-impact study is based on bibliographic data and metadata extracted for WoS-indexed journal articles based on matched publication lists of the projects and on information in the funding acknowledgement section of the papers. Record matching techniques have been used to link the publication list with the bibliographic database including automated procedures and manual validation and reliability checks.

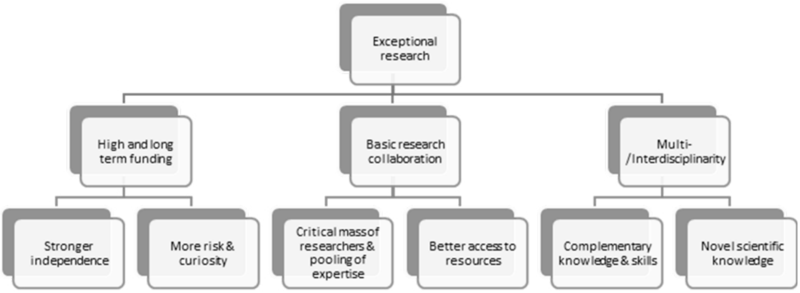
The publication-activity analysis is conducted for the entire period 2004–2017 and three subsequent and disjoint four-year sub-periods. The citation analysis is based on three-year citation windows (publication year and the two subsequent years) and, because of data availability, limited to the period 2004–2016. Only 'citable' papers (article, letter, note and review) have been taken into account. Bibliographic data are cleaned and processed to bibliometric indicators according to the standard rules in the field (see, e.g., Glänzel et al., 2009). A strict full-counting scheme has been applied to publications and citations. This applies to both subject matter and affiliation. The assignment of papers is based on the ECOOM classification system with science fields and disciplines. In this system, journals are assigned to and grouped into cognitive-logical disciplines. This scheme with 16 fields and 74 disciplines is hierarchically built on top of the Web of Science Subject Categories comprising about 250 categories (cf. Glänzel et al., 2016).

Propensity score matching was applied to identify an appropriate set of Stand-alone projects, another funding instrument of the Austrian Science Fund, as a *control group*. A *counterfactual analysis* was applied to identify statistically robust differences between network projects and stand-alone projects.

Finally, the qualitative analysis comprised *two online targeted surveys* including (sub)-project *coordinators* as well as *unsuccessful applicants*. The SFB (sub)-project coordinator survey yielded in the response of 211 (sub)-project coordinators of SFB networks out of 674 contacted, i.e. a response rate of 31.3%. *Individual interviews and two focus group interviews* with a total number of 31 participants were carried out with representatives from the networks, FWF, university management and R&I policy actors. Focus group 1 focused on researchers in the Social Sciences and Humanities (SSH), where eight carefully selected participants discussed their experiences with the SFB programme. Focus group 2 was dedicated to Medical and the Natural & Technical Sciences. This disciplinary approach enabled the validation of findings and additional data collection while taking into consideration the discipline-specific needs and requirements of researchers for excellent science and research funding.

The impact of SFB funding on outstanding research

SFBs incorporate a programme design, which inherently aims at exploiting the benefits from research collaborations. Through its programme characteristics, the programme may lead to *higher scientific quality, productivity and ground-breaking research results.*



Exceptional research
High and long term funding
Basic research collaboration
Multi-/Interdisciplinarity
Stronger independence
More risk & curiosity
Critical mass of researchers & pooling of expertise
Better access to resources
Complementary knowledge & skills
Novel scientific knowledge

Source: Dinges et al. (2020)

Figure 2: Impact pathways for funding outstanding research

Key hypotheses reflected in Figure 2 are that: 1) High and long-term funding of a group of researchers lead to stronger independence of researchers, more out of the box and curiosity-driven research; 2) The collaborative character of research facilitates the creation of a research-network of critical mass researchers, pooling of expertise, and better access to complementary resources; 3) The multi-/interdisciplinary character of the research networks allows researchers from different disciplines to look at similar questions, which may lead to entirely new combinations of complementary skills and knowledge and novel scientific knowledge.

Excellence: Publication activity and citation impact

In the bibliometric part of the analysis, we have used two basic sets of indicators, the first one reflecting publication activity and international collaboration, the second one regarding citation impact. The second set, in turn, consists of two parts, the standard set of relative indicators and the second part aiming to capture excellence as measured by outstanding impact. While the standard set of citation indicators sheds light on different aspects of factual citation impact and its different expectations, the second one supplements the linearly structured indicator model by performance profiles with seamless integration of measures of outstanding performance into the standard tools represented by the first set. This is summarised in nutshell below.

The citation-impact indicators form a triplet of mean observed, relative and normalised mean citations rates (MOCR, NMCR and RCR, respectively) according to Glänzel et al. (2009). This triplet allows the interpretation of how the observed citation impact (MOCR) relates to the expectations based on journals (RCR), where the papers in question have been published, and the disciplines (NMCR) to which these belong to. The most ‘favourable’ situation is NMCR>RCR>1, which means that the papers are published, on an average, in journals with a higher-than-discipline standard and receive even more citations than the standard set by the journals in which the papers are published. RCR<1<NMCR means that the latter standard is not reached and, for instance, NMCR<1<RCR means that the papers achieved a higher citation impact than expected based on the journals in they are published but these journals, on average, do not belong to the top journals in their discipline.

This set is extended by the citation classes according to the method of Characteristic Scores and Scales (CSS), which are compatible with the above set of relative indicators (cf. Glänzel et al., 2019). To capture excellence reflected by citation-impact, we apply four classes, which stand for ‘poorly cited’ (CSS1), ‘fairly cited’ (CSS2), ‘remarkably cited’ (CSS3) and ‘outstandingly cited’ (CSS4). Although CSS is not directly linked to percentiles, the distribution of papers over classes is about 70% (CSS1), 21% (CSS2), 6%–7% (CSS3) and 2%–3% (CSS4). Deviations of a profile from the reference standard provide a multifaceted picture of citation impact. All above-mentioned indicators can be calculated for any subsets such as international co-publications or research with a strong interdisciplinary orientation.

Bibliometric indicators for the SFB programme are provided in comparison with those for the matched set of FWF Stand-alone project publications and the complete Austrian population in Tables 1 to 3. The factual citation impact of SFB papers is above the journal expectation and that, in turn, is distinctly above the field-based expectation. The situation is stable, even improving. In other words, we find the most favourable situation here, NMCR>RCR>1, for the three periods between 2004 and 2016. Thus, the PIs of SFB projects in general publish in high impact journals (with respect to their field) and receive more citations than expected for these journals.

These indicators underline that the SFB programme clearly outscores both the Stand-alone projects and the Austrian overall publication set across all citation rates. The large shares of upper CSS classes reinforce the assessment of strong support for outstanding research by the programme.

The share of international papers in all SFB publications is increasing over time but is slightly below Austria's average share over the 14-year period. The interpretation of this deviation is not straightforward as co-publication patterns are influenced by multiple factors (subject profiles, size of community, expertise, economic factors, and others). Different selection biases might play a distinct role in the high-level SFB projects. International co-authorship proved to have a further positive effect on citation impact.

Table 1: Citation-impact indicators for the SFB programme publications in 2004–2016

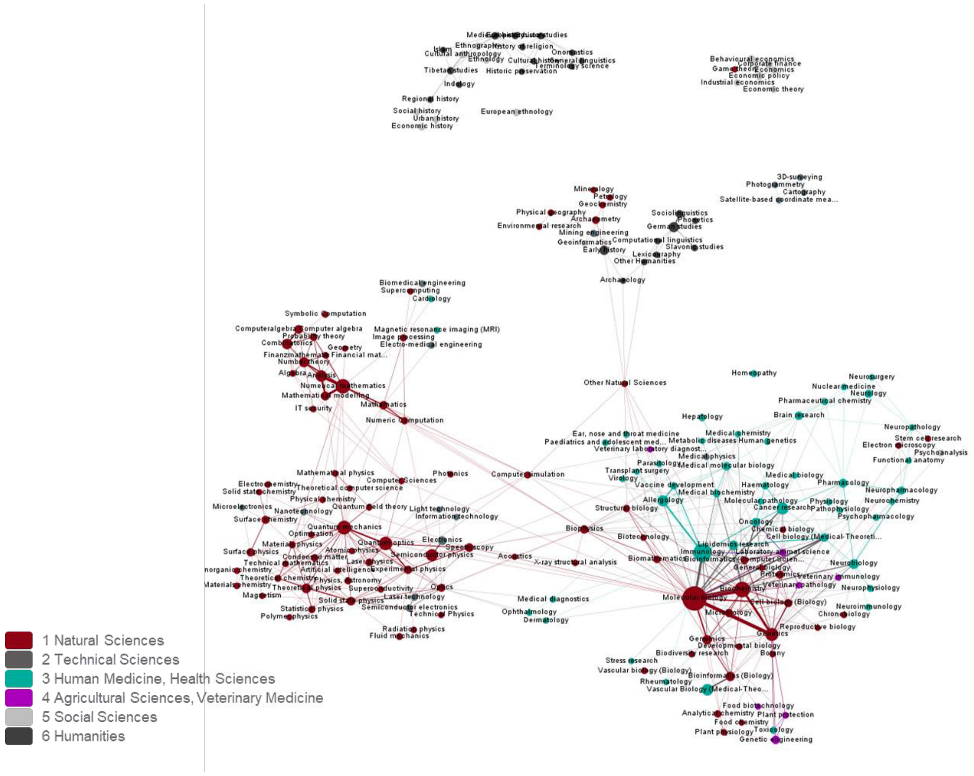
Survey and interview results highlight the perception that the SFB programme is primarily an instrument for highly experienced and established researchers. A large part of this pattern is attributed to the selection process and criteria, that place a strong emphasis on individual scientific excellence and publication track records, where young PIs with less experience and smaller networks are disadvantaged compared to senior researchers boasting scientific fame and awards.

Interdisciplinarity

As mentioned in the introductory section, SFB is laying great stress on supporting interdisciplinarity in research. Therefore, interdisciplinarity was analysed from three different angles.

1. Classification of sub-projects,
2. Publication results, and
3. Survey and interviews.

Ad 1. Interdisciplinarity was measured by the extent to which different disciplines of the three-level hierarchical ÖFOS 2012 classification are addressed within the same SFB sub-project. Based on SFB monitoring data of 331 sub-projects assigned to 195 sub-disciplines, we calculated and visualised the findings as a network, where nodes represent the sub-disciplines, which are connected when they are mentioned in the same project. The size of nodes represents the number of sub-projects, which are assigned to the respective subdiscipline. The size of the edges displays the number of joint projects between two sub-disciplines and the colour of the nodes refers to the highest level of the Austrian classification of science disciplines.



Source: Dinges et al. (2020) based on Web of Science Core Collection

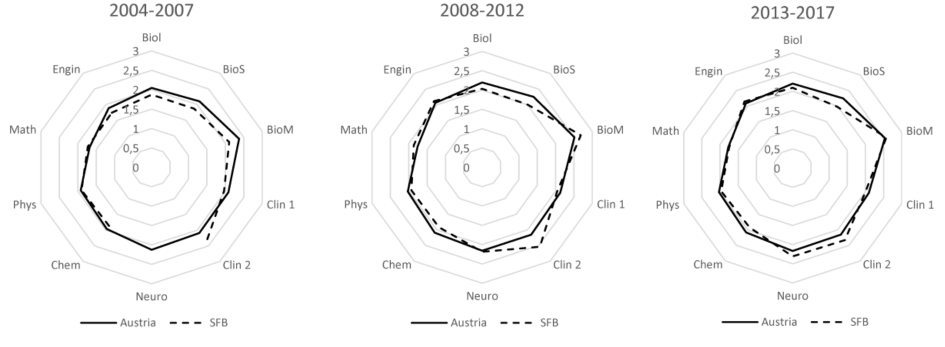
Figure 3: Connectedness of SFB sub-disciplines

The resulting network (Figure 3) displays four main clusters; among them two clusters with a strong interdisciplinary orientation and two disciplinary clusters.

- The first interdisciplinary cluster is the largest one in the network and situated in the bottom right area of the network. It comprises fields with clearly overlapping thematic orientation and is based on sub-projects assigned to “Biology”, “Medical-Theoretical Sciences, Pharmacy” and “Clinical Medicine”, especially “Molecular biology” (24.3 projects), “Immunology” (16.1 projects), and “Biochemistry” (12.7 projects).
- The second interdisciplinary cluster, located on top of the network, consists of several separate components and is mainly dedicated to the Social Sciences and Humanities with some connections to the Natural Sciences. In this cluster, no sub-discipline obtains a central position or is assigned to more sub-projects than others.
- The third cluster focusing mainly on “Physics, Astronomy” with single connections to disciplines in the Technical and Medical Sciences is positioned in the bottom left area of the network. Central disciplines are “Quantum mechanics” (10.6 projects) and “Quantum optics” (9.8 projects).
- The fourth cluster, finally, is formed by subdisciplines around (Numerical) Mathematics and Information Technologies, which is connected by single links with the first and the third cluster.

Bridging sub-disciplines connecting these four clusters are “Other Natural Sciences”, which link the interdisciplinary Medical Science cluster and the SSH cluster, and “Computer Simulation” together with “Biophysics” connecting Medical research (first cluster), Quantum research (third cluster) and Mathematics (fourth cluster).

Ad 2. To measure the extent of interdisciplinarity in the publications, we applied a special Hill-type indicator ${}^2D^2$ according to Leinster and Cobbold (2012), which takes real values ≥ 1. We furthermore used the 74 subfields according to the revised WoS-based Leuven-Budapest classification scheme (cf. Glänzel et al., 2016) for optimum granularity and compatibility with the above indicator analysis (Glänzel & Thijs, 2018). According to Zhang et al. (2016), values above 5.0 reflect strong interdisciplinarity. Figure 4 gives a detailed comparison between interdisciplinarity scores within the SFB programme and the Austrian standard displayed by major ECOOM fields. While the scores for Physics, Chemistry, Mathematics and Engineering are by and large in line with Austria’s reference scores, the scores for the output of SFB in the life sciences is less stable. The below standard interdisciplinarity in Biology, Biosciences is contrasted by interdisciplinarity scores above the national standard for the smaller fields Neurology and External Medicine (Clin2).



Source: Dinges et al. (2020) based on Web of Science Core Collection

Figure 4: Interdisciplinarity scores for SFB and Austria by science fields

The field comparison provides an explanation for the lower overall SFB scores (2004–2007: 1.88; 2008–2012: 2.01; 2013–2017: 1.98) compared to Austria (2004–2007: 1.99; 2008–2012:

2.08; 2013–2017: 2.09) and the world (2004–2007: 1.94; 2008–2012: 2.05; 2013–2017: 2.08). The publication profile of SFB is in fact more oriented towards Physics, which has overall a lower score than the other fields.

Ad. 3 SFB participants' own assessment of interdisciplinarity is in contrast to the findings of the bibliometric and network analysis. On the one hand, interdisciplinarity is seen as one of the key attributes that makes the SFB attractive and unique in the Austrian R&I funding system for basic research, while on the other hand interviewed SFB participants stress that interdisciplinarity is merely a means to an end, i.e., collaboration between disciplines forms only when and if there is a need for specific expertise, often in the context of using another discipline's analytical tools as opposed to interdisciplinarity as the integration of disciplines.

Survey and interview results highlight that researchers perceive their projects as highly interdisciplinary, which the network analysis and the bibliometric analysis highlight do not fully corroborate. The evidence on this apparent contradiction in opinions on interdisciplinarity shows that researchers.

- Have different understandings of the differentiation between multi- and interdisciplinarity, and a lack of intrinsic motivation for interdisciplinarity;
- Perceive the peer review process as detrimental to highly interdisciplinary projects with high levels of interdisciplinarity among non-closely related fields of science;
- Incorporate strategic considerations of disciplinary distribution in SFB proposals to maximize the chances of success.

Interdisciplinarity is one of the key attributes that makes the SFB attractive. It is understood not only as a strategic aim of the programme, but researchers highlight that the possibility to propose interdisciplinary research topics as among the key motives for SFB participation. The programme's orientation explicitly promoting interdisciplinarity is seen as a unique feature in the Austrian R&I funding system.

Discussion and Conclusions

The evaluation of the Austrian Science Fund's SFB Programme followed a theory-based evaluation approach. Impact pathways were delineated to derive key hypothesis about the contribution of the intervention towards its objectives. A mixed-method approach was pursued towards the empirical analysis to combine different perspectives and increase research integrity. The evaluation resulted in a differentiated picture of the factors contributing to the objective of funding outstanding research.

The analyses performed clearly show that SFB succeeded in supporting exceptional research as evidenced by the outstanding publication and citation record of the funded projects. The publication profile of the SFB programme and its projects in the period 2004–2017 displays a strong continuity in the growth and development of the scientific activity. Furthermore, the publication analysis shows that SFB researchers receive a high citation impact and that their work reflects a very high scientific standard. SFB projects exceed national averages and outperform Stand-alone projects along all metrics of citation impact. Moreover, the bibliometric analysis reaffirms the SFBs' highly successful publication strategy: The PIs of SFB projects in general publish in high impact journals (with respect to their field) and receive more citations than expected for these journals.

The excellence in scientific outcomes is not paralleled by achievements in terms of interdisciplinarity and international collaboration. SFB projects involve fewer internationally co-authored publications compared to the Austrian average. Interdisciplinarity is typically a result of very closely related (sub-) disciplines working in a sub-project. It is mainly found in fields of science, with clearly overlapping content such as biology and medical theoretical sciences and clinical medicine. In terms of average interdisciplinarity scores, the SFB programme lies below the average for Stand-alone projects and the Austrian average.

Acknowledgments

This work was supported by the Austrian Science Fund (FWF) through the project *Evaluation FWF Special Research Programmes (SFB)*. The authors want to thank all members of the evaluation team for valuable comments and discussions on the subject.

Abstract

This study explores the societal embeddedness of the websites of research projects. It combines two aims: characterizing research projects based on their weblink relationships, and discovering external societal actors that relate to the projects via weblinks. The study was based on a set of 121 EU-funded research projects and their websites. Domains referring to the websites of the research projects were collected and used in visualizations of co-link relationships. These analyses revealed clusters of topical similarity among the research projects as well as among referring entities. Furthermore, a first step into unveiling potentially relevant stakeholders around research projects was made. Weblink analysis is discussed as an insightful tool for monitoring the internal and external linkages of research projects, representing a relevant application of webometric methods.

Introduction

Publicly funded research projects are a prominent means to develop scientific research. In the context of Horizon 2020 (H2020), the EU's Framework Programme for research and innovation from 2014 to 2020, a broad variety of projects have been funded. Given the scope, size, and duration of many of those, evaluating their impact in a timely manner has to go beyond common metrics for scientific output, such as publications. Those, as well as citations, provide relatively belated signals of the – academic – impact of projects, and usually at a time when projects have already been finished. A more general question is whether funded research projects are raising any interest or attention in society, and whether this can be captured timelier. One of the measures to explore a project's embeddedness in society can be the analysis of the *digital response* that a project's web presence generates. In this, a research project's website can serve as a point of reference to which other entities on the Internet *respond digitally* in the form of weblinks.

Weblinks and webometrics

The field of webometrics has produced a broad body of research studying weblinks, how they form networks, and, among a variety of other questions, how websites can be ranked and measured based on their connections (Thelwall, 2012). However, researchers have also advised caution regarding inferences based on one-sided quantitative analyses of weblinks (Thelwall, 2006). The challenge of adequately characterizing and interpreting weblinks is considerable. While weblinks can be seen as *web-'citations'*, in a way comparable to scientific citations, such equivalence can be problematic when not considering the different motivations and contexts behind weblinks (Björneborn & Ingwersen, 2004). Nonetheless, it has also been argued that weblinks may be useful for covering the phases of research that precede the formal publication of research output (Thelwall, Klitkou, Verbeek, Stuart, & Vincent, 2010).

Using weblinks to characterize the digital response to research project websites

Considering the conceptual caveats around weblinks, it is obvious that the incoming links attracted by a website need to be turned into processable and meaningful metrics. This can be achieved by a combination of measures and may include a focus on the origins of web references (Thelwall, 2006). Furthermore, weblinks can – mimicking citation relationships – be combined in co-citations and bibliographic couplings (Björneborn & Ingwersen, 2004). This might as well be described as "heterogenous couplings" (Costas, de Rijcke, & Marres, 2020) more broadly. As far as heterogenous couplings assume networked structures underlying science-non-science interactions, they may be used for creating networks of web relationships as well. This would account for the fact that websites are (usually) embedded in networks of other web entities and thus, provide an opportunity for contextualizing the unique *digital footprint* of e.g., a project website. At the same time, considering a 'community' of web pages can also reveal insights regarding how much it refers to itself, as well as the extent to which it is being referenced from outside.

Our study aims to apply the concept of heterogenous couplings on the characterization of the weblink relationships of research projects. We investigate the relationships between the websites of research projects based on weblinks among them, as well as weblinks coming from outside their community. Accordingly, this research in progress revisits existing webometric methods and applies them to the analysis of the websites of publicly funded research projects.

Methodology

Our analysis was based on 121 research projects within the *Science with and for Society* (SwafS) program, funded under H2020, representing 77% of all SwafS projects funded by the end of 2020. We selected this portfolio of projects as study case because their objectives are linked to aspects such as science communication, careers and education, promoting gender equality, responsible R&I, and research ethics and integrity, and the engagement of citizens. The type of outputs and outcomes delivered by these projects requires the search or definition of valid forms of assessing their impact and monitoring their activities beyond the typical research related metrics. All projects included had started between 2015 and 2020. At the time of this analysis, 46 (38%) of all projects had ended already, the rest was still running. Each of the projects had a dedicated project website.

Identifying referring sources

To identify the web sites linking to a research project's website(s), we relied upon *backlinks*. Backlinks are the links that a website receives (Björneborn & Ingwersen, 2004). Multiple commercial services crawl the Internet for such backlinks and extract them. We used Majestic, an exhaustive source for webometric research (Orduña-Malea, 2021). This service operates a large database of weblinks and is broadly used for the task of optimizing web presences.[1]

Getting the backlinks for the projects' websites from Majestic, we did not use the path (or "URL") of the homepages of the project websites, since this would only return the backlinks referring to this specific page. Instead, we looked up the *root domain* in a given URL. This expanded the set of results by returning any link received by any webpage available under the root domain.[2] For a given website this means that both backlinks to the homepage and any sub-page are found, providing a more complete picture of the embeddedness of a website. We did not collect all the backlinks, but only focused on the referring domains. This was in order to prevent results from being biased by a large number of backlinks coming from one single

[1] https://majestic.com/company/about

[2] For example, in the URL https://europa.eu/, the part 'europa.eu' is the root domain.

domain (i.e., any link relationship between a project website and a referring website was counted just once). We collected all referring domains accordingly on January 13, 2021.
Since the SwafS projects are funded and conducted in a European context, we limited the referring domains to those originating from an EU member state or an associated country, based on the country codes coming with each referring domain or where the so-called top-level domain (TLD) indicates such a country.[3] This resulted in a final set of 4,606 referring domains. The projects in our set might have had different chances of gaining online attention, depending on the time they had already been running. We tested for a correlation between the number of days a project had been existing from its starting day until January 13, 2021, and the number of referring domains, returning a positive, moderate correlation ($r_s = .491$).

Creating networks based on co-link relationships

To analyze how the SwafS project websites relate to each other, we considered the overlap between referring domains and the project websites' root domains. Per project, we calculated the share of referring domains coming from other SwafS projects among all referring domains. Then, we created a matrix of projects based on the number of other projects that refer to both of them, establishing a *co-linked* relationship between them (see the graph on the left in Figure 1). In the field of bibliometrics, this is also known as a *co-citation* (Björneborn & Ingwersen, 2004; Costas et al., 2020). Next, we created the same matrix of co-linked projects, but this time using the number of *external* domains linking to more than one SwafS project. Finally, we connected the referring, external domains based on mutually linked project websites (see the graph on the right in Figure 1). This *co-linking* is also referred to as *bibliographic coupling* (Björneborn & Ingwersen, 2004; Costas et al., 2020).

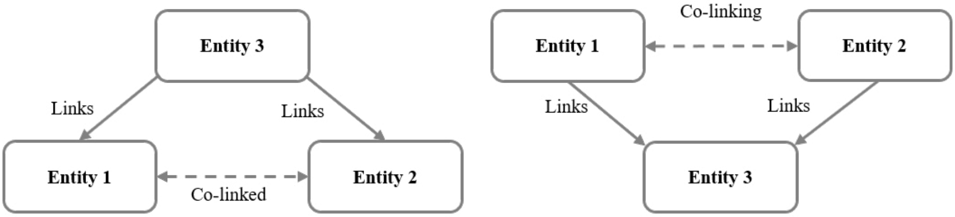

Figure 1. Schemes for a co-linked relation (left), and a co-linking relation (right).

In the networks with external referring domains, we did not include those with a '.com'-TLD. With 805 distinct cases found, this was the most common TLD, followed by '.eu' (424) and '.org' (390). Our reasoning was that domains with this dominant TLD could divert the focus from more interesting actors, which we assumed to rather be present with organization ('.eu', '.org') or country ('nl', 'de', etc.) related domains. For example, 90.1% of the project domains itself have an '.eu'-TLD. All networks were visualized with the VOSviewer software.[4]

Results

Overall, we observed a considerable weblink interconnection within the SwafS projects community. On average, 10.6% of the domains that refer to a SwafS project's website came from other SwafS projects in our set. However, the extent to which this was the case varied a lot: 24 projects were not referred to by any other project, whereas in the case of one project, 43.5% of all referring domains originated from other SwafS projects' websites. The extent of

[3] The top-level domain is the URL part following the so-called second-level domain. E.g., in the URL https://europa.eu/, 'eu' is the top-level domain, and 'europa' is the second-level domain.
[4] https://www.vosviewer.com/

the overlap becomes also apparent when mapping the weblinks among projects based on the number of other projects that refer to them (see Figure 2). What is relevant here are different clusters of projects that are formed based on weblinks. For example, the green cluster on the right refers to projects that are aimed at (gender) equality. The blue cluster (bottom left) can be related to citizen science. In between these clusters, the red and yellow clusters include projects focused on Responsible Research and Innovation (RRI).

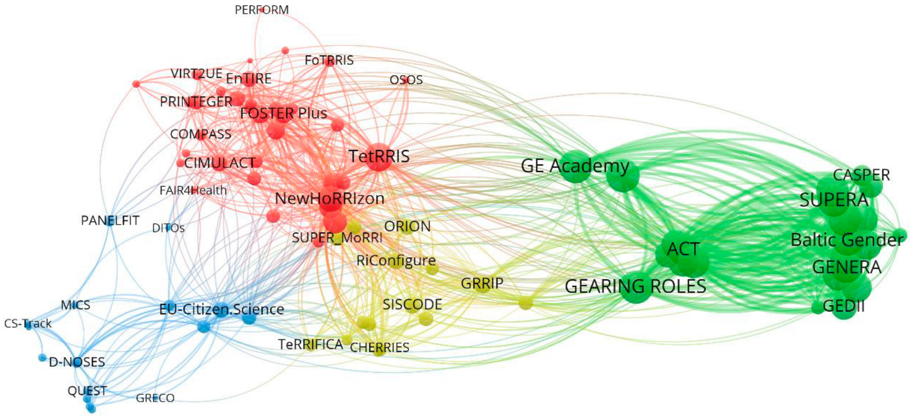

Figure 2. VOSviewer visualization of a co-linked network of research projects based on referring other research projects.

A similar pattern of clusters becomes visible when again looking at the co-linked network for the research projects, but this time only based on external sources of reference (Figure 3).

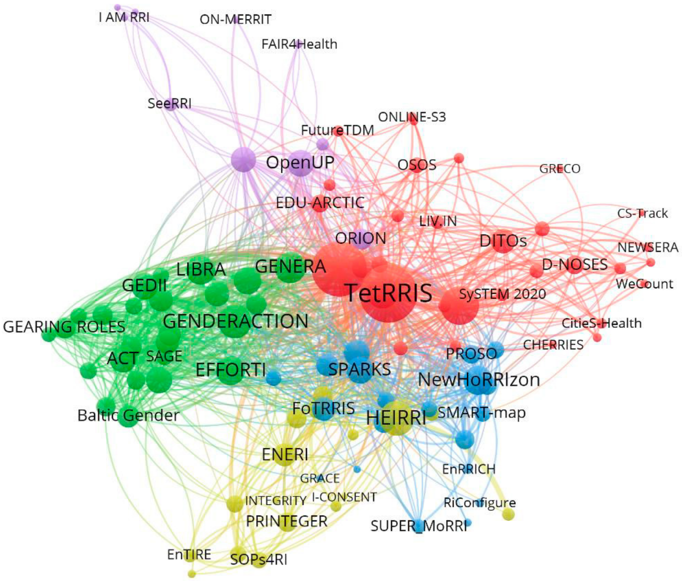

Figure 3. VOSviewer visualization of a co-linked network of research projects based on external referring domains.

Finally, coupling external referring domains based on concurrently cited research projects (Figure 4) revealed several clusters that reflect some of the topics also present in the cluster networks in Figures 2 and 3: For example, we again find a cluster related to gender equality (yellow), and a cluster relatable to citizen science (dark blue). The linking organizations include, among others, universities, science networks, museums, research institutes, and funding organizations.

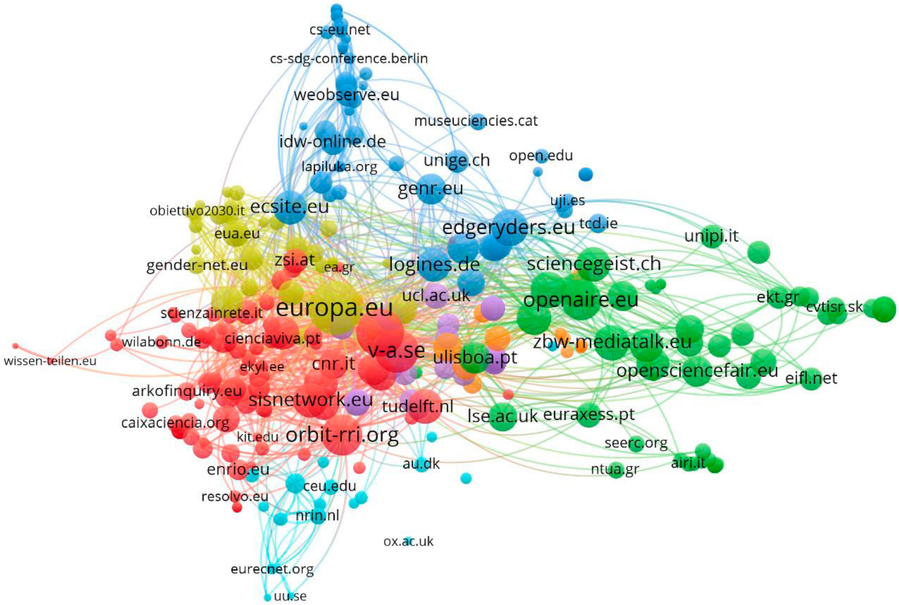

Figure 4. VOSviewer visualization of the co-linking network of referring domains.

Discussion

Our study shows how the weblink relationships of SwafS research projects capture underlying topical clusters. This could provide valuable insights into the relatedness of research projects and hint to possible synergies between them. Our proof of concept also shows the network of external actors based on the weblink connections with the projects. These external linking actors represent a unique source of relevant information on potential societal stakeholders (e.g., governments, museums, networks, etc.) who exhibit an interest in the projects. This hints to the potential value of weblink analyses to assess the ‘early’ societal relevance of (funded) projects, making this also very relevant for funding organizations. They could identify latent relationships existing among their funded projects at an early stage of the projects.[5]

The approach presented has relevance for both the ‘community’ analysis of research projects (i.e., the analysis of a set of projects from the same program or topic), and the analysis of individual projects. Combined with background information on the projects, a weblink analysis could illuminate underlying characteristics of individual projects (e.g., the relationships with other projects, or with other organizations), providing a unique tool to identify potential stakeholders relevant to each project.

[5] Project websites are typically created at the early stages of projects, while other outputs that could also point to project relationships – like reports or publications – generally take more time to be produced.

We conclude that the weblink analysis of scientific projects represents a strong monitoring tool that is able to characterize the internal and external linkages resulting from funded projects. This adds to the variety of applications of webometrics as well, and, more specifically, to existing research on science-related web presences (Orduña-Malea, 2021).

It should be noted that the approach presented is only a *snapshot in time*. The Internet is dynamic, and the numbers of referring domains can change quickly over time. Furthermore, research projects may have different requirements and ambitions regarding their online presence, which is connected to the numbers of links they may possibly receive. This requires caution especially when making inferences for individual cases.

We plan to further refine the approach described, including the analysis and classification of the referring sources to better grasp the underlying structures. In addition to that, insights could be obtained by breaking down results according to the countries of origin of referring sources and by connecting them to the origins of project participants.

We are also going to investigate how the approach described plays out in a different context – namely, on Twitter. For that, we aim to study connections between the Twitter accounts of the research projects and other Twitter accounts. This could eventually lead us to uncovering the "communities of attention" (Haustein, Bowman, & Costas, 2015) around research projects and thus, result in a more complete picture of the societal linkages to research projects.

Abstract

The Arabic Citation Index (ARCI) was launched in 2020. This study gives an overview of the scientific literature available in this new database. I analyse ARCI by using metadata available in scientific publications to characterize its coverage. First, I describe the data and the methods used in the analyses. As of October 2020, ARCI indexed 65,208 records covering the 2015-2019 period. Second, I explore the literature distributions at various levels (research domains, countries, languages, open access). Close to 99% of documents indexed are articles. Results reveal the concentration of publications in the Arts & Humanities and Social Sciences fields. Most journals indexed in ARCI are currently published from Egypt, Algeria, Iraq, Jordan and Saudi Arabia. Around 7% of publications in ARCI are published in languages other than Arabic. Then, I use an unsupervised machine learning model, LDA (Latent Dirichlet Allocation) and the text mining algorithms of VOSviewer to uncover the main topics in ARCI. These methods are particularly useful to better understand the topical structure of ARCI. Finally, I suggest few research opportunities after discussing the results of this study.

Introduction

Research excellence is often equated to publishing in English in high impact factors journals, as stated in the third principle of the *Leiden Manifesto* (Hicks et al., 2015). This is problematic for the humanities and social sciences where research tends to be more engaged on national issues and published in local languages. Identifying the peer-reviewed journals of regional relevance and importance is a major issue for all scientific stakeholders. Protecting excellence in locally relevant scientific research is key to preserve fields which have regional or national dimensions.

In 2020, the Arabic Citation Index (ARCI) was launched in the Web of Science platform, first in Egypt and later in the rest of the Arab World. Clarivate Analytics partnered with the Egyptian Knowledge Bank (EKB), as part of the Egyptian Ministry of Education, to power the first Arabic Citation Index. This launch is also part of Egypt's *Vision 2030* where knowledge, innovation and scientific research are key pillars to achieve scientific excellence (Egyptian Government, 2016). As mentioned by Dr. Shawki, Minister of Education & Technical Education in Egypt and President of the EKB Project, the "aim is to work toward becoming a more knowledgeable Egyptian community that encourages learning as a part of everyday life. We look forward to building our economy and exporting our sciences globally in the Arabic language." (Clarivate Analytics, May 2018).

The focus of ARCI is on the 22 countries of the Arab League and their scholarly research. ARCI joins other regional citation indexes, using the same core features with an Arabic language interface. The criteria for inclusion in ARCI are a subset of the Web of Science Core Collection criteria (Clarivate Analytics, 2019). The journals covered in ARCI are selected by a newly established Editorial board with members from Arab League countries who provide subject knowledge and regional insights. The selection process for ARCI is based on traditional scientific publishing standards and the research norms of the Arab region. First, there is an initial triage to confirm content accessibility and format for all titles considered for indexation in ARCI. All journals must have an ISSN. Several elements are evaluated in this first step: journal title, publisher information, URL for online journals, content access, DOI/pagination and timeliness/volume. Next, the journals are reviewed from an editorial perspective. In this second step, each journal is evaluated to confirm it provides scholarly content, with a clear scope statement, article abstracts, cited references, content relevance with the stated scope or mission, quality of language consistent with scientific communications and an editorial board reflective of the field of the journal.

Such indexing will provide more visibility to research published in Arabic facilitating contribution to local and international research efforts. ARCI is relatively new, and it requires a separate subscription to be accessed in the Web of Science platform. Very little is known about this new database which is still unfamiliar to many researchers. Therefore, the purpose of this study is to characterize the literature available in this new citation index. First, I describe the data and methods used in the analyses. Next, I explore few content distributions at various levels (research domains, countries, languages, open access). Then, I analyse the main topics covered in ARCI by using the Latent Dirichlet Allocation model and the text mining algorithms of VOSviewer (van Eck & Waltman, 2010). Finally, I discuss the results of this study, identify its limitations and suggest few research directions.

Data and Methods

Data

ARCI has a coverage back to 2015. ARCI data was extracted on October 5th, 2020. I have excluded 2020 since the year was not complete yet. Full records were exported from the Web of Science platform. The dataset under study consists of 65,208 records for the 2015-2019 period. Table 1 lists the distribution of records by publication year as well as the share they represent within ARCI.

Table 1. Number and share of ARCI records by year (2015-2019)

Publication Years	*Records*	*Share (%)*
2019	14,198	21.8
2018	15,307	23.5
2017	14,774	22.7
2016	12,013	18.4
2015	8,916	13.7

This database is well structured with 48 fields of information in each record allowing multiple bibliometric analyses (e.g. Publisher Information, Funding Information, Research Area, Open Access Indicator, Cited References, Citations, Usage Counts, ESI Highly Cited Paper/Hot Paper). In addition to essential metadata available in English as in the Web of Science Core Collection, ARCI has some specific information written in Arabic such as *authors names*, *article title*, *publication name*, *author keywords*, *abstract* and *author address.* ARCI records also show the ARCI times cited and the Total Times Cited Count (Web of Science Core Collection, Arabic Citation Index, BIOSIS Citation Index, Chinese Science Citation Database, Data Citation Index, Russian Science Citation Index, SciELO Citation Index) as well as the Cited References and the Cited Reference Count.

Methods

In this study, I use bibliometric methods to characterize the literature indexed in ARCI. The objective is to examine the local research landscape from various perspectives. Such analyses can help research managers and policy makers to better understand local research activity. I conducted a bibliometric analysis to study the journal distribution across countries and scientific productivity of countries. Then, I explored the distribution of publications by research fields, languages and access types.

Many machine learning algorithms have also been developed to understand, group or search information from large text databases. Such approaches have been frequently used to examine the structure of an aggregated literature. In natural language processing, a topic model is a statistical model to discover the abstract hidden semantic structures or topics that occur in a collection of documents. Latent Dirichlet Allocation (LDA) is a model proposed by Blei et al. (2003) used to classify text in a document to a topic. Previous studies have shown that LDA performed well to understand the topical structure of a scientific corpus (Han, 2020; Suominen & Toivanen, 2016; Yau et al., 2014).

LDA is a generative probabilistic model of a corpus. The basic idea is that publications are composed of groups of words with no sequential relationship between them. As documents can include multiple topics, there is a probability of topic distribution for each topic. Each record can be described by a distribution of topics. Each topic is characterized by a distribution over words, described as a distribution of terms in a fixed vocabulary.
There are many tools available for LDA. In this study, I applied the *LatentDirichletAllocation* model available in the Scikit-learn.org python library to perform LDA.

Results

In this section, I report the main findings of the study. First, I analyse the research domains in ARCI by number of records and the proportion they represent in the database. Next, I present the journals distribution by countries. Then, the most productive countries are examined, followed by an analysis of the languages of publications and their access types. Finally, I focus on the main topics covered in the Arabic scientific literature indexed in ARCI.

Research areas distribution

Research Areas constitute a subject categorization scheme that is shared by all Web of Science product databases. This is particularly helpful when analysing documents from multiple databases related to the same research areas. All 153 research areas in the Web of Science are grouped into five broad categories: Arts & Humanities, Life Sciences & Biomedicine, Physical Sciences, Social Sciences, and Technology.

I relied on the journal category and not on the topic covered in the individual publications to analyse the disciplinary coverage in ARCI. These categories or areas, which are defined at the journal level, are used as proxies for scientific fields.

The ARCI records relate to 21 research areas in the dataset under study. Currently, 11,070 records (around 17% of ARCI), do not contain data in the *Research Area* field. In Figure 1, I summarize the number of records within each of research area and the share of the database they represent. I have limited to the 16 research areas with a share higher than 0.5%.

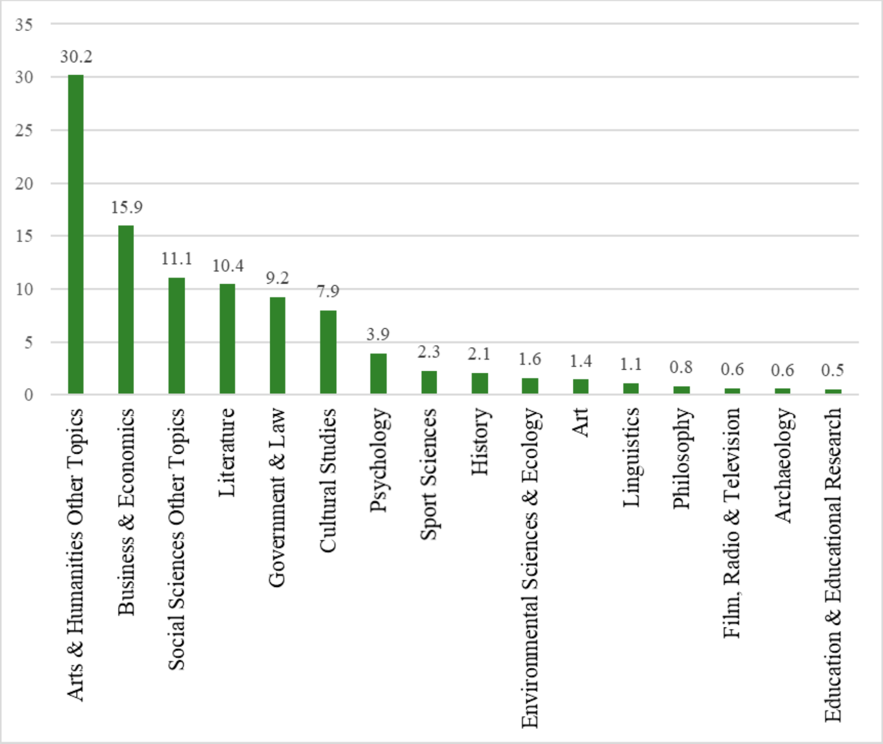

Figure 1. Share (%) of documents by research areas in ARCI (2015-2019)

I have also summarized the shares of the number of papers within each of the five broad domains in Figure 2.

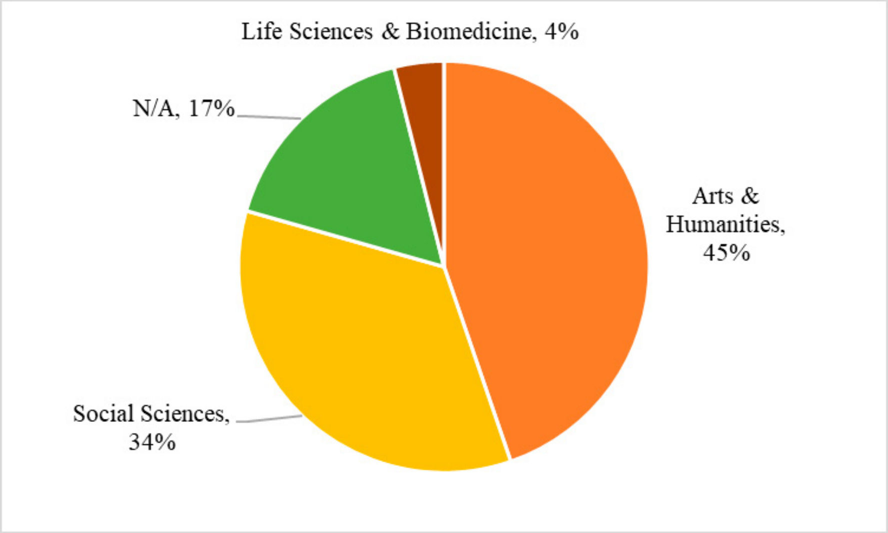

Figure 2. Share (%) of documents by broad categories in ARCI (2015-2019)

This figure shows ARCI contains mainly journals in the Arts & Humanities, and Social Sciences categories. These categories represent 79% of ARCI total coverage. Journals in Life Sciences & Biomedicine account for 4% of the coverage. As mentioned earlier, 17% of records retrieved do not contain information about the Research Area. It is worth noting there is no journal related to Technology or Physical Science categories. This confirms the current focus of ARCI. Local issues in Arts & Humanities as well as Social Sciences dominate the ARCI coverage.

ARCI also offers its own research categories. We retrieve similar results. However, some differences emerge. When analysing the records with the ARCI classification, only 242 records do not contain information about the research categories, representing less than 0.4% of the total database. Some categories standout such as Islamic Studies, Islamic Jurisprudence, Islamic Creed, Poetry and Hadith which are fields well studied in the Arab region.

Content coverage by countries

In this section I analyse the coverage by country. First, I examine the types of documents indexed in ARCI. Table 1 lists the number of documents per type and they share they represent in the database. ARCI is primarily composed of articles. Close to 99% of documents indexed are articles. Other document types all represent less than 1% of the database.

Table 1. Number and share of ARCI records by document type (2015-2019)

Document Type	*Records*	*Share (%)*
Article	64,467	98.864
Review	432	0.662
Editorial	104	0.159
Art and Literature	97	0.149
Other	62	0.095
Bibliography	43	0.066
Meeting	3	0.005

Now, I focus on the distribution of journals over countries, where each journal is assigned to a country based on the country in which the publisher is located. Before analysing the country distribution in ARCI, I examined the coverage of Arab journals in the various citation indices in the Web of Science Core Collection (WoS CC): Science Citation Index Expanded (SCIE), Social Sciences Citation Index (SSCI), Arts and Humanities Citation Index (AHCI) and Emerging Sources Citation Index (ESCI). This coverage is represented in Figure 3.

As of October 2020, 21,419 journals were indexed in WoS CC. 144 journals (or 0.67%) are published in 13 of the 22 Arab League countries: 66 in SCIE, 1 in SCIE and SSCI and 77 in ESCI. Out of these 144 journals, 134 (93%) are published in English only. The remaining 10 journals (7%) have published papers in several languages during the study period: English (78%), French (12.6%), Arabic (5.8%), Spanish (3.365%), Afrikaans (0.05%) and Italian (0.05%). The United Arab Emirates (UAE), Egypt and Saudi Arabia are the three most represented Arab countries in WoS CC with a total of 113 journals and a share of 78% of all journals published in the Arab region and indexed in WoS CC.

Although the criteria for inclusion in ARCI are a subset of the Web of Science Core Collection selection process, there is no overlap between WoS CC and ARCI. The distribution by country of publisher in ARCI is represented in Figure 4. ARCI indexes content from 19 of the 22 Arab League countries. Content for Djibouti, Comoros and Somalia is not indexed yet. Journals published in Egypt, Algeria, Iraq, Jordan and Saudi Arabia represent 79% of the journals indexed in ARCI.

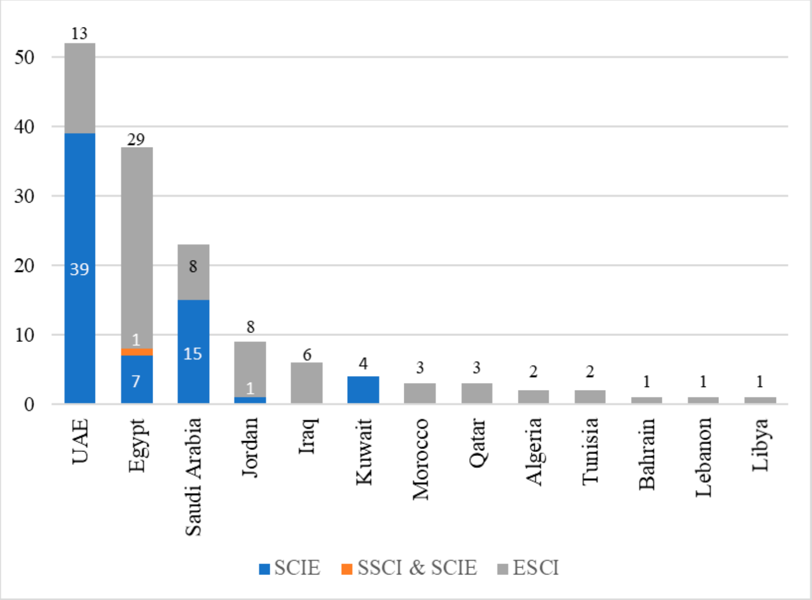

Figure 3. Number of journals by Arab country in WoS CC citation indices (September 2020)

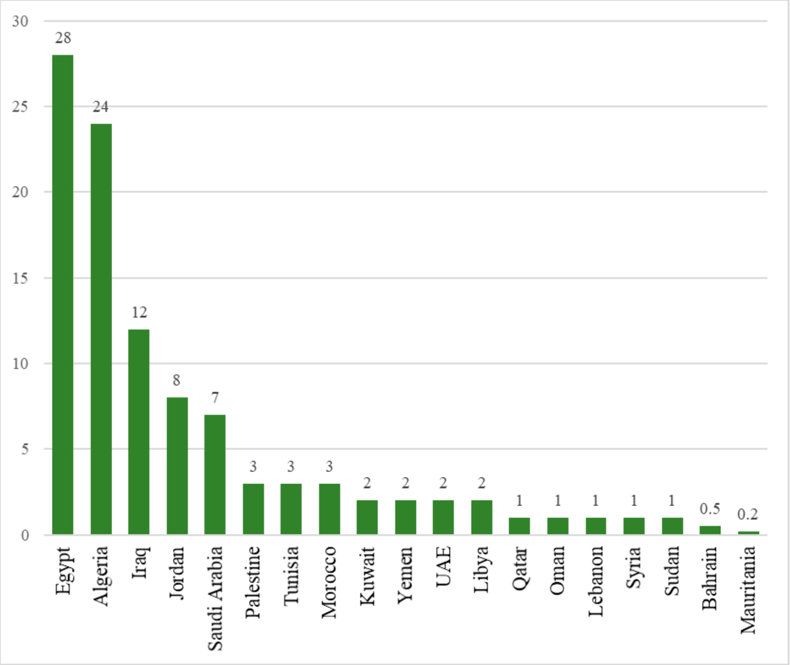

Figure 4. Share (%) of journals by country in ARCI (2015-2019)

Egypt and Algeria cumulate more than half of the journals indexed in ARCI. There is currently a concentration of journals published from these two countries in ARCI. The submission process is managed by the Egyptian Knowledge Bank (www.arcival.ekb.eg) and journals are evaluated according to the ARCI selection process as explained in the introduction of this paper. Several Arab countries have also set up national journal platforms and initiatives. For example, the Algerian Scientific Journal Platform (www.asjp.cerist.dz) and the portal of Moroccan scientific journals (www.revues.imist.ma) have been developed by their respective Ministry of Higher Education and Research. The common goal of such initiatives is to improve the visibility of local journals by improving their publishing standards. ARCI is still new and is still growing. It will be interesting to analyse how this new citation index evolves over time in terms of content coverage by journals' countries.

Languages coverage

Table 2 shows the coverage of records in terms of language of publications in ARCI. Arabic obviously dominates the database with 60,439 publications, representing a share of around 93%. The second most represented language is English with 3,221 records (4.94%) then followed by 1,406 publications in French (2.15%). 142 publications in 9 other languages represent 0.22% of this database.

Table 2. Number and share of records by language in ARCI (2015-2019)

	Language	*Records*	*Share (%)*
1	Arabic	60,439	92.69
2	English	3,221	4.94
3	French	1,406	2.16
4	Spanish	35	0.05
5	German	32	0.05
6	Persian	19	0.03
7	Hebrew	18	0.03
8	Italian	16	0.03
9	Russian	11	0.02
10	Chinese	5	0.01
11	Turkish	5	0.01
12	Amazigh	1	–

As ARCI aims to provide more exposure to journals published in the Arab League countries, it is no surprise to see Arabic as the dominant language. It is also worth reminding many journals indexed in ARCI provide publication in multiple languages. Several countries from the Arab League are former British or French colonies which explains why English and French are the main non-Arabic languages in ARCI. Other languages suggest that the research published in ARCI journals might also tackle regional issues of interest with neighbour countries.

Open access

The last few years have seen the development of several open access (OA) options (Bosman & Kramer, 2018; Lewis, 2012). Several scholars have studied the advantage of OA in terms of readership as well as citation impact (Basson et al., 2020; Cintra et al., 2018; Morillo, 2020; Piwowar et al., 2018; Riera & Aibar, 2013; Tang et al., 2017; Torres-Salinas et al., 2019; Young & Brandes, 2020). Since 2014, Web of Science has provided information to identify publications from OA journals. I use this information to analyse the access type of records indexed in ARCI. The statistics for various OA types and non-OA records in ARCI are presented in Table 3.

Close to 24% of papers indexed in ARCI and published between 2015 and 2019 are openly accessible. This is below the share of 31.8% of OA documents in the Web of Science Core Collection for the same period. We notice the various OA types have different shares in ARCI. *Bronze* is the main OA type with 11,029 papers representing close to 17% of ARCI. *DOAJ Gold* has the second highest OA share (4.49%) in this database with 2,927 papers published with this OA type.

Table 3. Number and share of records by Open-Access type in ARCI (2015-2019)

Open access type	*Records*	*Share (%)*
Non-OA	49,405	75.77
All Open Access	*15,772*	*24.19*
Bronze	11,029	16.91
DOAJ Gold	2,927	4.49
Other Gold	1,190	1.82
Green Published	623	0.96
Green Accepted	3	0.00
Unknown (no DOI)	31	0.00

Main topics

Before applying LDA, one must define the number of topics for the corpus. One option is to examine the performance of text clustering on a small dataset. Another way is to choose the number of topics based on judgments or tests (Blei et al., 2003). In this study, the corpus is organized into 10 topics which are listed in Table 4.

The model is applied on the combinations of words available in the title, abstract and author keywords of all records indexed in ARCI. I limited my study to words written in Roman script alphabets. All records have at least the title written in English. 84% of the publications found in ARCI have an abstract in English. Titles, abstracts and keywords written in Arabic and other non-Roman script languages are not analysed in this paper.

Table 4. 10 topics found in ARCI (2015-2019)

#	*Topic*	*#*	*Topic*
1	design islamic role	6	students skills learning
2	social media study	7	algeria economic study
3	iraq study administrative	8	physical effect players
4	saudi arabia education	9	comparative study law
5	children psychological relationship	10	international model heritage

It is straightforward to interpret the topics generated by the LDA model. The results are useful to understand the topical structure of ARCI by highlighting the main topics covered in the Arabic scientific literature indexed in ARCI.

Term map

When applying the LDA model on a corpus, it is assumed one document can address multiple topics. As shown in Table 4, this is helpful to have a precise understanding of the topical structure of a large corpus. However, it does not map the relationships between topics. The purpose of building a so-called term map of the publications in ARCI is to further clarify their contents. I used VOSviewer (van Eck & Waltman, 2010) to create such map.

Titles, abstracts as well as author keywords have been concatenated into a single string which has been used by the text mining algorithms of VOSviewer. I have limited this analysis to the terms which occur at least 15 times. 954 keywords have satisfied this threshold. For each of the 954 keywords, the total strength of the co-occurrence links with other keywords has been calculated by VOSviewer. Figure 5 shows the co-occurrence network for all the terms indicating for each pair of terms the number of papers in which these terms appear together.

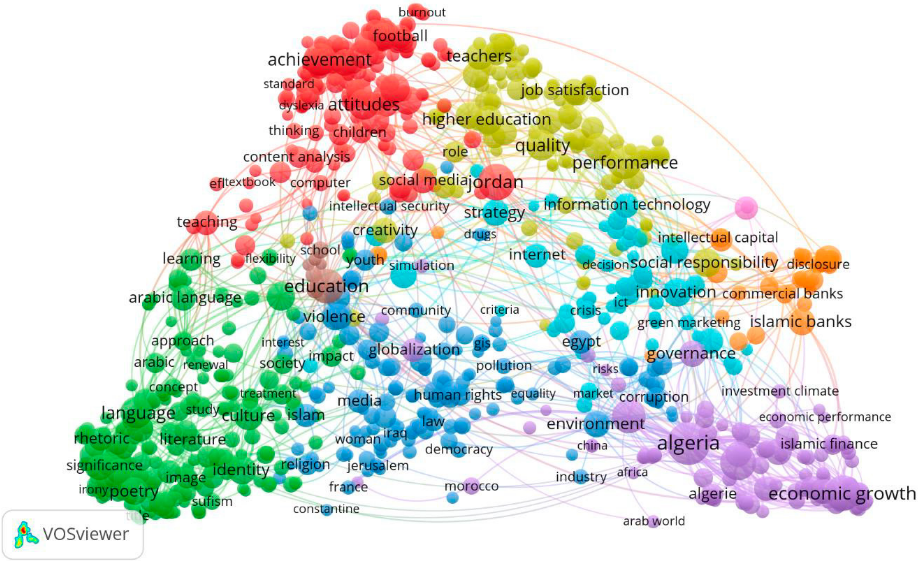

Figure 5. Term map highlighting the main topics in ARCI (2015-2019)

The clustering is useful in delineating the topics covered as well as highlighting the relatedness between them. The horizontal and vertical axes have no meaning. The size of a term reflects the number of records in which this specific term is mentioned. The proximity of two terms is an indicator of how these terms are related based on the number of co-occurrences. In general, groups of terms closely located together can be interpreted as topics. For readability purpose, labels are shown only for selected terms to avoid overlapping labels.

The terms have been clustered into 9 clusters with different colours. The map confirms a broad coverage of scientific literature as shown previously in the topic analysis. The term map shown in Figure 5 indicates some clear distinctions between research areas. These distinctions are not only visible in the structure in terms of proximity between terms but also in terms of colours. Within an area of the map, terms are usually coloured in a consistent way. For example, the lower right part in purple includes research areas related to Economics which are also closely related to the parts in orange (Finance) and teal (Strategy and Innovation). In the upper part of the map, the parts in red, yellow, and brown are more related to Education in general with some distinction on several aspects such as *achievement*, *attitudes, teaching* (in red), *higher education, quality, performance* (in yellow), and *school* and *education* (in brown). The lower left part in green corresponds to research areas related to Literature such as *language, petry, rhetoric, Arabic language, culture* and *identity.* Finally, terms corresponding to the field of Law tend to be located mainly in the blue part of the map with terms such as *law, human rights, democracy, equality, violence* and *community.* There is a clear heterogeneity in terms of topics covered in ARCI. One should remember some of the terms can of course be used in various contexts.

Discussion

The main objective of this study was to examine the structure of ARCI, the first Arabic Citation Index. 290 Arabic journals are indexed in ARCI as of October 2020. This indexation brings several benefits to the scientific community. This new index will improve the visibility of Arabic journals by making them more accessible. All journals indexed in ARCI need to meet selection criteria and essential publications metadata are provided. Such a database could greatly enhance the scholarly literature search. As a result, this will also help researchers to identify critical and influential research published in Arabic by providing access to highly curated peer-reviewed scientific content. Since research evaluation increasingly implies the bibliometric analysis of research output (Wilsdon et al., 2015; Wouters et al., 2015), ARCI could also provide useful bibliometric data sources to research managers for science assessment and research analysis. This would be helpful to *identify and reward excellence in locally relevant research* (Hicks et al., 2015).

Now, I discuss in detail the main findings identified in this analysis. This study reveals that ARCI contains mainly journals in the Arts & Humanities, and Social Sciences categories. These categories represent 79% of ARCI's total coverage. ARCI has a strong focus on local issues in Arts & Humanities as well as Social Sciences. It is important to keep in mind the well documented limitations on subject delineation where I used research areas of journals as proxies of categories to characterize the subject coverage.

As of October 2020, ARCI indexes content from 19 of the 22 Arab League countries, with more than half of the journals indexed in ARCI being published in Egypt and Algeria. Since ARCI is still new and under development, it will be interesting to track its evolution over time. It would also be interesting to analyse the contribution of each Arab League country to ARCI by using the author affiliations. It is worth reminding that the country of publisher of the journal is considered for its indexation in ARCI and not only the language of publication. Thus, ARCI does not include yet the journals published in Arabic in countries not members of the Arab League. As of now, most of the content found in ARCI is composed of articles (98.8% of the database). Since the Humanities tend to traditionally rely on book chapters and books, it will be interesting to analyse the evolution of the coverage by document type. Unsurprisingly, ARCI has a great share of papers published in Arabic (93% of the database). However, English and French are two other languages well represented in ARCI. Other languages suggest research published in ARCI journals may also tackle regional issues of interest with neighbour regions such as Europe and Asia.

Around 24% of the content indexed in ARCI is openly accessible. This share is below the proportion of Open Access (OA) documents in the Web of Science Core Collection for the same period. The OA information available in ARCI is particularly useful to better share scientific knowledge as well as to track the adoption of local OA mandates by research managers. The Global Open Access Portal (GOAP) presented a snapshot of the status of Open Access (OA) to scientific information worldwide. As identified in the GOAP, the Arab States face challenges but also opportunities (Unesco, 2016). Low level of awareness of the OA potential for researchers, publishers and policy makers tops the list of challenges. Lack of policy regulation, research funders' OA mandates and resources to manage OA projects also contribute to the low OA penetration in the Arab world. Nevertheless, several projects and initiatives have been undertaken to promote OA in the Arab region. 70 experts and policy specialists from several Arab Countries met in September 2015 to develop strategies to implement open access to scientific information and research in the Arab countries (Unesco, 2015). The Directory of Free Arab Journals (DFAJ), the first Arab directory of Open Access Journals which provides access to journals published by 172 publishers from 17 Arab countries, is also an example of such initiative.

The topic analysis as well as the term map are helpful to better understand the underlying structure of ARCI. Such techniques provide a great overview of the topics covered in this database. Overall, the clusters found with VOSviewer seem to be closely related and show a broad coverage of ARCI. The title, abstract and keywords in Arabic were not included in the topic analysis. It might be interesting to characterize the literature in ARCI by focusing on the Arabic content as well.

In conclusion, this paper offers a brief profile of the newest citation index in the Web of Science. This paper contributes also to the literature on regional citation indices (Huang et al., 2017; Jin & Wang, 1999; Leydesdorff & Jin, 2005; Moskaleva et al., 2018; Pajic, 2015; Seol & Park, 2008; Velez-Cuartas et al., 2016). One common purpose of such regional databases is to provide more visibility to local journals. ARCI is likely to have positive effects on regional research discovery as well as research management in the Arab region. Future research may seek to propose detailed mappings of ARCI to better understand its structure and impact. Finally, it will also be interesting to track its development and evolution by using dynamic topic models to study the time evolution of topics by using the text available in English as well as Arabic.

Network Effects and Research Collaborations: Evidence from IMF Working Paper Co-authorship

Dennis Essers[1], Francesco Grigoli[2] and Evgenia Pugacheva[3]

Abstract

An important trend in knowledge generation and diffusion is that the co-authorship of research publications has become remarkably more frequent. In this paper we study the role of co-authorship networks for starting and maintaining research collaborations. Relying on the network of the International Monetary Fund (IMF)'s Working Papers--which reflects well the endogenous nature of research collaborations--we document the presence of many authors with few direct co-authors, yet indirectly connected through short co-authorship chains. Two researchers are more likely to team up if their distance is shorter, likely reflecting reduced matching frictions. In addition, productive authors and authors with different co-author network sizes collaborate more, because of synergies between senior and junior researchers. Being employed in the same department and having citizenship of the same region also influence the decision to collaborate. We argue that incentives should be directed to researcher pairs that are initially more distant from each other in the co-authorship network.

Introduction

Knowledge and ideas are widely considered key contributing factors to long-term economic development. Their non-rival nature gives rise to increasing return to scale, which is the underpinning of endogenous growth (Romer, 1990). One major channel through which knowledge and ideas are generated and diffused is the publication of research papers, and an important trend in this respect is that papers are increasingly produced through collaborations across co-authoring researchers (Wuchty, Jones & Uzzi, 2007; Kuld & O'Hagan, 2018). Co-authorship has become a common feature of research publishing because teaming up allows researchers to exploit synergies and economies of scale by pooling ideas, skills, time, and funds (Liu et al., 2020). Multiple co-authorship links, in turn, give rise to collaboration networks, which play a crucial role in both knowledge generation and diffusion. For example, collaborating authors can combine their ideas to innovate, learn from each other, and then pass on the newly acquired knowledge to their current and future co-authors. Indeed, the empirical evidence suggests that knowledge spills over directly to co-authors (Azoulay, Graff Zivin & Wang, 2010; Borjas & Doran, 2015), as well as indirectly to the broader network of collaborating researchers (Hsieh et al., 2018).

This paper sheds light on how such collaboration networks are structured, formed, and maintained. More specifically, we study network properties; investigate the determinants of starting a new research collaboration; and assess whether these are the same factors that lead researchers to continue working together. For these purposes, we construct the co-authorship network of the near-universe of International Monetary Fund (IMF) Working Papers published over almost three decades (1990-2017) and combine it with detailed information on authors' employment history and demographic characteristics.

Several aspects make our dataset an ideal testing ground to study the endogenous nature of how collaborations between researchers are initiated and maintained. First, being one of the main research outlets of the IMF, the Working Paper series is widely read by central bank and government officials, academics, and researchers at think tanks. Working papers therefore contribute to broad-based knowledge diffusion, possibly more than peer-reviewed journal articles (often behind paywalls), which tend to be the focus of the existing literature on co-authorship formation. Second, compared to other IMF research publications, working papers leave more freedom to the authors: they reflect the authors' personal views rather than the institutional ones, can cover the geographical area and topic of interest of the authors, and do not restrain authorship to people within the same division, department, or even the IMF. Third, IMF staff--the main authors of the IMF Working Papers--does not arguably face the same "publish-or-perish" incentives of academia. Hence, we expect collaborations in our dataset to reflect personal preferences (e.g., researchers sharing a similar background) and practical considerations (e.g., researchers working in the same department), more than strategic ones (e.g., co-authorship with internationally renowned researchers that can help get the papers into top-tier journals and advance peoples' careers). Fourth, by focusing on working papers rather than on peer-reviewed journal articles, the problem of long publication lags distorting our findings is much less severe. Finally, we take advantage of our rich demographic and employment information on authors, absent from earlier studies such as Fafchamps, van der Leij & Goyal (2010), to test additional hypotheses about factors influencing research collaboration decisions and to control for possible confounders when making inference on the effect of pure network variables on the probability of collaborating.

The rest of the paper is structured as follows. We first explain the construction of our dataset and present key stylized facts about the co-authorship network of IMF Working Papers. We then describe our empirical strategy to evaluate the determinants of first and subsequent collaborations across authors, and discuss the econometric results. The final section summarizes our main findings.

Data and stylized facts

Dataset construction

We collected information on 6,152 IMF Working Papers written between 1990 and 2017 by 3,918 distinct authors. Based on the information obtained from the IMF website catalog and the text of the publications, for each working paper we compiled the list of authors, the year of publication, and the *Journal of Economic Literature* (JEL) codes used to classify publications by economic research area(s). JEL codes are available starting in 1997.

We complemented the information from the working papers with employee-level data for the years 1999 to 2017. This unique dataset, obtained from the IMF's Human Resource Department, includes annual information on the year of birth (in five-year intervals), tenure, department, citizenship (by region), and gender of IMF staff. We used fuzzy matching and performed extensive manual checks to merge the data.

For non-IMF authors of IMF Working Papers published between 1997 and 2017, we compiled information on their main affiliation based on email addresses where available from the papers, or manual search online in authors' CVs, LinkedIn profiles, and other websites. We organized these external affiliations into six mutually exclusive categories: universities, other international organizations, central banks, government agencies, non-profit organizations, and private companies.

We also collected citation counts for the working papers from Google Scholar. Relative to other sources of citations--such as Citations in Economics (CitEc), Web of Science, or Scopus--Google Scholar has broader coverage of citations in books, dissertations, and in the non-scholarly "grey" literature (e.g., government reports), as well as in non-English language publications (Martín-Martín et al., 2018). The citations we extracted are cumulative as of January 2019. To account for the fact that working papers were released at different times, we annualize the citation count by dividing it by the number of years since publication.

Finally, we define the universe of "active" potential co-authors in any given year t as S_t. This includes all authors since their earliest year of publication, t_0, until their latest year of publication, t_2. A pair of authors $\{i, j\} \in S_t$ is considered active from the year in which both authors are active, $t^{i,j}{}_0 = max\{t^i{}_0, t^j{}_0\}$, until the year in which either one of the two authors publishes his or her last paper, $t^{i,j}{}_2 = min\{t^i{}_2, t^j{}_2\}$. First collaborations are traced with a dummy variable, $fc^{i,j}{}_t$, that is defined only when the author pair is active, and that takes value one when authors i and j collaborate for the first time, and zero for the years before that. Subsequent collaborations are traced with another dummy variable, $sc^{i,j}{}_t$, which is defined only during the period in which the pair is active and after the first publication, and that takes value one in the year or years in which the pair publishes any other paper but the first, and zero otherwise.

Co-Authorship Network

Figure 1 provides an overview of the structure of the IMF Working Paper co-authorship network. To ease the visualization, we focus on the "core" network, which consists of those authors with a minimum of 10 publications and at least 10 different co-authors over 1990–2017. The nodes represent individual authors and the edges joining them represent co-authorship of a publication. The size of the nodes is proportional to the number of publications an author wrote over the entire period, including single-authored papers. The edge width is proportional to the number of repeated collaborations between two authors. Node grey tones refer to authors' affiliations, which are divided into the IMF (light grey) and the six other categories mentioned above (darker shades of grey).

The core author-level network is unsurprisingly dominated by IMF staff. Even in the full network (i.e., including authors with less than 10 publications and/or 10 co-authors), IMF staff accounts for the largest number of unique authors (54.2 percent) and for the largest number of publications by those authors. Academics, which include resident and visiting scholars at the IMF, come a distant second (24.6 percent), followed by central bankers (6.6 percent). Staff from other international organizations (2.8 percent) and authors affiliated with government agencies (1.8 percent), private companies (1.3 percent), or non-profits (0.9 percent) occupy a much less prominent role in the network.

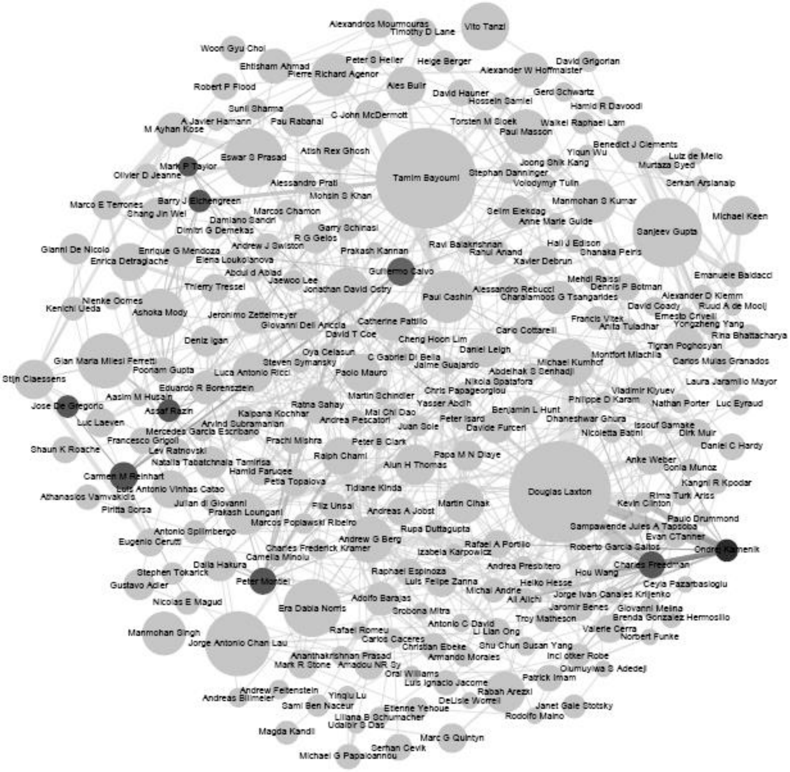

Figure 1. Core author-level network, 1990-2017

To gain further understanding of the network structure, Table 1 reports the key summary statistics generally used to describe networks. As shown in column (1), the full IMF Working Papers network counts 3,918 nodes and 9,027 edges, implying an average degree, or number of co-authors per researcher, of about 4.6. The network has a giant component (i.e., the largest group of nodes that are all directly or indirectly connected to each other) that covers 3,206 nodes, or almost 82 percent of all authors in the entire network. In other words, there are relatively few isolated authors or author groups. Moreover, research at the IMF does not seem to consist of distinct "islands" of researchers. The average distance, or length of the shortest path between two authors in the giant component of the network, is relatively short at about five. The average clustering coefficient, which measures the overlap in co-authorship (defined as the fraction of an author's collaborators that are themselves also co-authors, averaged over all authors with a minimum degree of two) equals more than 0.6.

Table 1. Network statistics

	IMF Working Papers				EconLit
	1990-2017 (1)	1990-1999 (2)	2000-2009 (3)	2010-2017 (4)	1990-1999 (5)
Total nodes (authors)	3,918	923	1,891	2,192	81,217
Total edges (co-authorship)	9,027	1,257	4,081	6,058	67,897
Average degree	4.608	2.724	4.316	5.527	1.672
Size of giant component	3,206	594	1,598	1,916	33,027
Share of giant component (percent)	81.8	64.4	84.5	87.4	40.7
Average distance in giant component	4.961	5.132	4.878	4.640	9.470
Average clustering coefficient	0.614	0.443	0.504	0.613	0.157

Columns (2) to (4) show the same summary statistics for the networks of authors that published IMF Working Papers within each of three sub-periods: 1990-1999, 2000-2009, and 2010-2017. The co-authorship network has grown larger and denser over time. The number of authors more than doubled from just over 900 during 1990-1999 to almost 2,200 during 2010-2017. Meanwhile, the number of co-authorship links nearly quintupled between the first and the third period, resulting in an increase of the average degree from 2.7 to 5.5. During the 1990s, the giant component already covered 64 percent of the authors publishing during that period, but this further increased to almost 85 percent in the 2000s and even more than 87 percent in the 2010s. The giant component also became more integrated, with an average distance progressively declining from 5.1 to 4.6 between the 1990s and 2010s. In addition, the extent of clustering rose considerably. Part of this can be ascribed to the higher share of multi-authored publications in recent years, which (by definition) increases the average clustering coefficient.

To put the attributes of the IMF Working Papers co-authorship network in perspective, column (5) reports the corresponding statistics from Goyal, van der Leij & Moraga-Gonzalez (2006) for the network of authors of all articles published over 1990–1999 in economics journals indexed in EconLit. Compared to the EconLit network, the IMF Working Papers network is much smaller and considerably more integrated, as evident from the much greater average degree, coverage of the giant component, and average clustering coefficient. Arguably, the most important explanation for this is that we focus on the publications of one institution, where potential collaborators may get to know each other more easily (even just because staff mostly works in the same premises) and researchers cover a smaller set of topics than in the field of economics more generally. Moreover, multi-authored publications are more common in our sample, especially so in more recent years.

Despite the IMF Working Papers network can be considered a special case of co-authorship networks, with people generally working in the same premises, the network measures in Table 1 indicate that the IMF Working Papers network exhibits "small world" properties, broadly in line with--but to an even greater degree than--what has been found for collaborations in economics journal articles (Goyal, van der Leij & Moraga-Gonzalez, 2006) and published papers and preprints in other fields of research (Newman, 2001). That is, the network consists of a large set of authors with few direct co-authors (relative to all possible collaborations); the network is nonetheless highly integrated, as the majority of authors are in some way connected to each other, mostly through short chains of co-authors; and the extent of overlap in co-authorship is very high (relative to a network where collaborations would be purely random). As Goyal, van der Leij & Moraga-Gonzalez (2006) and Hsieh et al. (2018) show, such patterns typically derive from a network architecture of interlinked "star" authors, a set of researchers that collaborate with many others, most of which are not direct co-authors themselves. These stars effectively act as connectors of different clustered parts of the network. Additional evidence for such a set-up in the IMF Working Papers network comes from the observed negative relation between individual authors' degree and their local clustering coefficient, as portrayed in Figure 2. Whereas the many researchers with only two or three co-authors have on average (at the median) around 80 percent (100 percent) of their co-authors collaborating with each other, the fewer researchers with over 20 co-authors seldom have clustering coefficients in excess of 0.2.

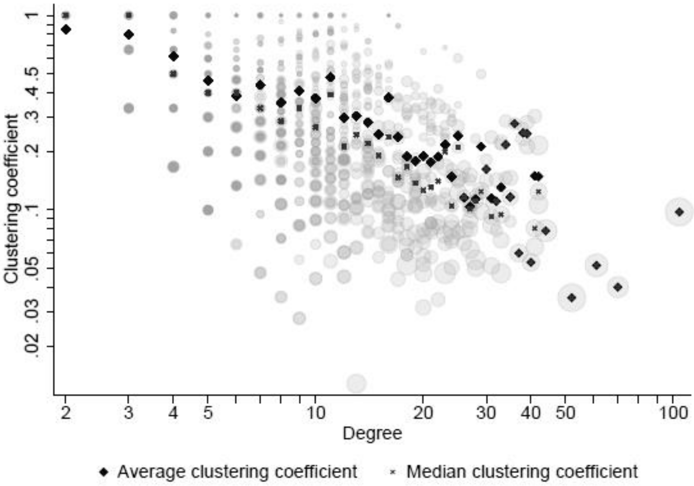

Figure 2. Author degrees vs. clustering coefficients

Notes: Dots represent individual authors, with dot size proportional to the total number of publications by author. Darker shades of grey correspond to more authors having the same degree-clustering coefficient combination.

Empirical strategy

It is reasonable to assume that researchers' decisions with whom they collaborate are mostly non-random, based on factors such as complementarity of skills, common research interests, and similarities in background. While some of these dimensions can be easily assessed from publicly available information (e.g., from researchers' publication track record), other relevant knowledge maybe only obtained indirectly through the researcher's network of acquaintances, of which the co-author network is an important subset. This would imply that, in addition to other pair and individual author characteristics, researchers' positions vis-à-vis each other in the co-authorship network may influence their decision to collaborate.

To study the determinants of first and subsequent collaborations between pairs of authors, we estimate the following logit specification on the sample of active pairs:

$$Pr(y^{i,j}_t = 1) = \Phi(\alpha + \beta N^{i,j}_t + \gamma C^{i,j}_{t-1} + \delta HR^{i,j}_t + \varepsilon^{i,j}_t)$$

where Φ is the logit function and the dependent variable $y^{i,j}_t$ is the dummy variable tracing first collaborations or, alternatively, subsequent collaborations, as defined in the Data section. The set of regressors includes network variables, $N^{i,j}_t$; pairs' characteristics, $C^{i,j}_t$ (both similar to the ones used in Fafchamps, van der Leij & Goyal, 2010); as well as our unique author-level data on IMF employment and demographics, $HR^{i,j}_t$. The variation in our dataset is mostly cross-sectional, as the large majority of author pairs were active only for a short period of time, thereby reducing the need (and feasibility) to control for pair fixed effects.

To compute the network variable regressors, we first define the network graph G_t with the authors being the nodes and the collaborations between t - 9 and t being the edges. We allow for a 10-year window as relations formed at the time of a co-authorship arguably tend to last for some time. The first network variable we include in the regressions is proximity, which is defined as the inverse of the (shortest) distance between the pair of authors in G_t. When computing this distance, however, any co-authorship between i and j is ignored, so that the minimum distance is equal to two (i.e., the pair has a common co-author) and maximum proximity is equal to 0.5 (even after the initial collaboration). This allows us to use the variable also as a potential determinant of subsequent collaborations. If there is no link between i and j, proximity takes the value of zero. The second network variable is the number of shortest paths between authors i and j in G_t, which is also computed excluding the direct link between i and j. If the two authors are not connected at all, the number of shortest paths takes the value zero.

The pairs' characteristics include research ability, the propensity to collaborate, and research (area) overlap. We proxy research ability with a measure of research productivity. More productive or talented authors are, in general, looked up to and other authors may want to connect with them. As a result, they may be more likely to start new collaborations. At the same time, relatively talented authors may be more interested in working with equally talented co-authors. Hence, we compute a productivity score for each author $i \in G_t$ as the number of "points" author i accumulated between t - 9 and t, where points for each published working paper are given by *citations*/(*number of authors* + 1). We use the average of the productivity scores for each couple of authors to get an aggregate productivity measure for the pair. We also compute the absolute value of the difference in the productivity scores of the two authors to proxy the difference in research ability. The sign of the coefficient for the latter variable will depend on whether more productive researchers look to match with each other or whether co-authorship reflects collaborations between experienced researchers and juniors. In the regression we include the one-year lag of both the average and the absolute difference in productivity to mitigate simultaneity concerns.

A researcher's propensity to collaborate is also likely to affect the probability of starting new collaborations. A researcher with many collaborators in the recent past may be intrinsically more eager to also collaborate in the future. Moreover, if an author is already well-connected, he is easier to reach out to and this may lead to new collaborations. A proxy for that propensity is the number of co-authors that each author had over the past 10 years. The measures of propensity to collaborate for the pair are the lagged average of each author's propensity to collaborate, as well as the lagged absolute value of the difference in the propensities. Research overlap is linked to shared research interests and may thus also condition the probability that two authors start a new collaboration. Researchers sharing similar interests are probably attending similar conferences, seminars, and other events, which create opportunities to connect and start collaborations. We measure research overlap as in Fafchamps, van der Leij & Goyal (2010), relying on the JEL codes we discussed in the Data section. Specifically, we define the field of research with the first letter of the JEL classification; and calculate for each author i the fraction of working papers that has been dedicated to each JEL classification letter between t - 9 and t. Working papers with multiple JEL codes are assigned proportionally to each of the different codes. We then calculate the research overlap between authors i and j using a cosine similarity function and include its lag in the regressions. For subsequent collaborations, the calculation of research overlap excludes the papers on which the authors of the pair previously worked together.

Finally, we also control for other employment and demographic characteristics. Specifically, we include a set of dummy variables indicating whether the pair of potential co-authors work in the same IMF department or did so in the past year; whether their gender is the same; and whether their region of citizenship is the same.

Results and discussion

First collaborations

We first present the results for the determinants of starting a new collaboration. The sample includes both collaborating author pairs and author pairs that never collaborated but were active. In Table 2, we report the logit regression results in terms of odds ratios. Column (1) shows that network distance is a key determinant of first collaborations. For example, for a pair of unconnected researchers (i.e., with proximity at zero) that becomes connected via a common co-author (i.e., with proximity at 0.5), the odds of starting a new collaboration are about 30 times higher; similarly, doubling the number of shortest paths connecting the researchers in the pair is associated with an increase in the probability of initiating a collaboration by a factor of nearly four. These effects are large, which is expected in the case of new collaborations.

Potential co-authors with a smaller network distance may simultaneously be closer in terms of other "non-network" dimensions of distance, such as differences in research interests, socio-cultural backgrounds, or physical locations. In what follows, we control for several proxies of these dimensions and, differently from previous papers such as Fafchamps, van der Leij & Goyal (2010), we also include controls based on employment and demographic information. However, we recognize that, even after including all controls, estimates may still reflect the influence of other unobserved factors that ultimately drive co-authorship of a working paper (e.g., interest in a very specific research question within a particular sub-field, or closeness to the same water cooler or coffee corner). Hence, strictly speaking, the results on the role of network distance for research collaborations should not be interpreted in a causal way.

In column (2), we include the pairs' characteristics. As these variables enter the specification with a lag, our sample reduces to those author pairs that remained active for at least two years in a row. By excluding "one-off researchers", this sample is likely to be more representative of the relations across authors that have a somewhat more persistent interest in research. Distance variables now have even larger odds ratios, suggesting that more research-oriented people are even more prone to rely on the network around them. The average productivity of the pair of authors is significant only when other variables are included, indicating that more productive author pairs are more likely to start collaborations. Relying on the significant coefficients in columns (3) and (4), we find that a one standard deviation increase in average productivity is associated with a 9 to 10 percent higher probability of starting a new collaboration. At the same time, when the individual productivity of the authors forming the pair diverges, the probability of starting a new collaboration declines, but the effect is not robust to the inclusion of all other determinants. A larger average propensity to collaborate--measured by the number of connections for each author of the pair--is negatively associated with the probability of starting to collaborate, suggesting that authors with many connections (generally more senior staff members with an established network, more options in terms of potential collaborations, and less time to allocate to research) may be less eager to look for new ones. However, pairs of authors having more heterogeneous propensities to collaborate are more likely to start a collaboration. One possible explanation for these results is that senior staff members are often tasked with more managerial duties compared to junior staff, who has more time for research. Therefore, these findings may to some degree reflect an efficient allocation of resources.

In column (3), we include research overlap, which turns out to be insignificant for the probability of starting a new collaboration. This finding is easier to understand when we include the employment and demographic variables in column (4). The odds of starting a new collaboration for author pairs in the same department increase by a factor of more than five, compared to author pairs of researchers from different departments. That is, authors team up because they are in the same department rather than because they dealt with similar research topics in the past. Having citizenship of the same region also favors the start of new collaborations, by a factor of about 1.3. This may reflect the importance of similar backgrounds, including native languages, and education and professional experiences, among other dimensions. In the presence of the other variables, being of the same gender is not significantly related to the likelihood of starting to work together. As shown in columns (1) to (4), the magnitude of the coefficients on proximity and the number of shortest paths varies depending on what control variables we include in the specification. However, as we add controls, the number of observations declines significantly. To understand what drives the changes in the magnitude of the coefficients, in column (5) we report the results of the regression including the same regressors as in column (1) (i.e., proximity and the number of shortest paths) but restricting the sample to the one of column (4). Our findings suggest that both the restriction of the sample and the addition of extra controls play a role, as the size of the coefficients is larger than in column (1) but smaller than in column (4).

Subsequent collaborations

Table 3 presents the estimation results when the dependent variable is the dummy variable for subsequent collaborations. The number of observations is many times smaller than for initial collaborations, because the dependent variable is defined only for author pairs that collaborated at least once. The results in column (1) suggest that proximity and the number of shortest paths--calculated excluding the direct connections between each pair of researchers--are associated with a higher probability of continuing to collaborate, but the effect is unsurprisingly much smaller than for first-time collaborations (cf. Fafchamps, van der Leij & Goyal, 2010). For example, reducing the distance between a pair of researchers from three to two almost is associated with a doubling of the chances of continuing to collaborate (compared to an increase by a factor of 11 in the case of initial collaborations); similarly, doubling the number of shortest paths connecting the researchers in the pair is associated with an increase in the probability of repeating a collaboration by a factor of about 1.5. In other words, the network distance between authors is particularly important to start a new collaboration, but once the connection is established, it becomes much less relevant for continuing to collaborate. This result is in line with the interpretation that collaboration networks may transmit important, not directly observable information about authors that helps to overcome matching frictions. Once this information is internalized through actual collaboration, the network effects strongly diminish.

Pairs	3,325	3,289	3,244	2,865	2,865
Pseudo R^2	0.011	0.033	0.036	0.090	0.031
AUROC	0.574	0.636	0.637	0.718	0.627

Notes: Proximity is multiplied by 10. All regressions include a constant. Heteroskedasticity and autocorrelation robust standard errors in parentheses. ***p <0.01, **p <0.05, *p <0.1.

The results for the author pairs' characteristics are very similar to the ones for initial collaborations, as shown in column (2). Specifically, author pairs with a larger average productivity are more likely to continue collaborating. However, if productivity differences between the authors of the pair are large, they are less likely to continue working together. The number of established connections, which measures the propensity to collaborate, reduces the probability of continuing to collaborate. And larger differences in terms of the propensity to collaborate increase such probability. As in the case of new collaborations, these results can be explained by referring to the seniority of staff and the allocation of resources.

When we add research overlap in column (3), we find that it has a negative and significant effect on the probability of continuing to collaborate. However, once we include the employment and demographic variables in column (4), research overlap turns insignificant, while being employed in the same department and having citizenship of the same region are still important determinants of the probability of continuing to co-author, increasing the odds by more than a factor three and 1.2, respectively. Being of the same gender now leads to an increase in the likelihood of continuing to collaborate with a factor 1.2.

As for first collaborations, we re-estimate the specification in column (1) with the sample of column (4) to test whether the results are driven by the additional regressors and/or the restricted sample. The estimates reported in column (5) confirm that, again, both these factors play a role.

A commonly used statistic to assess the classification performance of logit models is the area under the receiver operating characteristic curve (AUROC). As reported in column (4) of Table 2, the AUROC for the richest specification of initial collaborations suggests that with a 94 probability the model will assign a higher predicted value to a randomly selected collaboration than to a randomly chosen non-collaboration. Such probability is somewhat lower at 72 percent in the case of subsequent collaboration, as shown in column (4) of Table 3. Overall, we conclude that our logit models have a satisfactory performance in terms of distinguishing collaborating from non-collaborating (or no longer collaborating) author pairs. We have verified that our regression results are also robust to restricting the sample to IMF Staff only; to the exclusion from the sample of all collaborations of author pairs in papers involving at least one other author that collaborated (either separately or jointly) with both authors of the pair in the past (i.e., making abstraction of "middleman/woman effects"); and to defining the network of authors and collaborations over a shorter period *t* - 4 to *t*.

Conclusion

In this paper, we study how research collaborations are structured, initiated, and maintained, using the co-authorship network of the near-universe of IMF Working Papers published during 1990-2017. We combine information on the papers with a unique dataset of demographic and employment details of the authors, which allows us to better control for possible confounders. Being a widely read research outlet where authors express their personal views on topics of their interest, and given that IMF staff does not face the typical "publish-or-perish" incentives of the academia, the IMF Working Papers series constitutes an ideal testing ground to examine the endogenous nature of co-authorship formation.

Network statistics indicate that the IMF Working Papers co-authorship network became larger and more integrated over the three decades of the sample period. Moreover, the network exhibits "small world" properties, even more so than in the broader but earlier sample of economics journal articles constructed by Goyal, van der Leij & Moraga-Gonzalez (2006): it consists of many authors with few direct co-authors, yet indirectly connected to each other through short co-authorship chains, and shows a significant degree of clustering. These properties are characteristic of a network architecture where interlinked "star" authors act as connectors of different clusters in the overall network.

The empirical investigation of the determinants of co-authorship relations reveals, above all, that two researchers that are closer to each other in the existing co-authorship network are significantly more likely to collaborate, especially so in the case of first-time collaborations. This result corresponds well with Fafchamps, van der Leij & Goyal (2010) and suggests that the network transmits important, not directly observable information about authors that helps to overcome initial matching frictions.

In addition, we find that author pairs with a higher average productivity are more likely to start and continue collaborations. At the same time, researchers with an established network of co-authors seem to be less in search of new ones; yet, authors with different co-authorship network sizes are more likely to start and maintain a collaboration. These findings likely reflect synergies between senior staff members--generally tasked with more managerial duties--and junior staff--who have more time for research. Being employed in the same department and having citizenship of the same region increase the likelihood of both starting and maintaining a collaboration. Meanwhile, greater overlap in research areas, derived from JEL codes used in earlier papers, has no significant independent effect. This suggests that similar backgrounds, including native languages and culture, more so than common research interests, play a role in the decision to team up--a novel result that we were able to uncover thanks to our rich author-level data. Finally, being of the same gender is not significantly related to the probability of initial collaboration, but once a co-authorship link is formed, authors of the same gender are more likely to continue collaborating.

Our findings provide important insights for formulating policies aimed at fostering knowledge generation and diffusion, which ultimately promote economic growth. In particular, the results of this paper suggest that if research collaboration is to be stimulated, incentives should be directed to researcher pairs that are initially more distant from each other in the co-authorship network, and that have lower average productivity, similar network sizes, and/or more heterogeneous backgrounds.

Acknowledgments and disclaimer

Abstract

We study how different document representation techniques affect the outcomes of clustering based on textual information. Our dataset consists of titles and abstracts for 15,907 publications from the social sciences and humanities. We compare established document representation techniques such as TF-IDF and Latent Semantic Indexing with word and document embedding techniques (Word2Vec and Doc2Vec) in terms of the quality of the clustering outcomes. Quality is assessed by calculating silhouette scores and the average textual coherence of the clusters. The results show that word and document embeddings are promising feature engineering techniques in the context of clustering social sciences and humanities publications. The average of Word2Vec embeddings works best for identifying textually coherent clusters.

Introduction

Clustering scientific documents or publications based on relations between them has been at the core of scientometric research since the early years of the field (Small & Crane, 1979). When no or only very coarse document classification systems are in place, or when we want to develop a better understanding of the topics or specialties a document belongs to, clustering becomes an important go to method. It allows to organically construct groupings of similar documents based on specific commonalities between them from the bottom up (Waltman, Boyack, Colavizza, & Van Eck, 2020). Depending on the granularity of the final clustering results, light can be shed on the knowledge base of disciplines, subdisciplines, or research specialties (Sjögårde & Ahlgren, 2018, 2019).

Throughout the years, many clustering techniques have been studied and the appropriateness of different bibliographic variables has been analyzed. Co-citation relations between documents or journals and bibliographic coupling have traditionally been at the center of the stage. In more recent years, topic modeling and other textual relations have been explored extensively (Boyack et al., 2011; Wang & Koopman, 2017). In addition, hybrid combinations of text and citation data have proven to be promising when it comes to identifying granular clusters of documents (Boyack & Klavans, 2014; Janssens, Zhang, De Moor, & Glänzel, 2009). In this study we investigate textual features and their usefulness for document clustering. We study the clustering outcomes for a dataset which contains publications from the social sciences (SS) and humanities (H) (SSH). For a considerable share of the documents in this dataset, no citation or reference data are available. Citation coverage is a well-known problem in the context of the SSH. We compare established document representation techniques such as TF-IDF and Latent Semantic Indexing with word and document embedding techniques (Word2Vec and Doc2Vec) in terms of the quality of the clustering outcomes. Quality is assessed by calculating silhouette scores, textual coherence of the clusters, and inspecting a cluster visualization. We conclude with a discussion of the results, the limitations, and pathways for future research.

Data

Data are collected from VABB-SHW, the Flemish bibliographic database for the SSH (Verleysen, Ghesquière, & Engels, 2014). We have selected all journal article publications for which abstracts and titles are available for the publication years 2011–2015. Titles and abstracts of English language publications have been merged together into one text field (TAs). TAs that were shorter than 65 words have been dropped; after this operation, 15,907 publications are left in the data set. SpaCy is used to tokenize the TAs. First a TA is split into individual tokens. These tokens are lower-cased and stemmed with the Porter stemming algorithm. Finally, stop words and punctuation are removed as well as tokens shorter than 3 characters.

Methods

k-Means clustering and clustering quality

In their seminal study 'Mapping the backbone of science', Boyack and colleagues make use of the *k*-Means algorithm to cluster documents based on their relative location on different maps. In more recent work, Wang and Koopman (2017) compare the performance of *k*-Means and the Louvain algorithm in the context of their Astro dataset. They apply these two clustering algorithms on semantic representations of the articles. For their application, both *k*-Means and the Louvain algorithm appeared to be competitive with other clustering solutions (Wang and Koopman, 2017, p. 1029). For this study, *k*-Means clustering is implemented in Python with the open source machine learning library scikit-learn (Pedregosa et al., 2011). The Mini Batch variant is used (Sculley, 2010). MiniBatch *k*-Means uses randomly sampled mini-batches or 'chunks' of the data to reduce the computation time. When a sample is drawn, the *k*-Means algorithm is run and the centroids are initiated and updated.

The quality of the clustering outcomes is measured by calculating average Silhouette scores and a metric for textual coherence. The Silhouette score is a measure of internal consistency or cohesion of the clusters compared to all other clusters (the separation) (Rousseeuw, 1987). The average Silhouette score thus gives an idea of the overall performance of the clustering solution. The textual coherence is a metric based on the Jensen-Shannon divergence (JSD). JSD computes the distance between two probability distributions; in this case the word vectors for the documents and the clusters they belong to. A higher score indicates more textually coherent clusters. This metric has been described extensively in Boyack et al. (2011).

For visual inspection, we map the clustering outcomes of *k*-Means on a t-SNE plot. t-SNE or t-distributed stochastic neighbor embedding is a highly effective technique well-suited for reducing high-dimensional data to two or three dimensions (van der Maaten & Hinton, 2008). Additionally, journal discipline classifications for the publications are mapped onto the t-SNE visualization.

Term frequency and inverse document frequency (TF and TF-IDF)

For each document, the number of times a term appears is counted (Term Frequency). Term frequency-inverse document frequency (TF-IDF) is a modification of this counting scheme and corrects for very common terms, or terms which are specific to a document. IDF is the inverse function of the number of documents in which that term occurs and is multiplied with the TF. This standard approach to text vectorization has proven itself over the years and has repeatedly been shown to be a worthy competitor for more advanced NLP (Natural Language Processing) techniques (Lelu & Cadot, 2019).

Latent Semantic Indexing (LSI)

The second approach tested is Latent Semantic Indexing (LSI), or Latent Semantic Analysis (Deerwester, Dumais, Furnas, Landauer, & Harshman, 1990). LSI makes use of Singular Value Decomposition to transform the document-term matrix into a reduced matrix with a fixed number of latent 'topics' or factors as features. LSI takes into account co-occurrences of words – the semantic meaning – to reduce a document to a predefined number of topics. The technique has been shown to be successful for large scale clustering applications with scientific publications (Boyack et al., 2011). We make use of the Gensim implementation of the LSI algorithm. We have evaluated the clustering outcomes for different numbers of latent topics ranging from 50 to 1000.

Word2Vec and Doc2Vec

Word2Vec is a technique to represent words with a unique list of numbers, the vectors (Mikolov, Chen, Corrado, & Dean, 2013; Mikolov, Sutskever, Chen, Corrado, & Dean, 2013). The context of the word is used to build a semantically meaningful vector representation of a word. It is a deep learning model that tries to predict the word to be embedded by training a neural network with the words in its direct context. Documents vary in length, however, and Word2Vec is a model that transforms individual words into vectors. Each document will be represented as a vector of n terms vectors. To obtain vectors of the same dimension for each document, we first sum all n terms word vectors per document and then calculate the arithmetic mean such that each document has a single x-dimensional vector of the same length. We use the Gensim implementation of the skip-gram model with negative sampling for our analysis.
Another extension of Word2Vec is Doc2Vec (Le & Mikolov, 2014). In Doc2Vec a document is represented by a vector of fixed size. Doc2Vec trains a model to construct a unique vector for every document. These unique document vectors are concatenated with the word vectors which are shared between documents and then averaged. Each document vector is thus a combination of a paragraph or document vector and Word2Vec vectors. Doc2Vec has been implemented in the study of scientific publications and has, for example, been used in conducting detailed similarity analysis among paragraphs (Thijs, 2020).

Results

The optimization of the *k* value for *k*-Means according to the average silhouette scores led to very different results in terms of the granularity of the clustering solution. TF-IDF and LSI produced solutions of 73 and 42 clusters respectively. LSI produces clusters of higher quality in terms of silhouette scores. In contrast, the textual coherence is higher for TF-IDF. This might not be a surprise, as smaller clusters tend to be more textually coherent.

Table 1. Clustering quality for the different feature processing techniques.

	Number of clusters	Feature vector size	Average Silhouette score	Textual coherence (above random)
TF-IDF	73	9,849	0.01362	0.0422
LSI	42	50	0.0724	0.0389
Word2Vec average	40	25	0.0908	0.0434
Doc2Vec	22	15	0.0520	0.0324

The Word2Vec average strategy turned out to be the best performing feature vectorization method. With this processing technique, the *k*-Means algorithm divided the set of documents into 40 clusters. Whereas the average silhouette score is only slightly better than that for LSI, the average textual coherence is higher than was the case for other methods. This is an interesting finding, as the textual coherence is biased towards smaller clusters. As already noted by (Boyack et al., 2011), here too the textual coherence of the clusters decreases as the size increases. It would thus be no surprise if we were to find a higher coherence for the TF-IDF solution. The latter yielded 73 and generally smaller clusters. The computational cost, however, is quite large. The number of features for TF-IDF is 394 times larger than the number of features needed for Word2Vec.

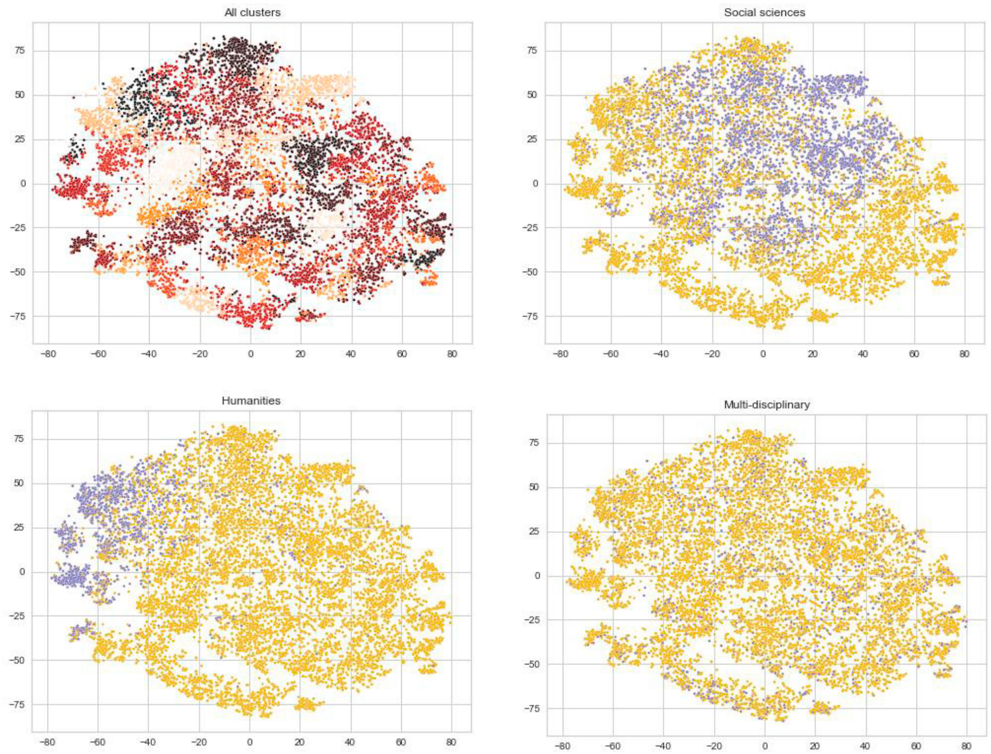

Figure 1. visualization of t-SNE embedding. (a) upper left: K-means overlay, (b) upper right: publications in SS journals highlighted, (c) publications in H journals highlighted, (d) publications in multi-disciplinary journals highlighted. Note: Axes should not be interpreted quantitatively.

In figure 1 we display t-SNE visualizations of the Word2Vec average document embeddings. The scatterplot in the upper left corner overlays the t-SNE embedding with shades indicating the clustering generated by *k*-Means. It becomes clear that, although most groups are more or less distinguishable in both cases, there exists considerable overlap between the clusters generated by *k*-Means. The remaining three plots overlay the t-SNE embedding with journal classifications of the publications. The journals have been classified according to the OECD fields of science (for details see Guns, Sīle, Eykens, Verleysen, and Engels (2018). In the upper-right corner, publications in SS journals are highlighted. We can see that the upper-right section of the scatter plot is densely populated with publications in SS journals, gradually fading to the upper left.

On the scatterplot in the lower-left corner publications in humanities journals are highlighted. Here we see that they are positioned opposite to the publications in SS journals highlighted in the upper-right scatterplot. The upper left region of the scatterplot highlighting the humanities seems to be most densely populated, fading to the right hand side, the corner in which SS publications are. This fading over is an interesting pattern, indicating that there might be important cognitive cross-over areas between both the SS and H. As we can see in the upper left corner, one of the clusters which is found by *k*-Means (in white) nicely overlaps this fading area. The fourth and last scatter plot highlights publications in multi-disciplinary journals.

These are journals which have been assigned to multiple OECD FOS discipline codes. As one would expect, these publications are dispersed over the scatterplot, popping up in multiple clusters of documents.

Limitations

The clustering algorithm used in this study demands for a pre-specified number of clusters. Additionally, only one similarity measure has been tested (Euclidean distance). It would be interesting to compare the *k*-Means clustering algorithm as well as the similarity measure to other current approaches used in a bibliometric context. Boyack et al. (2011), for example, make use of the DBSCAN algorithm and cosine similarity. Other studies make use of the Leiden algorithm or the Louvain algorithm for community detection (Wang & Koopman, 2017). Similarity approaches like the cosine similarity and BM25 similarity have been shown to perform well in a text clustering context (Waltman et al., 2020).

Conclusion and future research

In this paper we have shown that state-of-the-art vectorization techniques (Word2Vec and Doc2Vec) work well in the context of clustering SSH publications based on textual information. Although the outcomes of the different vectorization techniques in terms of silhouette scores and textual coherence were nearly identical, Word2Vec average turned out to be the best strategy to identify 40 well-divided and coherent clusters. The contextual sensitivity of Word2Vec might be a possible explanation.

A next step consists of studying different clustering algorithms and similarity calculations. Additionally, studying these clusters of documents in detail will yield interesting insights into specialized communities. The clusters can be thought of as the knowledge base of research specialties or disciplines. In another phase we will add an additional, more granular layer to the clustering presented above. A detailed content analysis and second round of clustering for the different document groups will yield insight into what these clusters actually represent. Are they representations of one or many subject specialties?

We hypothesize that while some document clusters might be representative of local or regionally oriented specialties, others will be part of the knowledge base of more global communities. For the latter, it will be difficult to reach any conclusions without taking the broader context into account. For the former, however, by studying their bibliographic, cognitive and social characteristics we will be able to broaden our understanding of research specialties in the SSH as well as bibliographic units.

Status and Challenges of Open Government Data in Nigeria: An Informetric Analysis of Websites of Government Ministries and Organizations

Ifeanyi J. Ezema

ifeanyi.ezema@esut.edu.ng
University Librarian, Enugu State University of Science and Technology Enugu (Nigeria)
Department of Information Science, University of South Africa (South Africa)

Abstract

Globally, democratic principles revolve around transparency, accountability and greater involvement of the citizens in government programmes and activities for sustainable development. This can only be achieved if the people have access to government information and this is why agitations for freedom of information continue to heighten. Open government data (OGD) play major roles in democratization of information and a propeller of transparency and open governance. This paper adopted descriptive informatics and literature review approach to examine the websites of major government ministries and agencies in Nigeria including Nigeria Data Portal to determine the availability and status of open government data. Findings reveal that while some websites have presence of OGD, over 60% are yet to provide such data in the website. Also the data portal has several government data which are rarely updated. The paper also identified several challenges of OGD in Nigeria and proposed recommendations to mitigate the challenges.

Introduction

The major ingredients of democracy are citizens' active participation and transparency of leaders in the activities of government through open governance. Agitations for democratic culture globally is often anchored on human rights which entails freedom of expression, rights to government information and ability to use these rights for sustainable socio-economic and political development. Since Nigeria returned to democratic government in 1999, citizens have been deeply engaging government for good leadership anchored on open and good governance. An interesting way of achieving open government is making government data available to the people (that is freedom of the citizen to access government information). Fortunately, Nigeria enacted Freedom of Information Act in 2011, (Federal Republic of Nigeria 2011) and by implication, Nigeria government is expected to run an open government driven by open government data (OGD) which will facilitate wider access to public sector information (PSI).

Open data is defined by The International Open Data Charter (ODC) as "publicly available data that can be universally and readily accessed, used and redistributed free of charge. It is structured for usability and computability" (Van-Belle et.al. 2018). But Attard, Orlandi, Scerri, & Auer, (2015: 402) defined Open Government Data as "government-related data that is made open to the public." This appears similar to that of Economic Commission for Africa (2017) which described open government data as "any government-produced or government-commissioned data that are freely available and publicly accessible." Perhaps, a more elaborate definition is that provided by Janssen & Helbig (2015) and Jetzet (2016) who observed that such data is multi-dimensional providing valuable information for socio-economic and technological development of the country. Global interest in OGD began as a result of Open Government movement within the first decade of 21st century (Bauer & Kaltenbock 2012). Open government data and open governance are interrelated because it is through the availability of open government data that a country can achieve open government.

Interest in open government data is heightened by its critical contributions to national development and impact in transparent governance. The fruits of such open governance are opportunities for speedy economic growth (Jetzek, Avital, & Bjorn-Andersen, 2012), public accountability (Viscusi, Spahiu, Maurino, & Batini, 2014; Worthy, 2015); contributions to social inclusion (World Wide Web Foundation 2015), job creation and growth of knowledge economy (Carrara, Chan, Fisher & van Steebergen 2015). Vickery (2011) provided economic implications of open government data estimating the aggregate direct and indirect economic impacts from use of public sector information in the European Union economy to the tune of billions of euros yearly.

Recent developments reveal a growing interest in the public use of OGD and also from the academia in the reuse of government data for academic and research purposes and this has been underscored by the study of Kučera (2018) who posited that globally OGD forms critical component of research material since government has the infrastructure and personnel for aggressive data collection not withstanding several challenges. Such challenges to a large extent impede the implementation of freedom of information in many African countries as reported by Asogwa & Ezema (2017). The publication of OGD is another challenge and has been well documented in the works of Chlapek at al., (2014); Kucera (2015) and Kucera et al., 2015).

A recent study by Ezema (2019) examined open government data in selected government websites in Nigeria and revealed an availability of open government data in six of the eight government agencies selected for the study. However, a major weakness of the study is that the number of government agencies covered is so small and requires further investigation. With the growth of electronic governance, government data continue to emerge daily in several government websites, but little is known about the status of these data in Nigeria; their management for research and scholarly communication; and likely management challenges – as major studies on OGD in Africa did not cover Nigeria (see Economic Commission for Africa (2017) & Van-Belle et. al. 2018). The purpose of this paper therefore, is to examine the status open government data in Nigeria using informetric analysis of government websites, explore their management challenges and provide recommendations for improvement. Specifically, the paper intends to:

a. Ascertain the availability of open government data in major government agencies in Nigeria
b. Determine the adoption and availability of open government data in Nigeria government ministries
c. Examine the presence of open government data in Nigeria data portal
d. Determine the currency of the available open government data in Nigeria data portal.
e. Explore the challenges of managing open government data in Nigeria

Materials and Methods

This study adopted descriptive informetrics to examine some government websites in Nigeria so as to determine their status in terms of presence of open government data, their types, currency and accessibility. A literature review approach was also used to articulate strategies of managing them and challenges therein. Data were extracted from the websites of 26 Federal Government Ministries and 16 selected major government agencies and parastatals (from September 2 to 10 2020) to determine the availability and status of open government data in the websites. Within the same period additional, data were extracted from Nigeria Data Portal http://nigeria.opendataforafrica.org/ which is maintained by the National Bureau of Statistics responsible for collection of data on each of the 36 states in Nigeria and Abuja. The portal covers many key areas of national development such as health, agriculture, education, trade and investment, women and child issues, demography among others. Data from the websites were analyzed by identification of presence of open government data with a remark on the expected data to be seen in the websites, data from Nigeria Data Portals were analyzed using frequency and percentages and presented in tables.

Results

Table 1: Selected Government agencies in Nigeria and availability of Open Government Data

S/N	Name of Government Agency	Websites	OGD presence	Remarks
1	Budget and National Planning	http://www.nationalplanning.gov.ng	N/A	Budget proposal and breakdown. Real data not available
2	Central Bank of Nigeria	https://www.cbn.gov.ng/	A	Data on GDP, inflation and other financial issues
3	Economic and Financial Crime Commission	http://www.efccnigeria.org/efcc/	N/A	Data on convictions. No data on recoveries made No data on state corruption index
4	Independent National Electoral Commission	https://www.inecnigeria.org/	A	Data on only recent election results Absent of data on past election result
5	National Bureau of Statistics	https://nigerianstat.gov.ng/	A	Robust data all regions of Nigeria but many of them not updated.
6	National Population Commission	http://population.gov.ng	N/A	No active website at the time of study
7	Nigeria National Petroleum Corporation	https://www.nnpcgroup.com	A	Data on oil and gas production and trade
8	Nigeria Stock Exchange	http://www.nse.com.ng/	A	Robust data on financial market
9	Independent Corrupt Practices and Other Related Offences Commission	https://icpc.gov.ng	N/A	Annual report up to 2015 No data on cases investigated No data on recoveries made No data on states corruption index
10	Nigerian Centre for Disease Control	https://ncdc.gov.ng	A	Data on weekly epidemiological report from 2016. A-Z list of infectious diseases with their symptoms Disease situation report Update on Covid-19 in Nigeria
11	National Agency for Food and Drug Administration and Control	https://www.nafdac.gov.ng/	N/A	There is a page on drug data but no content No periodic data on registered drugs No periodic data on drug abuse and rehabilitation, drug reactions No data on pharmaceutical industries
12	National Agency for the Prohibition of Trafficking in Persons	https://www.naptip.gov.ng/	A	Few data on offenders. No periodic data on trafficking trends, conviction, rehabilitation of victims
13	Nigerian Communications Commission (NCC)	https://www.ncc.gov.ng	A	Presence of period statistics on connected and active telephone lines, VoIP, fixed wired/wireless from 2017 to 2020. Tele density statistics, subscribers' operation data etc.

Table 1 (cont.): Selected Government agencies in Nigeria and availability of Open Government Data

S/N	Name of Government Agency	Websites	OGD presence	Remarks
14	National Drug Law Enforcement Agency (NDLEA)	https://ndlea.gov.ng	N/A	No periodic data on drug use, drug manufacturing and distribution pattern, drug crimes and convictions.
15	National Universities Commission	https://www.nuc.edu.ng	N/A	No periodic statistics on professor/students ratio, students enrolments, graduation, academic and non-academic staff, accreditation performance, university ranking, etc.
16	Nigeria Immigration Service	https://immigration.gov.ng/	N/A	No periodic data on immigrants' registration, processed passports, visas issued, ECOWAS travel certificate, resident permits.

The table above shows that of the 16 government agencies, only 8(50%) have robust data. Surprisingly, the two agencies of government (Economic and Financial Crime Commission (EFCC) and Independent Corrupt Practices and Other Related Offences Commission) which are responsible for investigation and prosecution of financial crimes have no data in their websites to show the periodic data on arrests and number of convictions. One also expects to see data on recovered assets among other related issues. It is also a source of worry that National Population Commission has no active website considering its critical roles in overall national development.

Table 2: Availability of open government data in Nigeria Federal Ministries

S/N	Ministries	Websites	Expected Data	OGD presence
1	Agriculture	http://fmard.gov.ng/	Publications from the ministry available	N/A
2	Aviation	http://aviation.gov.ng/	Inactive website	N/A
3	Defence	http://www.defence.gov.ng/	Articles, speech and few publications are available	N/A
4	Education	http://www.education.gov.ng/	Data on number of schools, enrolment, graduate outputs etc, but data are not updated	Available
5	Environment	http://environment.gov.ng/	Data on pollution, oil spillage, open defecation etc.	N/A
6	Federal Capital Territory	http://fcda.gov.ng/	Housing development, public infrastructure, urban migration etc.	N/A
7	Finance and Economic Development	http://www.finance.gov.ng	Budget allocation, economic growth, financial institutions, trade and investment etc	Available
8	Foreign Affairs	http://foreignaffairs.gov.ng/	Nigeria's international collaborators, trade partners, foreign policies, population in diaspora etc.	N/A (Inactive website)
9	Health and Social Services	http://health.gov.ng/	Disease burden (communicable and non-communicable), health facilities, immunization trends, number of health personnel, mortality rate, covid-19 etc.	A data only on health facilities

Table 2 (cont.): Availability of open government data in Nigeria Federal Ministries

S/N	Ministries	Websites	Expected Data	OGD presence
10	Information & Communication	http://fmic.gov.ng/	Data on journalists in Nigeria, statistics print and electronic media in Nigeria, household internet and telephone connectivity, etc	N/A
11	Internal Affairs	http://www.interior.gov.ng	Population statistics, death and birth statistics, immigration data, prison data, crime statistics etc	N/A
12	Justice	http://www.justice.gov.ng/	Statistics of legal personnel, data on asset recovery, jurisprudent data, statistics of bills, etc	N/A
13	Labour and Productivity	http://labour.gov.ng	Unemployment statistics, data on job creation, labour migration, child labour statistics, etc.	N/A

18	Niger Delta	http://nigerdelta.gov.ng/	Data on oil spillage, statistics on gas flaring, data on infrastructural development of Niger Delta region, etc.	N/A
19	Petroleum Resources	http://petroleumresources.gov.ng/	Data on petroleum production and use, statistics of oil spillage, data on international oil market, etc.	N/A
20	Works and Housing	http://www.pwh.gov.ng	Data on road networks, statistics of housing development, data on electric supply and house hold utility, statistics of building collapse, etc	N/A
21	Science and Technology	https://scienceandtech.gov.ng/	Patents statistics, scientific research data, statistics of technological innovations, etc.	N/A
22	Trade and Investment	http://nid.fmiti.gov.ng	Statistics of small and medium enterprise, export and import statistics, statistics of industries in the country, etc.	N/A
23	Transportation	http://www.transportation.gov.ng	Data on road use, statistics of air travels, ships and ferries, statistics of registered automobiles, etc.	N/A

Table 2 (cont.): Availability of open government data in Nigeria Federal Ministries

S/N	Ministries	Websites	Expected Data	OGD presence
24	Women Affairs and Social Development	https://www.womenaffairs.gov.ng/	Data on women empowerment, statistics of female enrolment in schools, data on gender equality, statistics of female genital mutilation, data on widowhood practices.	N/A
25	Water Resources & Rural Development	https://waterresources.gov.ng/	Data on household water supply, irrigation development, country's water mapping, fresh water ecosystem, aquatic life etc.	N/A
26	Youth and Sports	https://youthandsport.gov.ng/	Employment statistics, data on job creation, data on youth empowerment, etc	N/A (Inactive website)

Table 2 shows that data are available in only 4 (15.4%) of the twenty-six government ministries in Nigeria. These ministries are Education, Finance, Power and Health while the remaining 22 (74.6%) have no open government data in their website. It is even more surprising that two of the ministries (Youths and Sports Development and Foreign Affairs) have no functional websites. Also the Ministry of Youth and Sports Development with the published link https://youthandsport.gov.ng/ cannot connect to any server as at 7.53 pm September 8, 2020. For the Ministry of Foreign Affairs which portrays the country to the global community, a screen shot of the current state of the website is presented as fig. 2.

Fig 1: A screen shot of Ministry of Foreign Affairs website when visited on September 8, 2020 by 7.27pm.

To determine the status of other open government data, Nigeria Data portal (http://nigeria.opendataforafrica.org/) was visited and indications from table 3 reveal that the portal has only 181 data sets in 18 sectors with 17 unclassified data sets out of which economic sector (banking and financial management) has the highest proportion (39.2%) followed by issues related with governance (13.3%), oil and gas has 12 (6.6%) data sets. Labour and productivity has 10 (5.5%) data sets while agriculture, health and education has 7 (3.9%) each; while mining and solid minerals, water resources and disaster control has 0.6% respectively

Table 3: Open Government Data found in Nigeria Data Portal

S/N	SECTORS	No of Data sets	Percentage
1	Banking and Financial Management	71	39.2
2	Governance	24	13.3
3	Others (unclassified)	17	9.4
4	Oil and Gas	12	6.6
5	Labour and Employment	10	5.5
6	Agriculture	7	3.9
7	Education	7	3.9
8	Health	7	3.9
9	Transportation	5	2.8
10	Population	4	2.2
11	Power and Energy	4	2.2
12	Infrastructure	3	1.7
13	Crime control	2	1.1
14	Youth Development	2	1.1
15	Telecommunication	2	1.1
16	Mining and Solid Mineral	1	0.6
17	Water resources	1	0.6
18	Disaster control (Fire, flooding etc)	1	0.6
19	Land use	1	0.6
	Total	181	100.0

A major concern about the data sets found in the portal is that greater a percentage of the data sets appears to be outdated. As can be seen in table 3, analysis of a sample of major data sets from critical sectors of the government reveal that many of them have not been updated for a very long time and therefore, may be unreliable. For instance, 17(28.3%) of the data sets were last updated in 2014, while 14(23.3%) were updated last in 2016 and 10(16.7%) were updated last in 2017. Those that may be regarded as current were updated in the year 2019 and 2020 representing 11.7% and 3.3% respectively.

Table 4: Currency of the Data sets by years

Year	No of data sets	%
Year 2012	3	5.0
Year 2014	17	28.3
Year 2015	4	6.7
Year 2016	14	23.3
Year 2017	10	16.7
Year 2018	3	5.0
Year 2019	7	11.7
Year 2020	2	3.3
Total	60	100.0

Discussions

The availability of open government data in websites of government agencies in Nigeria appears to be grossly inadequate and does not present the country as prepared for running an open and inclusive government. Findings indicate that only half of them provide open government data capable of creating access to information in the website even when there is freedom of information law in the country. This appears antithetical to the potential benefits of open government as has been articulated by Hassan & Twinomurinzi (2018). It is also sad to note that some government agencies with presence of OGD, very critical data were not provided. For instance, the Independent National Electoral Commission (INEC) provides data only on recent election results, without the archives of the past ones. Similarly, data on voters' registration is scanty as it provides only the number of registered voters in Nigeria without a breakdown by states, local governments and possibly at ward levels. Also the website of National Agency for Prohibition of Trafficking in Persons contains few data on offenders with absence of periodic data on the trends of trafficking, and yearly convictions across the country; and complete absence of data on rehabilitation of victims of the traffickers. Available data provided by Nigeria Communication Commission is quite commendable as it contains adequate data on a number of variables on telecommunication in Nigeria. However; a more worrisome situation is a complete absence of data from National Universities Commission, the regulatory agency for all the universities in Nigeria.

In relation with an earlier study conducted by Ezema (2019), it can be deduced that availability of OGD dropped from 75% to 50% as more government agencies were included in the current study, but agencies without active website remain the same. This means that National Population Commission an agency with a very important task of conducting and updating the national population is still without active website at the time of data collection and this has very serious implications as most of policy issues and government decisions hinges on it.

An examination of government ministries shows even a worse situation than the government agencies discussed above. Only four of the ministries provided OGD in their websites while some of the ministries do not have functional website – an indication of absence of online digital contents for the public. A more disturbing situation is the case of Ministry of Foreign Affairs which is the mirror of Nigeria to the global community but without functional website at the time of data collection and this is also the case of Ministry of Youths and Sports Development. Policy-related issues such as merging and de-merging of some ministries by subsequent administrations in Nigeria could have resulted to this. Bu surprisingly, an attempt to visit the website of Ministry of Lands and Urban Development which has been merged with other ministries by the present Buhari Administration using the published link http://www.landsandhousing.gov.ng came up with Ministry of Justice and the two ministries have never been merged which shows some other issues rather than merging may be responsible for this development. The poor presence of OGD in the websites could also be attributed to lack of awareness of its potential contributions in driving socio-political economy of the country which has been pointed out by Helbig & Birkhead, (2015) and Kvamsdal (2017).

Interestingly, the creation of online data portal for aggregation of OGD in Nigeria is a good development as this will facilitate greater access among the public (see Nigeria Data Portal http://nigeria.opendataforafrica.org/). The portal however, requires periodic update of data because the latest population data in the portal was 2006. Other government agencies also maintain website that provide open government data for the interest of the citizens. A good example is National Bureau of Statistics (https://nigerianstat.gov.ng/) which provides open government data on key national development indicators.

Challenges of OGD in Nigeria

A major challenge of management and utilization of OGD all over the world is lack of awareness of their existence. This has been reported in the study conducted by Martin, Helbig & Birkhead, (2015) using survey and focus group discussion. Another problem generally in Africa is lack of true commitment for transparency and open government which is evident in paucity of policy framework in many African countries. Other challenges of OGD as identified by Nayek (2018) include lack of metadata standards for better discoverability and interoperability as published data often do not relate to data expected by users. These are global challenges but there are localized ones in Africa with special reference to Nigeria as summarized below:

Poor ICT infrastructure to Support Digital Open Government Data: The reality is that implementation of OGD is dependent on robust and efficient ICT infrastructure and regular power supply. Unfortunately, Nigeria still suffers from technological challenges arising from poor and irregular Internet connectivity among majority of the citizens and even government organizations (Ezema 2013). In addition, quantity of public power supply in the country is low because installed capacity for power generation is 12,522 MW but only 3,384 MW is generated to serve over 200 million people (USAID 2019) and this is grossly in adequate.

Lack of skilled personnel for OGD: A related challenge is the paucity of skilled manpower for organization and management of OGD in Nigeria. Though, studies show a relative improvement in skilled manpower to maintain technological facilities (Ezema, Ugwuanyi & Ugwu 2014), there is still need to train personnel in critical ICT areas.

Attitude towards transparency and open government*:* Though many African countries including Nigeria have enacted freedom of information laws, government programmes and activities are often shrouded in secrecy (Asogwa and Ezema 2017) and this is still prevalent in many government agencies even in Nigeria. Consequently, many government agencies and establishments find it difficult to openly publish government data and this is often the case with data that are likely to expose corrupt practices among government officials.

Policy framework for open government data: As has been observed, Nigeria's policy framework on OGD is still in a draft stage and therefore, there is no legal guideline for its implementation. It is surprising that over six years after the draft, nothing has been done with its publications for purpose of implementation.

Strategies for Managing Open Government Data in Nigeria

In Africa, Nigeria remains one of the countries that is yet to fully implement open government data. The number of countries in the region releasing their national data catalogues keeps increasing, with eight out of the 10 countries maintaining a reference catalogue of some kind (Van-Belle et al. 2018). For Nigeria to join other countries in Africa that has fully implemented OGD, the following strategies are hereby proposed:

- As major information providers to researchers and scholars, academic and research libraries are positioned to create awareness about OGD through seminars and workshops within the universities and research institutes. In addition, online selective dissemination of information where librarians provide links of government data to researchers in accordance with their research profiles will likely stimulate the interest of researchers on OGD.

- Government should as a matter of urgency publish OGD draft policy to facilitate its implementation in Nigeria. Such policy document is very important as issues such as legislations, action plan, sanctions for violation of the law and the kind of government data that must be made freely available will be well articulated.
- Government agencies should seek the services of librarians and other information professionals skilled in creation and assigning of metadata to assist in providing metadata for every open government data uploaded for public consumption. For the standardization of OGD metadata, the Nigeria Library Association should constitute a team of skilled experts to develop a standard for metadata description of open government data in Nigeria.
- To ensure greater access to open government data in Nigeria, academic and research libraries must engage their skilled staff in data mining and archiving of OGD for enhanced information services delivery to their readers. Downloaded open government data should be archived in the library websites and also provided in other electronic databases of the library.
- There is a need to link all to Nigeria data portal to create a webometric control of the portals. This should be part of the policy framework for OGD in Nigeria. There ought to be a government agency with legal mandate to collate organize and manage all open government data to ensure global visibility and accessibility to all citizens of the country.

Conclusion

It appears that there is genuine interest in implementation of open government data in Nigeria given the desire of the citizens to participate actively in the programmes and activities of government. The attempts by a few government agencies and organizations in making government data freely available on their websites are indications that the agitations for transparency and accountability are perceived outcomes of democratic culture in Nigeria. However, available evidences show that a greater proportion of government agencies are yet to provide OGD in their websites. Part of the reason perhaps is the inability of government to publish the draft policy guidelines for open government data which is an indication of lack of political will for implementation of OGD in Nigeria. The global rating of any government is dependent on level of transparency and accountability which are often assessed by free availability of open government data to the general public. This paper has been able to articulate strategies to mitigate these identified challenges against the full implementation and management of OGD in Nigeria.

User Engagement with Scholarly Twitter Mentions: A Large-scale and Cross-disciplinary Analysis

Zhichao Fang[1]

[1] *z.fang@cwts.leidenuniv.nl*
Centre for Science and Technology Studies (CWTS), Leiden University, Leiden (The Netherlands)

Abstract

This study investigates the extent to which scholarly Twitter mentions of scientific papers are engaged with by Twitter users through four types of user engagement behaviors, i.e., liking, retweeting, replying, and quoting. On the basis of a dataset consisting of nearly 8.7 million scholarly Twitter mentions, our results show that there are 55.4% of them have been engaged with by Twitter users through at least one engagement behavior, whereas the remaining did not attract any user engagement. Liking and retweeting are the most common user engagement behaviors. From the disciplinary perspective, scholarly Twitter mentions pertaining to Social Sciences and Humanities are more likely to trigger user engagement. Twitter engagement indicators (i.e., likes, retweets, replies, and quotes) are moderately or strongly correlated with each other, but are weakly correlated with scholarly impact indicators (i.e., citations and Mendeley readers). The analysis of user engagement uncovers the impact of scholarly Twitter mentions on the Twitter universe, shedding light on the characterization of deeper levels of Twitter reception of science information.

Introduction

Twitter mentions of scientific papers (hereinafter "scholarly Twitter mentions") are widespread, thus providing considerable evidence for quantitatively studying science-social media interactions (Costas et al., 2020). The presence of scientific papers on the Twitter platform also offers the possibility for users to engage with science-focused discussion in the Twittersphere (Fang et al., 2021). However, how Twitter users interact with scholarly Twitter mentions, which was specifically referred to as "secondary Twitter metrics" by Díaz-Faes et al., (2019), has not been extensively studied in existing altmetric literature. Therefore, this study aims to present a large-scale and cross-disciplinary analysis of user engagement situations of scholarly Twitter mentions. Specifically, this study seeks to address the following explicit research questions:
RQ1. To what extent are scholarly Twitter mentions engaged with by Twitter users through different engagement behaviors (i.e., liking, retweeting, replying, and quoting)?
RQ2. Do engagement situations of scholarly Twitter mentions vary across subject fields of science?
RQ3. How do Twitter engagement indicators of scholarly Twitter mentions correlate with scholarly impact indicators (i.e., WoS citations and Mendeley readers) of tweeted papers?

Data and methods

Dataset

We retrieved a total of 6,229,001 Web of Science-indexed (WoS) papers published between 2016 and 2018 from the CWTS in-house database, and searched their scholarly Twitter mentions recorded by Altmetric.com until October 2019. For the matching with Altmetric.com data, WoS papers are restricted to those with DOI or PubMed ID assigned. On the whole, there are 2,035,648 WoS papers with at least one scholarly Twitter mention received, totally generating 8,692,499 unique scholarly Twitter mentions.[1] Note that to explore user engagement behaviors around scholarly Twitter mentions, in this study the analyzed tweets are limited to those can be engaged with through the engagement functionalities provided by Twitter. Therefore, as listed in Table 1, there are four main types of scholarly Twitter mentions considered in this study, including original tweet, reply tweet, quote tweet, and hybrid tweet. Their proportions in our dataset are also presented in Table 1.

Table 1. The four tweet types with engagement functionalities.

Tweet type	*Concept*	*Number*	*Proportion*
Original tweet	An original tweet is a tweet originally posted by a Twitter user.	7,037,233	81.0%
Reply tweet	A reply tweet is a response to a tweet.	449,544	5.2%
Quote tweet	A quote tweet is a retweet with comment added.	1,174,714	13.5%
Hybrid tweet	A hybrid tweet is a reply tweet with link(s) to other tweet(s) attached. A hybrid tweet is both a reply tweet and a quote tweet.	31,008	0.3%

Twitter engagement indicators

As the tweet example given in Figure 1, at the bottom of a tweet there are four primary engagement indicators displayed and publicly available through the Twitter API, including likes, retweets, replies, and quotes. We focused on these four Twitter engagement indicators and collected them for the 8.7 million scholarly Twitter mentions in our dataset with the Twitter API in February 2021.

3 **Likes**: times a tweet has been liked.

4 **Replies**: times a tweet has been replied. Detailed content of replies are visible at the bottom of the tweet, while the total number of replies received is accessible with the Twitter API.

Figure 1. The four Twitter engagement indicators of a tweet example.

CWTS publication-level classification

To compare the user engagement situations of scholarly Twitter mentions across subject fields of science, we applied the CWTS publication-level classification system (Waltman & Van Eck, 2012) to assign scholarly Twitter mentions with subject field information based on their mentioned scientific papers. The CWTS classification clusters WoS papers into micro-level fields based on their citation relationships. These micro-level fields are then algorithmically assigned to five main subject fields of science, including *Social Sciences and Humanities*

(SSH), *Biomedical and Health Sciences* (BHS), *Physical Sciences and Engineering* (PSE), *Life and Earth Sciences* (LES), and *Mathematics and Computer Science* (MCS).[2] For our dataset, a total of 7,336,299 scholarly Twitter mentions (accounting for 84.4%) refer to scientific papers with the subject field information assigned by the CWTS classification system, involving 3,992 micro-level fields. This set of scholarly Twitter mentions and micro-level fields was drawn as a subsample for studying the subject field differences of user engagement. Figure 2 shows the distribution of the micro-level fields in the subsample.

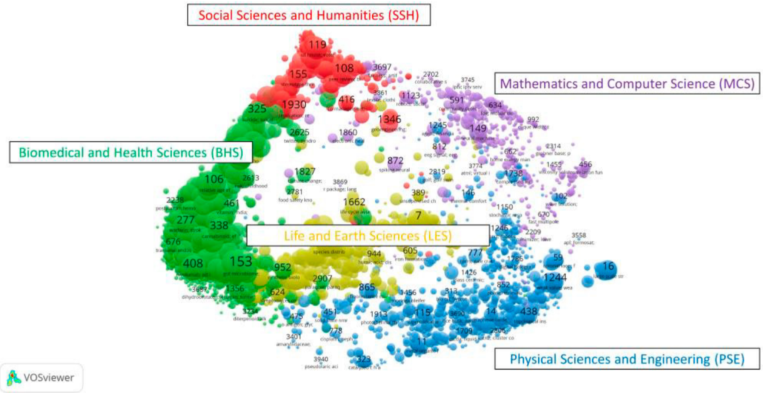

Figure 2. Distribution of micro-level fields of the five subject fields of science. Each node represents a micro-level field with the size determined by the number of scholarly Twitter mentions inclusive. Micro-level fields belonging to the same subject field are indicated in the same color.

Analytic approaches

To unravel the overall user engagement situations of scholarly Twitter mentions, descriptive statistics of Twitter engagement indicators are first conducted. Besides, we compared the relationships between the analyzed Twitter engagement indicators and scholarly impact indicators. To this end, WoS citations and Mendeley readers were selected as indicators reflecting the scholarly impact of papers. The former was retrieved from the CWTS in-house WoS database recording citations accumulated up to March 2020, and the latter was collected through the Mendeley API in July 2020. We aggregated both scholarly impact indicators and Twitter engagement indicators at the paper level and then performed Spearman correlation analyses amongst them.

Results and discussion

Overall user engagement around scholarly Twitter mentions

Among the 8.7 million scholarly Twitter mentions, 55.4% have been engaged with through at least one of the four analyzed engagement behaviors, namely, the overall coverage of Twitter engagement among scholarly Twitter mentions is 55.4%. More specifically, Table 2 presents the descriptive statistics of the four engagement indicators to reflect the extent to which scholarly Twitter mentions are engaged with through different behaviors. Liking is the most common engagement behavior, with 47.7% of scholarly Twitter mentions being liked by Twitter users. Followed by retweeting which involves 35.7% of scholarly Twitter mentions. In contrast, replying and quoting, the two engagement behaviors with original comment added by Twitter users, are relatively scarce, with only 10.3% of scholarly Twitter mentions being replied and 8.4 % being quoted at least once.

Table 2. Descriptive statistics of the four engagement indicators.

Engagement	*Total number*	*Coverage*	*Mean*	*Min*	*Q1*	*Q2*	*Q3*	*Max*	*SD*
Likes	26,071,539	47.7%	3.00	0	0	0	2	28,368	24.23
Retweets	15,669,405	35.7%	1.80	0	0	0	1	33,009	21.15
Replies	1,388,947	10.3%	0.16	0	0	0	0	1,033	1.24
Quotes	1,347,088	8.4%	0.15	0	0	0	0	804	1.47

Users engagement around scholarly Twitter mentions across subject fields

For each type of user engagement behavior, the micro-level fields in different subject fields of science are plotted in Figure 3 based on the coverage of corresponding engagement among their inclusive scholarly Twitter mentions.

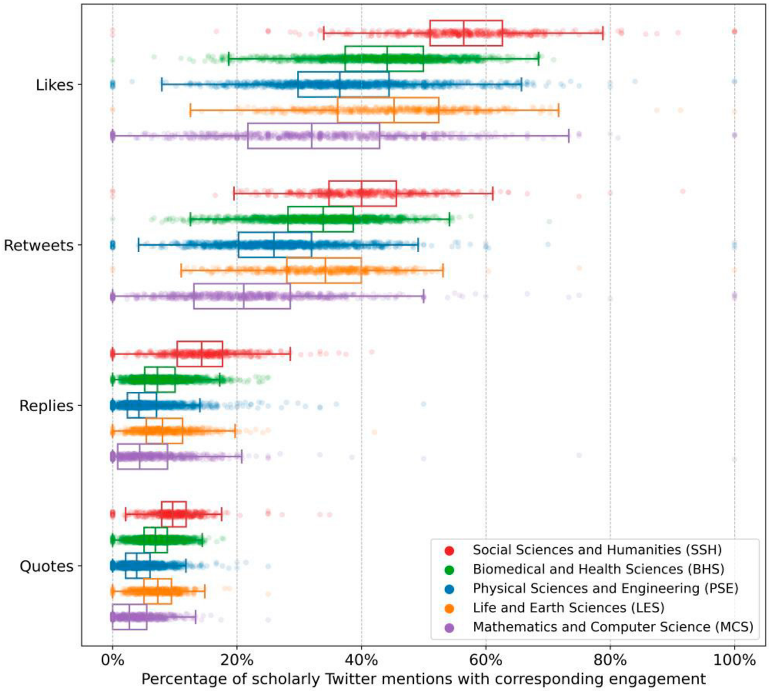

Figure 3. Coverage of the four types of user engagement among scholarly Twitter mentions across the five subject fields of science.

Generally speaking, the disciplinary differences are similar across the four Twitter engagement indicators. Social Sciences and Humanities is the subject field with related scholarly Twitter mentions more likely to be engaged with by Twitter users, regardless of what kind of user engagement behavior. Next, scholarly Twitter mentions in the fields of both Life and Earth Sciences and Biomedical and Health Sciences attract relatively high levels of user engagement as well. By comparison, there are less scholarly Twitter mentions in relation to Physical Sciences and Engineering and Mathematics and Computer Science being engaged with on Twitter. Similar to the more active Twitter mention events observed for social sciences, health sciences, and life sciences-related research outputs (Costas et al., 2015; Haustein et al., 2015), there are more active user engagement behaviors around scholarly Twitter mentions of these subject fields, suggesting a consistent Twitter users' interest in sharing, discussing and disseminating research progress in terms of society, health and environmental problems.

Correlations between scholarly impact and Twitter engagement

We performed Spearman correlation analyses among the two scholarly impact indicators (i.e., WoS citation and Mendeley readers) and the four Twitter engagement indicators, and Figure 4 shows the results. As confirmed by previous studies (Zahedi et al., 2014), the two scholarly impact indicators, WoS citations and Mendeley readers, keep a moderate correlation. However, the correlations between scholarly impact indicators and Twitter engagement indicators are weak, reinforcing the idea that scholarly metrics and Twitter metrics reflect different aspects of the impact that scientific papers made. Twitter engagement indicators are moderately or strongly correlated with each other, indicating intrinsic relationships among user engagement behaviors within the Twitter universe.

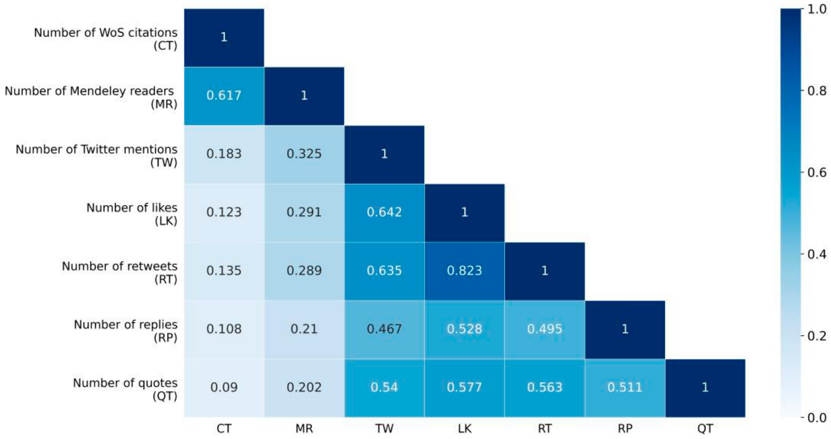

Figure 4. Spearman correlations among scholarly impact indicators and Twitter engagement indicators.

Conclusions and future outlook

This paper presents a large-scale and cross-disciplinary analysis of Twitter user engagement for nearly 8.7 million scholarly Twitter mentions. We found that even though scholarly Twitter mentions widely brought research outputs to the Twitter landscape, only 55.4% of them have been engaged with by Twitter users through at least one of the four engagement behaviors (i.e., liking, retweeting, replying, and quoting), showing a deeper level of Twitter reception of science information. Comparatively speaking, scholarly Twitter mentions about social sciences, life sciences and health sciences exhibit a higher coverage of user engagement. Liking and retweeting, as the two basic user engagement behaviors without additional original commentary added, are the most common and are strongly correlated with each other. In addition to likes and retweets, other Twitter engagement indicators are also moderately correlated, reflecting intrinsic relationships among Twitter users' engagement behaviors. However, the correlation between scholarly impact indicators and Twitter engagement indicators are generally weak. These two types of indicators might tell different stories of the reception and dissemination of scientific knowledge.

For future research, we will take into consideration the features of scholarly Twitter mentions (e.g., the inclusion of hashtags or mentioned users, the originality of tweet texts) as well as the demographics of Twitter users (e.g., number of followers, Twitter activity) to explore what kinds of scholarly Twitter mentions are more likely to trigger user engagement behaviors, thus paving the way toward a better understanding of how and why Twitter users interact with science.

Abstract

Information technology affects most aspects of human life. Social Media (MedSos) is an information technology product. One of the uses of social media in the academic world is Altmetrics. This indicator is used to measure the impact or influence of social media on indexed papers. Indonesia is one of the countries with the highest social media users in the world. Therefore, this study is proposed to measure the possibility of a correlation between comments / mentions on papers shared on social media and the number of citations obtained. In solving this problem, we propose a method that uses Text Mining to perform Natural Language Processing (NLP) so that machines can understand the meaning of human language and maximize class distance; we used the Support Vector Machine (SVM) algorithm method for classifying opinions in a scientific article. We found that publications shared on social media will have more citations. Papers that have a greater number of positive sentiments will have a large number of citations, whereas the number of tweets on a paper has no effect on the value of positive sentiments and tends to be more contradictory.

Introduction

In its development, information technology is very influential in almost all aspects of life. One example of the results of information technology is social media. Social media is used by people who use it to meet needs, support activities, and open up opportunities to realize new hopes (Akram et al., 2017). The research progress creates this and is one of the developments in communication technology.

Currently, social media has grown rapidly along with technological advances and has penetrated various layers and groups of society. However, there are still few matters concerning social media's impact or influence on researchers' indexed papers in its development. Therefore, sentiment analysis is required regarding this matter based on several factors and criteria. To obtain data with positive or negative review comments that affect the study's h-index or number of citations. Although the h-index has its drawbacks, it is still used as long as there is no better substitute (Rochim et al., 2020).

In previous research, Xiaoli in 2020 discussed dynamics of topic inheritance research and topic innovation by using cross-collection topic models and measuring direct and indirect scientific influence through "citations" (Chen and Han, 2020). Previous research entitled "Sentiment Analysis using a Support Vector Machine" (Nomleni, 2015) discussed the classification of textual documents into several classes, such as positive and negative sentiments and the effects and benefits of sentiment analysis. In this study, the classification of public complaints against the government on social media, Facebook and Twitter, was used with Indonesian language data using a Support Vector Machine (SVM) run in a distributed computer using Hadoop. A study entitled "Adapting SVM for Natural Language Learning: Case Studies Involving Information Extraction" (Li et al., 2008) discussed two techniques to help SVM with the NLP problem's two unique features: unbalanced training data and difficulty obtaining adequate training data. The research problem is how to measure the impact of papers in social media that correlate with several citations. Jason in 2010 stated that Altmetrics (social media in scholars) would become scientometrics 2.0 (Jason et al., 2010). Most of all database indexers, i.e., Scopus, IEEE Xplore used Altmetrics to figure impact profiles of authors from social media.

Methodology

The methodology used in the research adopts an experimental method from various international papers obtained from the Altmetrics website. It discusses how social media's positive comments come to the number of citations in indexed scientific papers made using the Support Vector Machine method to produce some descriptive analysis.

This research begins with data collection totaling 50 different scientific papers from the Altmetrics website (accessed April 13, 2020). This study's data type is primary data as test data obtained from the Altmetrics website and secondary data obtained from Kaggle created by Ali Toosi as training data. The dataset contains 50 datasets of scientific papers, with 700 comments for each dataset. After all the data are collected, the data translation process into English will then be carried out.

Sentiment Analysis Process

Figure 1 illustrates stages of data or documents that enter the system, which are then carried out, cleaning the document to eliminate unnecessary words. After that, the parsing or tokenization process is carried out to divide or break the document into terms based on the stop word and then delete it to filter words or documents. Finally, the stemming process is carried out to obtain common words according to applicable standards.

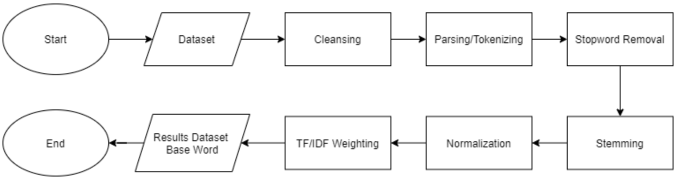

Figure 1. Flow diagram sentiment analysis process

1) Cleansing used aims to remove unnecessary words and characters as noise reduction; Perform cleaning to change all capital letters and documents to lowercase and remove characters other than punctuation, repeating letters, and hyperlinks. Table 1 (Process no.1) presents samples of the cleansing process.

Table 1. Sample of Processing.

No.	Process	Sentence	Results
1.	Cleansing	~~RT @ learn_learning3:~~ It requires large amounts of the image of the person who is the generation source of the video~~.~~	It requires large amounts of the image of the person who is the generation source of the video.
2.	Parsing and Tokenization	but it requires large amounts of the image of the person who is the generation source of the video.	[but, it, requires, large, amounts, of, the, image, of, the, person, who, is, the, generation, source, of, the, video]
3.	Stopword	[~~but, it~~requires, large, amounts, ~~of, the,~~ image, ~~of, the,~~ person, ~~who, is, the,~~ generation, source~~, of, the,~~ video]	[requires, large, amounts, image, person, generation, source, video]
4.	Stemming	[requires, large, **amounts**, image, person, **generation**, source, video]	[require, large, **amount**, image, person, **generate**, source, video]

2) Parsing and tokenization were used to divide large parts of the document into words chop off each word in the text and change all uppercase letters to lowercase. Table 1 (Process no.2) presents samples of the parsing and tokenization process that divides or breaks a large part of a document (sentence) into words; the process chops off each word in the text.

3) Stopword Removal was used to filter words or documents identified as conjunctions, articles, and prepositions. Stopword Removal is the process of removing unnecessary words based on the stopword dictionary in English ('between,' 'yourself,' 'but,' 'again,' 'there,' and so forth). Such words have no meaning. Table 1 (Process no.3) presents the process of stopword removal.

4) Stemming is used to find a root word in a word and remove prefixes, suffixes, and combinations of prefixes and suffixes (Zainuddin et al., 2014). Table 1 (Process no.4) presents samples of stemming that changes the processing of words into basic words by eliminating prefixes, insertions (infixes), suffixes, and combinations of prefixes and suffixes.

5) Normalization is used to measure variable values on a broader scale and change the previous value to become 1. The data should be scaled before training is carried out on the data normalized with mean = 0 and standard deviation = 1. The normalization formula is

$$\text{New Value} = \frac{[Old\ Value(Average)]}{Standard\ Deviation} \tag{1}$$

Data that have been normalized will be divided into training data and testing data using the cross-validation method.

6) Weighting. In weighting this term, the results of the stemming process will be used in calculating the number of documents' Term Frequency (TF), the number of documents that have a term (DF), and the IDF value such as the formula (Nomleni, 2015), (Amrizal et al., 2018). Table 2 presents a sample of the weighting process.

Table 2. Weighting.

Tweet	*Rank*
Ability	0.50
Able	0.69
Work	1.00
Year	0.71

7) TF-IDF Weighting. The method used to find a representation of the value of the data set is trained, and the results form a vector between a document and a word. This method combines a two-weight calculation concept, specifically Term Frequency (TF) and Inverse Document Frequency (IDF). TF determines the word-for-word weight in a document and IDF serves to construct contributions from words into a document. Term Frequency is the frequency of occurrence of words (F) in a sentence (D), and Document Frequency (DF) is the number of sentences in which a word (F) appears (Nomleni, 2015). This word weighting will produce a word weight value, which indicates the importance of each word in the document (Vijayarani et al., 2015). This TF-IDF weighting calculation is formulated in the following equation:

$$\text{idf} = \log\left(\frac{N}{df}\right), \tag{2}$$

where

N = number of document collections, and df = number of documents containing pre-determined term (f)

$$\mathrm{W_{dt}} = tfdt \times idft, \tag{3}$$

where

W_{dt} = weight term (t) against the document, (d)

idf = inversed document frequency (log/(N/df)).

$tfdt$ = number of occurrences of term (t) in the document (d), and

Support Vector Machine Algorithm (SVM)

SVM is used as a classification algorithm to find the best hyperplane by maximizing the distance between classes. Classification is done to find a hyperplane or the boundary line (Decision Boundary), which separates a class from another class.

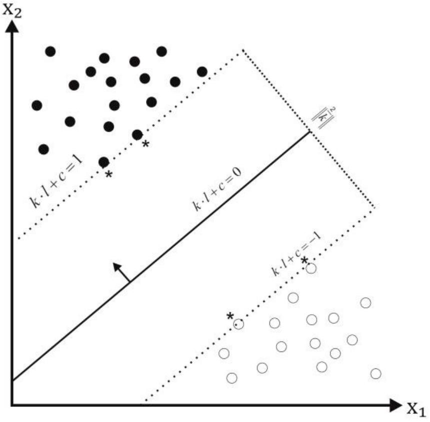

Figure 2. When the wrong hyperplane is positive (+1) and negative (-1).

Figure 2 shows a solid line that is the best hyperplane found by the SVM algorithm, located right in the middle of the second class. The distance between the hyperplane and the data object is different from the near (outermost) class, given an asterisk or star and the data object. The outermost closest to the hyperplane is called the Support Vector (Marafino et al., 2014).

Precision, Recall, and F-Measure

After the SVM classification process is complete, testing of the classification is carried out to measure the performance value of the system that has been created. The formulas used for Precision, Recall, Accuracy, and F-Measure are as follows:

$$\text{Precision} = \frac{TP}{TP+FP}, \tag{4}$$

$$\text{Recall} = \frac{TP}{TP+FN}, \tag{5}$$

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN}, \text{and} \tag{6}$$

$$\text{F} - \text{Measure} = 2 * \frac{precision*recall}{precision+recall}. \tag{7}$$

Precision is the ratio of true positive predictions compared to total positive predicted results (Irawan et al., 2018), Recall is the ratio of true positive predictions to total true positive data (Flach et al., 2015). Accuracy is the number of correctly predicted documents divided by the total number of documents, and F-Measure is a weighted average comparison of precision and recall (Lipton et al., 2014).

Results and Discussion

From the results of the research that has been conducted, the results obtained from the experiment are Precision, Recall, F-Measure, Accurate, the number of citations, and positive and negative sentiments from each paper.

Table 2 presents the confusion matrix and results of SVM. This method is used to avoid a perfect score but fails to predict anything in the not-yet-visible data (overfitting).

Table 2. Confusion matrix and results of SVM.

Actual Data	*Predict Data*		*Precision*	*Recall*	*F-Measure*	*Accuracy*
	Positive	*Negative*				
Positive	19	6	0.76	1	0.86	0.96
Negative	0	115	0.95	1	0.97	

Positive class:

$$Precision = \frac{TP}{TP+FP} = \frac{19}{19+6} = 0.76 \qquad F-Measure = 2 \times \frac{precision \times \ recall}{precision + recall} = 2 * \frac{0.76 \times \ 1}{0.76+1}$$

$$Recall = \frac{TP}{TP+FN} = \frac{19}{19+0} = 1 \qquad = 0.86$$

Negative class:

$$Precision = \frac{TN}{TN+FP} = \frac{115}{115+6} = 0.95$$

$$Recall = \frac{TN}{TN+FN} = \frac{115}{115+0} = 1 \qquad F-Measure = 2 \times \frac{precision * recall}{precision + recall} = 2 \times \frac{0.95 * 1}{0.95+1} = 0.97$$

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} = \frac{19+115}{19+115+6+0} = \ 0.957 \times \ 100\% = 96\%$$

Test Results

The measurement results for each paper obtained by the average Precision, Recall, and F-Measure using the SVM classification are presented in Table 3.

Table 3. Sentiment analysis results.

Figure 3 illustrates the comparison of the correlation between the total number of tweets and positive sentiment. In measuring validity between citations data and positive data, we used Spearman's Rank-Order Correlation method. We found that the citations index has a reasonably low correlation. The correlation between citations and positive sentiment is 0.085. Even though this number is very small, it indicates that positive sentiment influences citations. It can be concluded that the higher the positive sentiment, the larger the number of citations. Figure 4 presents a graph between the number of tweets and the sentiment in the opposite direction. Furthermore, using Spearman's Rank-Order Correlation test between the number of tweets and the positive sentiment gave a negative value of −0.183. However, it can be concluded that it does not affect the sentiment score.

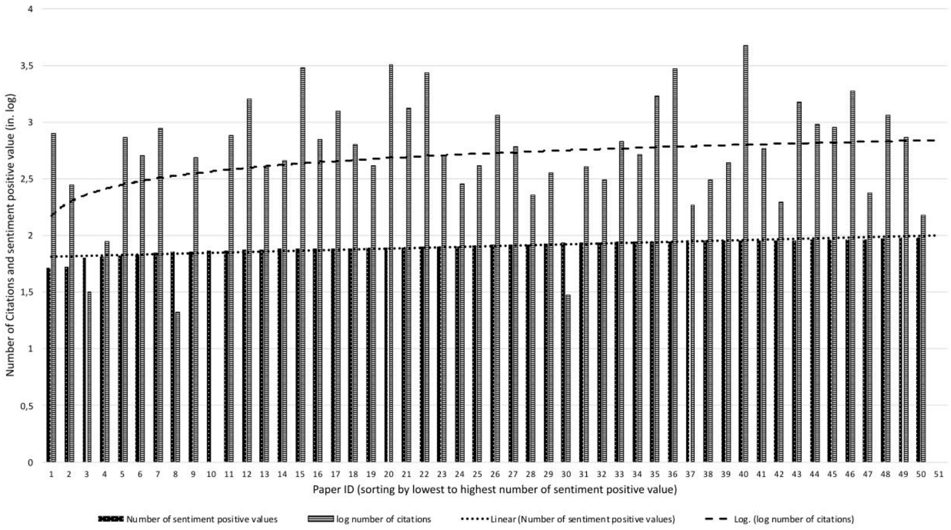

Figure 3. Distribution of the correlation between positive sentiment and number of citations.

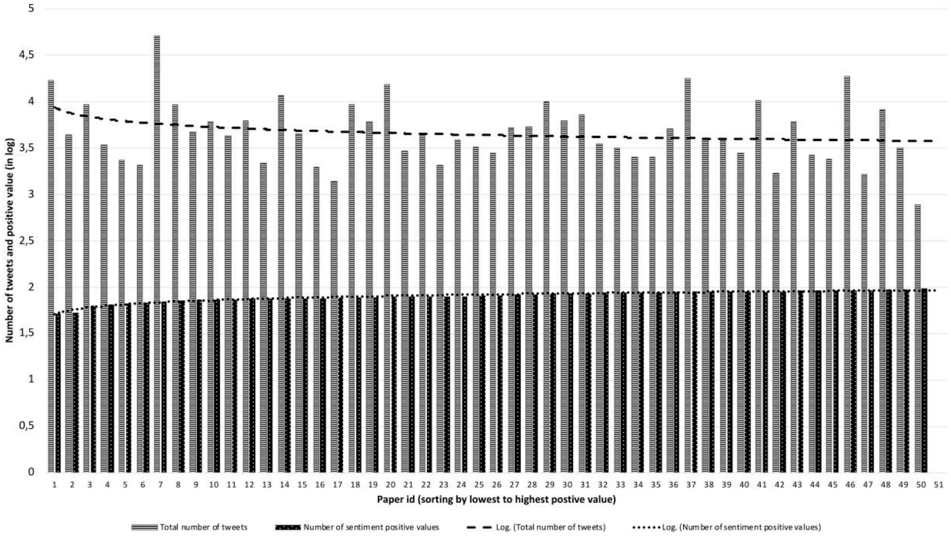

Figure 4. Distribution of the correlation between total tweets and positive sentiment.

Conclusion

We have found that there are correlations among the number of citations of papers obtained, the number of tweets of papers, and number of positive sentiments on papers. We have found that there is a correlation of 0.08 between the number of citations obtained and the number of positive sentiments on a paper. The correlation test between the number of tweets and the number of positive sentiments is −0.183. We can conclude that the number of positive sentiments obtained by the paper will affect the number of citations it gets. The number of tweets obtained by papers on social media has no impact on the number of citations they obtain.

However, this influence is not so significant that it needs to be investigated more. It indicates that the papers that have more several positive sentiments have a larger number of citations.

Abstract

This paper analyses the relationship between academic mobility and the structure of universities' thematic portfolios. To do this, we examined millions of authorships on a global scale through the study of authors' affiliation trajectories across institutions and scientific topics. Specifically, we analyzed all articles and reviews available in the Dimensions database and used a publications-based classification of 4,064 scientific topics to map the publishing activity of 4,078,913 disambiguated authors. Examining a sample of 1,189 Leiden Ranking universities over the recent period of 2015-2020, we show that after researchers move to a new institution, they tend to publish on similar research topics to those of their peers already at the same institution. This result suggests that mobile researchers' choices of institution may be driven either by potential thematic affinity (*homophily*) or by the adoption of the topics already developed at the new institutions (*adaptation*). Areas of future development are also suggested.

Introduction

Mobile researchers play an important role in the process of discovery. They drive knowledge exchanges (OECD, 2010) that are vital for the transfer of "tacit knowledge", which cannot always be transmitted through formal communication channels (Gertler, 2003). When researchers move, they bring with them different perspectives and ideas. These perspectives are considered to be important for knowledge recombination (Ganguli, 2015; Stephan & Levin, 2001), which leads to new opportunities for scientific innovation (Franzoni, Scellato & Stephan, 2018). It is therefore important to gain a better understanding of the skills and expertise that mobile researchers bring to host institutions, as well as how this can influence their own and their institutions' ability to explore and develop uncharted scientific areas.

Despite the importance of mobility flows to scientific innovation, much of how institutions attract new scholars, and how prospective newcomers compare to the native faculty in terms of the topics in which they publish remains unclear. This paper attempts to address this challenge by comparing the topics of publications by mobile researchers to the knowledge base of receiving institutions based on the topics of native researchers. The question we address is *how do the research areas of newcomers (researchers moving to a new university) and native researchers (researchers who begin their publishing careers at a university) differ within and across universities?*

Database and methods

We use the Centre for Science and Technology Studies (CWTS) in-house version of the Dimensions database. This database contains publication data spanning several decades. This analysis focuses on the universities featured in the most recent release of the Leiden Ranking (https://www.leidenranking.com/). This approach allows us to track mobility between a homogeneous set of institutions (Macháček et al, 2020). While we present the analysis of the restricted set of universities, our indicators capture the mobility events of researchers with institutions not covered by the Leiden Ranking[1].

Classification of authorships into 'newcomers' and 'natives'

We start by identifying the first affiliation of researchers based on their first publication in the whole Dimensions database (i.e., the *original* affiliation of the author) according to the time sequence of their overall publication history. This means that we look at scholars' entire publication history and not just at their publication activity in the period under analysis (i.e., 2015-2020). Then, as a second step, we identify all the authorships of each researcher at her original affiliation or *native authorships* and identify all the authorships of each researcher as a *newcomer* to another university[2] or *newcomer authorships*. We aggregate the two kinds of authorship at the institutional level – in this case for Leiden Ranking universities – in the period between 2015 and 2020. Our choice for a recent period is because it allows us to have a more contemporary overview of the workforce composition of institutions' in terms of mobility. We also consider the micro-fields of the publications of the authorships previously identified and split the set of overall authorships of a university into two:

1. *Native authorships*. Micro-field information weighted by the number of authorships by those researchers whose first affiliation was already at the current institution in the period. This can be interpreted as the micro-fields profile vector of university natives in a given period.
2. *Newcomer authorships*. Micro-field information weighted by the number of authorships by those researchers whose first affiliation was not at their current institution in the period under analysis. This can be interpreted as the micro-fields profile vector of university newcomers in a given period.

Each university is characterised by these two micro-fields vectors. This is used to compare the overall research profile (dis)similarity, as captured by micro-fields, between institutional natives and newcomers. To compute the similarity between the vectors we use the cosine similarity measure as described in the next section.

Cosine Similarity

Starting from the overall set of authorships in the output of a university in the period 2015-2020, we measure the cosine similarity of the micro-fields from the newcomers to a university, and we compare it with those of the native researchers.

As micro-fields we use the publication-level classification develop by Waltman & van Eck (2012). This publication-level classification is composed by 4,064 scientific micro-fields obtained algorithmically based on citation relationships among publications. This fine-grained classification allows for the advanced study of the thematic profile of universities and individual researchers from a topical point of view, in which micro-fields can be seen as specialized research areas.

Similarity is constructed using the standard cosine similarity measure to compare the vectors of research topics of newcomer authorships (vector **A**) and the vector of research topics of native authorships (vector **B**). Consider for example, a university with a single newcomer. The newcomer author $\boldsymbol{a}$ to university $\boldsymbol{u}$ in the period of the analysis, wrote three papers assigned to three topics $\boldsymbol{i}$. Let us assume that one micro-field, say $\boldsymbol{\alpha}$, has been used in all three papers. The

[1] For example, mobility linkages of researchers with other local universities or other types of research organizations (e.g., umbrella research organizations like Inserm, CSIC, CNRS, etc.) are also considered in the identification of mobile researchers.

[2] It is possible that a publication contains both newcomer authorships and native authorships if the same publication is authored both by natives and newcomers. In these cases, the publication is weighted by the number of authorships that are '1' (native) and '0' (newcomer).

component[3] $\boldsymbol{\alpha}$ will be 3. Thus, the components quantify the number of publications of an author in each micro-field.
More formally, we calculate the cosine similarity as follows

$$\theta = \cos(\gamma) = \frac{\mathbf{A} \cdot \mathbf{B}}{\|A\|_2 \|B\|_2}$$

, is defined for each pair of vectors $\boldsymbol{A}$ and $\boldsymbol{B}$.
Other indicators, such as the number of researchers, the number of micro-fields, the number of publications (**P**), the proportion of natives and the proportion of newcomers, are also provided (See Table 1).

Results

Table 1 provides some summary statistics of the variables used in the analysis.

Table 1. Descriptive Statistics.

Statistic	*Number Researchers*	*Number Micro-Fields*	*P*	*Proportion - Natives*[4]	*Proportion - Newcomers*	*Cosine Similarity*
N	1189	1189	1189	1189	1189	1189
Mean	4613.84	1188.23	8703.16	0.65	0.34	0.78
SD	4684.81	558.30	8775.40	0.13	0.13	0.15
Min	2	1	1	0	0	0
25%	1789	778	3368	0.57	0.24	0.73
50%	3043	1079	5771	0.67	0.33	0.82
75%	5483	1542	10443	0.76	0.43	0.89
Max	43016	2984	65289	1	1	1

Institutional cosine similarity distribution

In Fig.1 we compare the distribution of $\boldsymbol{\theta}$ from different perspectives. Fig.1 a) shows that there is a tendency towards a high cosine similarity between the thematic profiles of newcomers and natives across universities, represented by most institutions having $\boldsymbol{\theta} > 0.7$. Thus, institutions were more likely to attract newcomer researchers working in the same topics as the natives. To better understand this result; in Fig.1 b) we also compare the distribution of $\boldsymbol{\theta}$ with a null model obtained considering a randomised assignment of newcomers[5]. The plot clearly supports a legitimate tendency of universities to have newcomers covering similar topics as those developed by native researchers (high values of $\boldsymbol{\theta}$), as the actual distribution (the blue bar) contrasts with the randomized distribution (the red bar). The randomized set is strongly shifted to the left, meaning that when the authorships are randomly assigned to universities, including the corresponding micro-fields of each authorship and the cosine similarity is recalculated, the

[3] Component here refers to the elements of the vectors of authorships.

[4] Note that the proportion of natives and newcomers in the table refers to the distinct number of researchers falling in those categories from the perspective of institutions for the period 2015-2020.

[5] These randomized sets are obtained considering the period 2015-2020 and assigning researchers randomly to universities. The hypothesis is that institutions have a general tendency to pick researchers that are similar to their existing researchers, so if you shuffle the researchers and attribute them randomly to universities, we can check this specific hypothesis.

differences between the authorships of the newcomers and the authorships of the natives are substantially different. In Fig.1 c) we repeat this same analysis but considering the Jaccard index. This is a test of robustness of the results to avoid possible spurious effects induced by sparse vectors in the cosine similarity. The plot confirms the pattern emerging from Fig.1 a). This reassures us that the $\boldsymbol{\theta}$ is not sensitive to spurious effects and high values of $\boldsymbol{i}$. These results demonstrate that universities' newcomers and natives tend to research similar topics. However, as we measure the similarity between newcomers' authorships after they become affiliated with the new university - and not before they join the institution, we cannot discern yet whether newcomers do *adapt* to the thematic profile of their new universities, or whether the newcomer's choice of a new institution is driven by *homophily*, i.e., moving to universities already working on the same topics as the researcher was already working. This is clearly a topic to study in future research.

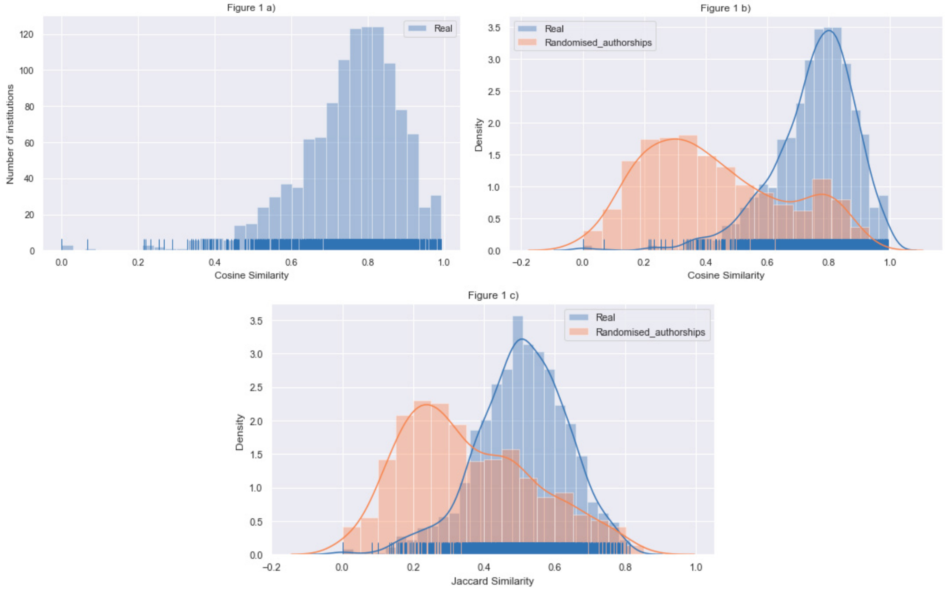

Figure 1. Cosine similarity distributions.

One potential explanation for the patterns observed in Fig. 1 is that generalist universities, already working in most micro-fields, will attract newcomers already working in common micro-fields. More specialized or smaller universities, working in more focused sets of micro-fields, may exhibit stronger differences in the comparison between newcomers and natives. This extent is explored in Fig. 2, where it is visible how indeed universities that work in very large sets of micro-fields tend to have higher cosine similarity values, with newcomers and natives being more similar, while smaller or more focused universities exhibit a larger variability (i.e., some have thematically similar newcomers, others however attract newcomers that work on more differentiated profiles at the universities).

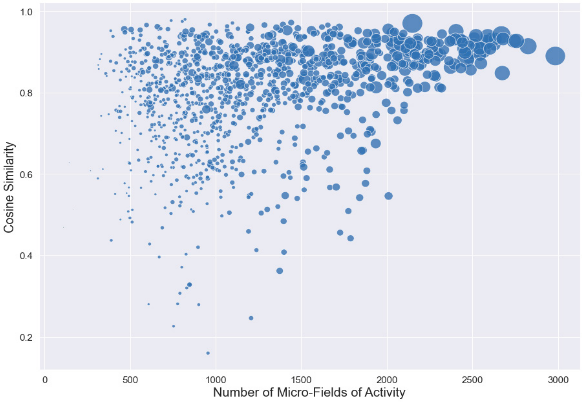

Figure 2. University cosine similarity measures of Leiden ranking universities – newcomers vs. natives.

Note: only universities with at least 100 researchers are considered in the plot; the size of the circles represents the size of the university workforce.

Discussion and conclusions

The results in this paper should be seen as a preliminary first step in order to better understand innovation patterns and the underlying recombination processes taking place at universities. There are two main conclusions that can be drawn from this analysis that can help pave the way for future research into the thematic dynamics of mobile researchers. First, universities seem to generally attract new researchers who continue to work in the same areas of the native researchers. Second, there is some relationship between the breadth of topics a university is already developing, and the ability of newcomers to substantially differentiate the profile of their new universities. In more generalist universities the potential effect of newcomers on the breadth of topics at the universities is lower, while the role of newcomers in differentiating the university profile seems more possible in specialized universities.

The two conclusions above point to some preliminary recommendations in the study of how mobile researchers could influence the thematic profile of their receiving universities: 1) the approach proposed here is more relevant to smaller and specialized universities (e.g. technical universities, medical schools, etc.), where a greater diversity in the (dis)similarities between the profiles of newcomers and natives in these universities is observed, therefore opening the possibility to analyse in which cases newcomers play a more relevant role to enlarge or differentiate the original thematic profile of their new institutions; 2) for generalist universities, it is more advisable to study them breakdown by thematically focused units (e.g. departments, faculties, institutes or research groups), instead of studying them as a whole, since only then it would be possible to assess the potential role of mobile researchers to transform, or give continuation, to the thematic profiles of the units.

It is important to highlight some of the limitations of our current study. There are two elements that will need to be further explored in future research. First, we study the output of the university once the newcomers have already joined the university, but we do not compare it with the previous thematic profiles of the newcomers. It may just be that newcomers will adapt their publishing and scientific interests to their new institutions. That is, newcomers simply ‘do in Rome what the Romans do’. Another possibility is that there may be a general tendency for universities to hire researchers with similar capabilities to their current knowledge base, or that researchers prefer to move to universities established in their own research areas. Neither of these two elements is directly measured in this paper but rather we point out the possible existence of *adaptation* and/or *homophily* mechanisms based on this preliminary evidence. We plan to address these mechanisms in the future by measuring the similarities between newcomers and natives before newcomers acquire their new affiliations. The aim is to systematically determine whether mobile researchers have already worked on the topics of their new universities, or whether they have adapted their profiles after they have moved. This could provide policy makers with advanced analytical tools to unveil the latent thematic capacity of newcomers as well as to assess the ability of newcomers to influence (or not) the thematic profile of their institutions. Such information has the potential to support and evaluate university (and its units) policies on their mobility, recruitment, and talent attraction strategies, particularly in relation to their thematic profiling.

Finally, we have not yet explored the role of collaboration in our analysis, as collaboration can be the most common approach for newcomers and natives to converge on their thematic profiles. Thus, it may very well be that newcomers influence natives to work together in the new topics they bring (Ganguli, 2015; Stephan & Levin, 2001), or vice versa; but if the level of collaboration is high between natives and newcomers, the thematic differences between would also be small. In future research we will therefore also account for the effect of collaboration in our analysis.

Abstract

Software Engineering is a 52 years vast field of knowledge. Along the time, a massive quantity of techniques, methods, and tools have been proposed by a vast academic and industrial community, involving a large spectrum of subjects. Aiming to compile the body of knowledge of Software Engineering, we created "The Software Engineering Observatory Portal". The portal allows analyzing software engineering evolution and researchers' contributions through data visualization. So far, the portal relies on data of the International Conference on Software Engineering (ICSE) and IEEE Transactions of Software Engineering (TSE), the premier venues in the area. A video explaining the usage of the portal is available at **https://youtu.be/57Y80z9ymVw**. The portal is available at **https://mivianferreira.github.io/docs/TheSoftwareEngineeringObservatoryPortal**/.

Introduction

Over the five decades of Software Engineering, a great deal of knowledge was produced. Some initiatives have been done to compile knowledge about Software Engineering and its evolution. An essential contribution in this context is the Guide to the Software Engineering Body of Knowledge (SWEBOK) of the IEEE Computer Society (Bourque et al., 2002; IEEE Computer Society et al., 2014). In a lecture at ICSE 2018, Briand Radell, the president of the NATO Software Engineering Conference (1968-1968), highlighted the importance of knowing Software Engineering history. He made a five-decade retrospective of the area and declared: "So I hope you'll forgive me for choosing to focus primarily on historical issues, but I hope these observations encourage at least some of you to pay a little more attention to the past". Besides knowing the past, it is essential to analyze the evolution of an area of human knowledge, including Software Engineering. Such analysis may aid in answering questions such as: *What subjects the academic community has mostly considered? How much effort has been made in research on such subjects? Which papers have been most cited by researchers? Who are the researchers that have extensively contributed to Software Engineering advances? Which subjects have been mainly investigated currently?*

We constructed a web-based tool called "The Software Engineering Observatory Portal" that aims to provide resources for Software Engineering evolution analysis through data visualization. So far, we based the portal on works published in the premier Software Engineering venues: the International Conference of Software Engineering (ICSE) and the IEEE Transactions on Software Engineering journal (TSE). We retrieved data of research papers published in Transactions on Software Engineering from 1975 to 2018, accomplishing 3,357 papers. From ICSE, we gathered data of papers published from 1988, the first year IEEE Xplorer provides data of the conference, to 2018. As far as we know, this is the first initiative to compile historical data on Software Engineering with data visualization techniques. The audience of "The Software Engineering Observatory Portal" is the Software Engineering community as a whole. The portal may grow in many ways, such as: by providing other kinds of data visualizations, by considering data from other venues, and by providing updated data. Besides, the portal may be extended to other areas since the interest on investigating academic research status is global (Ioannidis et al., 2020). A video explaining the usage of the portal is available at **https://youtu.be/57Y80z9ymVw**. The portal is available at **https://mivianferreira.github.io/docs/TheSoftwareEngineeringObservatoryPortal**/.

This paper presents "The Software Engineering Observatory Portal", its main features and its construction. Moreover, this article details how the data were retrieved, describes and exemplifies the visualizations provided by the portal, and presents the conclusion of the work.

Method

We built the database applied in portal by retrieving the metadata of ICSE (data from 1988 to 2017) and TSE (1975-2017) documents. To do so, we constructed a web crawler. We collected only documents available in the IEEE Xplorer digital library, as this library presents a complete metadata structure about ICSE and TSE documents. To include a document returned by the crawler in the database, we used the following criteria: full articles, short papers, research in progress, and works available in electronic format. We carried out the exclusion of documents from the database according to the following criteria: tutorials, panels, lectures, and keynote talks; call for workshops and symposium; proceedings and round tables; presentation of sessions and tracks. We stored the collected data in a CSV file that has the following fields: title of the work; name of the authors (separated by semicolons); affiliation of the authors (separated by semicolons); year of publication; the number of downloads; keywords of the authors; keywords IEEE, NON-INSPEC or INSPEC; publication venue (ICSE or TSE).

Data Pre-processing

After retrieving the documents, we performed a pre-processing stage of the data. At this stage, we carried out the following steps:

1. Data pre-processing: we removed the documents that met the exclusion criteria and mined the keywords not returned by the web crawler. To do so, we performed a manual inspection of the articles.

2. Keywords standardization: in this step, we performed a manual inspection of the data and joining keywords with the same semantic meaning as a single keyword. This step is important because the keywords are used in the portal to classify the subjects investigated by each work. Not performing this step will introduce bias in the data. We constructed a tool to automate this step.

3. Disambiguation of authors' names: the name of an author may appear in diverse ways in the papers. This step is essential to avoid introducing bias to the authors' data. We performed a semi-automatic disambiguation process by implementing scripts to pre-process the data. We intend to develop an automatic disambiguation process to make the portal update faster and less laborious.

4. Papers results classification: the portal provides visualization based on the kind of software engineering approach presented in the works. This step consisted of setting a category for each study by reading its abstract. We used the categories defined by Mary Shaw (Shawn, 2013) to classify the studies' results. The first and the second authors carried out this classification. After that, the results were discussed among the four authors to mitigate threats to this study. This process took a significant amount of time. Due to this, so far, the portal only provides such data for ICSE papers.

Visualization Techniques

We used D3.js, CanvasJS library, Javascript, and HTML to construct the portal. It provides five types of data visualization, described as follows.

- Data Table: we chose this visualization because it is considered the most appropriate to identify the most cited ICSE and TSE Engineering papers since their titles are usually long. Besides, we used the table to present other important data related to the articles, such as authors, number of citations, year of publication, and link to the article in the *IEEE Xplorer* database. The table is presented as a search engine, ordering (increasing and descending) of all fields, paging, and choice of entries viewed per page, ensuring a good usability.

- Dispersion Plot: we used the dispersion plot to show data of authors whose contributions have a significant impact. We consider that the author's contribution is determined by the number of citations of an author and the number of articles published by that author – thus establishing the need to use the dispersion plot. To determine the authors whose contributions have a high impact, we represented each author by a circle, whose area is proportional to the number of citations, i.e., the greater the number of citations of an author, the greater the circle's size. The x and y axes represent the number of citations of an author and the number of articles published by an author. To facilitate the visualization of the data, we subdivided the authors into three categories: All, with all authors; Top-10, with only the ten authors with the highest number of citations; and Top-100, with the 100 authors with the highest number of citations. Besides, there is a tool-tip in each of the circles where we displayed the author's name, number of citations, and articles.

- Keywords Cloud: this visualization shows a cloud with the subjects investigated in the area. In this cloud, the larger the font size of a keyword label, the larger the number of works considering the related subject. This visualization allows researching keywords according to a time frame chosen by the user. For instance, the user may want to see the cloud of works published from 2015 to 2018. When the user move the cursor on the word, the portal shows the corresponding number of papers. Hence, when the user clicks the word, the portal shows a data table with all the works in which the chosen keyword appears.

- Overlapping areas: we used this visualization to show the amount of research done on the top subjects that have been investigated in Software Engineering. In this visualization, each layer represents a keyword. The x and y axes represent the years used for data analysis and the number of occurrences of the keywords, respectively.

- Pareto Chart: we developed this visualization with CanvasJS. The portal provides a Pareto's (80/20) chart of the following data: number of citations/article, number of citations/author, and number of articles/author.

Results

In this section, we exemplify the use of "The Software Engineering Observatory Portal".

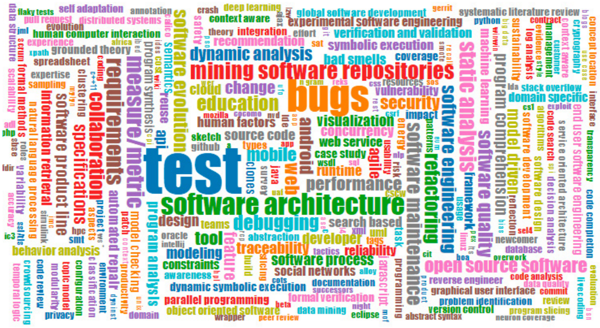

Figure 1. Keywords cloud of ICSE with data from 2015 to 2018.

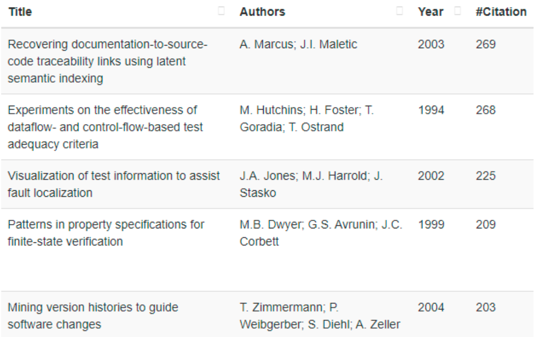
The most investigated subjects in a given period.
The user selects the range of years and the portal shows the most investigated subjects in a keyword cloud. Figure 1 shows the keywords cloud of 1988 until 1990.

The most cited papers
The number of citations of a paper is an indicator of its relevance. The portal provides a table with data of the publications, including the number of citations. Figure 2 shows an example of this table.



Title	Authors	Year	#Citation
Recovering documentation-to-source-code traceability links using latent semantic indexing	A. Marcus; J.I. Maletic	2003	269
Experiments on the effectiveness of dataflow- and control-flow-based test adequacy criteria	M. Hutchins; H. Foster; T. Goradia; T. Ostrand	1994	268
Visualization of test information to assist fault localization	J.A. Jones; M.J. Harrold; J. Stasko	2002	225
Patterns in property specifications for finite-state verification	M.B. Dwyer; G.S. Avrunin; J.C. Corbett	1999	209
Mining version histories to guide software changes	T. Zimmermann; P. Weibgerber; S. Diehl; A. Zeller	2004	203

Figure 2. Table with the data of the most cited ICSE papers.

The researchers that have mainly contributed to Software Engineering advance. The portal provides visualizations of data about the number of articles and the number of citations by author. The visualization is a Dispersion plot, as shown in Figure 3. Figure 4 shows the Pareto chart of citations per article of ICSE. When the user moves the mouse over the curve, the portal shows the cumulative number of articles corresponding to the percentage of citations.

The most investigated subjects along with Software Engineering evolution. The 11 most researched topics in ICSE were: test (236 occurrences); bugs (147 occurrences); software architecture (132 occurrences); measure/metric (87 occurrences); requirements (85 occurrences); education (74 occurrences); empirical study (59 occurrences); software quality (56 occurrences); software process (54 occurrences); software engineering (53 occurrences); and reuse (52 occurrences). We used an overlapping areas chart to show the evolution of the number of studies on those subjects. Figure 5 shows the chart for ICSE.

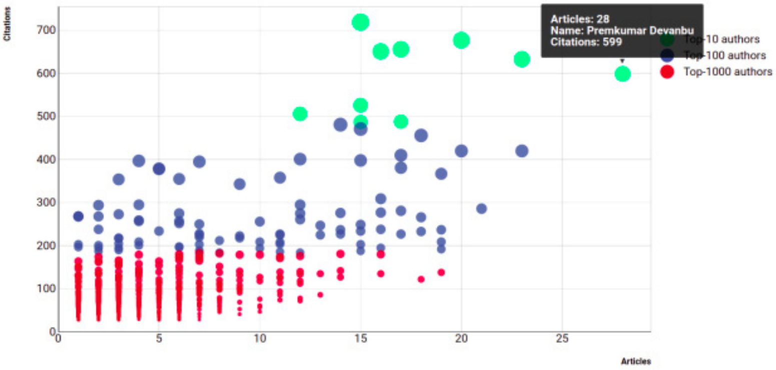


Figure 3. Dispersion plot with data of the 1000 most cited ICSE papers.

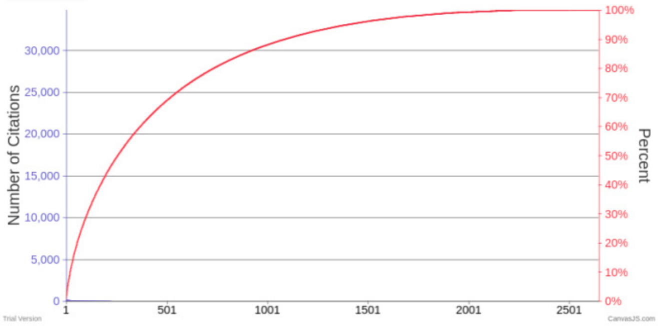

Figure 4. Pareto chart with number of citations of ICSE papers.

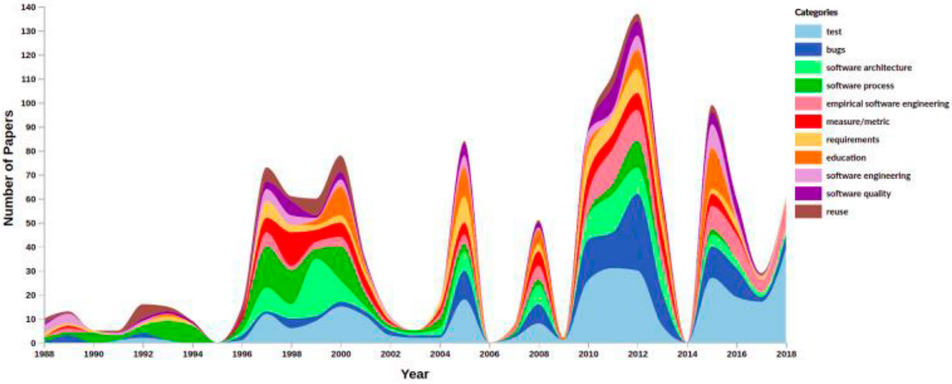

Figure 5. Overlapping area showing the evolution of number of papers considering the top-10 most investigated topics - data of ICSE.

Related Work

Visualization is a powerful resource to aid bibliometrics analysis. The study of Muñoz et al. (2020) shows that there are many tools for this purpose. The main difference between those tools and our portal is that the portal is an on-line and interactive tool containing pre-processed data of an specific area, Software Engineering. Besides, the visualizations resources provided by the portal are also different. Liao et al. (2018) used data visualization charts, such as co-authorship networks and keywords density map, to analyze bibliometrics data in Medicine. The visualization they used are different from the ones we applied. Moreover, they did not construct a portal as we did. Other initiatives have been taken to compile the body of knowledge on Software Engineering, such as the SWEBOK (Bourque et al., 2002; IEEE Computer Society et al., 2014) and Boehm's work (Boehm, 2006). However, as far as we know, this work is the first one that compiles Software Engineering historical data by applying visualization techniques. We used the Overlapping Area chart in our work on Software Engineering evolution considering ICSE data (Sousa et al., 2019).

Conclusions

This paper presents a web-based tool called "The Software Engineering Observatory Portal" that provides resources for analyzing the evolution of Software Engineering, as well as data of contributions, number of citations, and subjects primarily investigated in the area. The portal applies data visualization and relies on papers publishes in ICSE and TSE, the premier software engineering discussion forums. The analysis provided by the portal is of interest to the Software Engineering community as a whole, especially the academia. As part of the pre-processing data was done manually and it is exceptionally laborious, we are developing an automatic tool to construct a thesaurus of Software Engineering and adapting the gathering data process to the new structure of IEEE Xplorer. Besides, we are investigating a proper approach to disambiguate authors' names. We believe that the portal could be applied to other Computer Science disciplines whose publications are available in IEEE Xplorer.

Abstract

One of the challenges in the sociology of science is to increase our ability to describe and analyze the epistemic effects of research governance. One reason for our current limitations in doing so is an epistemic divide between different fields that study (parts of) this question. Science policy studies focus on developments in research governance but lack interest in its epistemic effects. Studies of epistemic properties of research often lack interest in the institutional environment in which research is conducted. Moreover, scientometric methods are not often combined with qualitative methodologies. This lack of mixing methods hampers progress because for the study of the epistemic effects of research governance it is often necessary to employ a range of methods at the same time. This research-in-progress paper reports on an in-depth study of a biomedical research school in the Netherlands. Over the last 20 years, spurred on by science policy and external evaluations, the school has attempted to bring about more integration in its research program. We aim to offer a mixed-method approach that can be used to advance the sociology of science its ability to trace epistemic effects of attempts to steer research content in public research organizations.

Introduction

One of the challenges in the sociology of science is in the limited ability we currently have to describe and analyze the epistemic effects of research governance. One reason for this is the split between fields that study parts of this question. Science policy studies analyze the dynamics of research governance but do not study its epistemic effects. Fields in which the epistemic properties of research are central, notably science and technology studies, often lack interest in the institutional environment in which research is conducted (Gläser & Laudel, 2016).

The methodological divide that emerged in the 1980s (Wyatt et al., 2017) between those that employ quantitative methodologies and those that employ qualitative methodologies makes solving this all the more difficult. This methodological divide hampers progress because for the study of the epistemic effects of research governance it is necessary to employ a range of methods at the same time. In recent years, there is a renewed interest in the integration of perspectives and methods (e.g. see Wallace and Rafols, 2018) and we aim to contribute to this research agenda.

Our substantive interest in this paper is the epistemic effects of research governance within public research organizations. Public research organizations have increased their strategic capacity (Thoenig & Paradeise, 2016) in response to changes in science systems that introduced new external pressures and demands. One way in which research governance takes place within public research organizations is through the development and implementation of strategic goals. The advantage of focusing on the epistemic effects of strategic goals is that these are well documented in, for instance, self-evaluation documents and mission statements. They can also be discussed with staff and management in interviews. We regard the analysis of the implementation of strategic goals in public research organizations as interesting test cases to establish new connections between sociological concepts used to describe epistemic effects and bibliometric measures used to operationalize these concepts (Gläser & Laudel, 2001).

In this research-in-progress paper we present an ongoing in-depth study of research governance in a single biomedical research school in the Netherlands. We draw on documents, in particular those written in the context of three external evaluations conducted in the time span of 20 years, have gathered publication data which was validated by the research school itself, and are doing interviews with staff members and the management team of the research school. Drawing on this variety of sources allows us to develop links, in a systematic way, between epistemic changes in the research conducted at the research school and the steering mechanisms employed by the management team of the research school to implement its strategic goals.

Our approach involves three steps. In the first step we analyze the strategic goals at the level of the research school over time. The second step consists of an analysis of changes in the research content of research conducted employing bibliometric methods. Here we seek to test the hypotheses formulated in step one and employ a range of bibliometric methods understood as 'partial indicators' (Martin & Irvine, 1983) in search of the expected effect. The third step, is to unpack the mechanisms that produced the epistemic effect found bibliometrically. This step consists of identifying the steering mechanisms employed in the research school from interviews and document analysis and, where possible, relate them to the epistemic changes observed with bibliometrics.

Case description: Strategic goals of a biomedical research school

The biomedical research school we study was established in the 1980s and soon rose to a prominent position, nationally and internationally, in its subfield. The school is comprised of three research units that themselves consist of principal investigators (PIs) groups. Each unit contains somewhere between 5 and 10 PI-groups, but the number of groups changes over time.

An important external pressure that drives organizational change in the research school is the Dutch research evaluation cycle. Every 6 years a research evaluation is conducted by an external review committee which is followed by a mid-term evaluation 3 years on and preceded by a self-evaluation the outcome of which is send to the external review committee as a preparation. Conducting the evaluation is mandatory for all research schools and departments in Dutch public research organizations. The evaluation report is usually basis for discussion between a management team of a school or department and senior level management at the university (for instance the dean of the faculty).

Conducting the self-evaluation increases the need for strategic capacity within the research school. Similarly, the external evaluation and its cyclical nature increases the need to reflect on and act on the outcomes of the evaluation and report on these actions and their results in the subsequent evaluation. It thus pushes a management team to continuously change (or improve) the organization by, for instance, establishing new strategic goals and a strategic agenda, new organizational processes and so on. As an example, consider the following quote from the introduction to the self-evaluation report of the period 1999-2006:

> "The advise of the ERC [External Review Committee, TF] is seen as a major tool for the Board and Management of [research school] to sustain and improve the quality of their research and education programs and to give foundation to strategic decision-making procedures. (…) [W]e have chosen to describe our strategic goals for the next 5 years and hope that the External Research Committee will give us feedback that will help us to further improve and clarify our strategy." (self-evaluation report 1999-2006)

The biomedical research school we study went through three evaluations in the last 20 years (evaluations of the periods 1999-2006, 2007-2012, 2013-2018). A constant factor in these evaluation reports is reflection on the coherence of the research profile of the school. The research in the school covers all main topics concerning the biomedical subfield it is part of and argues this diversity makes it unique. Yet it also aims to achieve coherence. This is discussed both at the level of each research unit (that individually have to be coherent) as well as across the research units. In the first evaluation report we can read that one of the strategic goals is 'To maintain a strong and coherent research program'. Later on in the document this goal is expanded upon:

> A recent change is that all three [research units] have defined their research programs around larger (sub) themes, further strengthening the coherence of the research and increasing the critical mass, in line with the research strategy of the Faculty and the research strategy 'Focus and Mass' of the KNAW [Royal Dutch Academy of Sciences, TF]. (self-evaluation report 1999-2006)

As the quote shows, the school's strategic goal for a coherent research program is implemented through the development of larger subthemes, composed of PI-groups, within the three research units. The strategy is legitimated by connecting it to the notion of critical mass which is one of the pillars of Dutch science policy since the 1980s (e.g. See Franssen, 2020). This organizational development was continued over the next 13 years and in the last evaluation, concerning the period 2013-2018 the structure of the research school is discussed again. The self-evaluation describes the research units as well governed and interconnected (both internally and between them) entities:

> All three [units] involve basic as well as clinical programmes and are led according to a shared governance principles (…) executed by the [unit] leader together with one or more basic and clinical scientists from the [Unit]. This shared governance system enables shared responsibility for the scientific progress of programmes, for linking activities and seeking collaborations between PIs and [units] (…) Due to the increasingly complex and multidisciplinary [biomedical subfield] research objectives, [research school's] new structure facilitates much needed inter[unital] and translational research. (self-evaluation report 2013-2018)

As this quote shows the biomedical problems the school is focused on require different disciplinary knowledges to be connected. The need for connectivity is stressed by pointing to collaboration across units and between basic and clinical research. In the evaluation report this self-evaluation is however criticized for not describing how coordination and collaboration are organized between the research units. The evaluation argues for this to be developed further:

> In the self-evaluation report there is only a sparse description of how – and by which means – the coordination and collaboration between [units] – [unit 1], [unit 2] and [unit 3] - takes place. During the site-visit it was described that the Executive Boards meet on a monthly basis, however, a more detailed description of how collaboration between the three [units] are facilitated by the Executive Board is needed, both strategically and on a daily basis. (evaluation report 2013-2018)

What is alluded to in these evaluation reports is, we argue, a concern with increasing knowledge integration both within each of the three research units as well as across these research units. The concept of integration has a long history in science studies and has primarily been studied in relation to integration of scientific communities (Gläser & Laudel 2001). In our case knowledge integration is a policy goal (see Luukkonen & Nedeva, 2010) within a public research organization in order to develop a more coherent research profile. As a first step, in this work-in-progress proceeding, we propose two hypotheses and their operationalization, to analyze the implementation of this strategic goal:

Hypothesis one: diversity within research units goes down due to the increase in integration of the research program of each research unit.

> This hypothesis is tested through measuring the cognitive diversity within research units, operationalised as a diversity measure of the distribution of publications in each research unit across micro clusters.

Hypothesis two: diversity between research units goes down due to increased integration between research units.

> This hypothesis is tested through measuring cognitive similarity between units, as shown by topics of publications and referencing practices. This is operationalised in two measures:
>
> - Cosine similiarity of the microclusters of publications between research units.
> - Cosine similiarity of references of publications between research units.

Using these indicators, we find evidence of the dynamics of integration between research units. This data will be combined with insights from interviews and documents to explain the mechanism behind increasing knowledge integration within the public research organization.

Data and Methods

We have composed a dataset of all publications of the staff of the research school between 2000 and 2019 which was validated by the administrative personal of the university medical center to which the research school belongs. We have subsequently divided the publications into three periods in line with the evaluation cycles that the school underwent, 2001-2006, 2007-2012, 2013-2019.

These publications were linked to CWTS in-house version of Web of Science. Each publication in the Web of Science is assigned to a cluster using the CWTS article-level algorithm (Waltman & van Eck, 2012). At the lowest level of granularity it consists of some 4000 microclusters. For each publication from the research school the microcluster it belongs to was determined, much like one would use the Web of Science journal categories. An upside to using the microclusters is that these are based on citation links between papers rather than journal-based. Moreover, we circumvent the category 'multidisicplinary journals' which is hard to interpret and holds many publications of the research school especially in the third period.

To assess cognitive diversity within a unit, we use conventional indicators of diversity (variety, Shannon entropy, and Shannon evenness), as explained in detail in Rafols et al. (2012). The cosine similarity is used to assess the degree of similarity between vectors representing different units, where a vector per unit describes, the number of publications of a unit across clusters. This indicator is repeated using a vector where each dimension is a reference with the number of times a reference is cited by paper. The relative similarity due to collaborations is computed as the similarity between units including co-authored papers between units minus the similarity without co-authorships, divided by the similarity between units with co-authorships.

Results

Hypothesis 1: Cognitive diversity within units

We use number of microclusters (variety) and Shannon as measures of the diversity of topics to which publications belong. Given that the number of publications is increasing, we also compute Shannon diversity to measure the balance of topics. Against expectations of integration, we find that the measures of diversity increase, whereas the measure of balance is stable since the second period. These results shows that topical diversity within research units is not reduced as a consequence of a strategic decision to increase coherence. In the next step of this paper we will use other measures of integration, such as bibliographic coupling between PI-groups within research units, to assess the extent to which the implementation of strategic goals has led to an increase in integration without affecting diversity as measured through microclusters here.

Table 1. Diversity measures: Number of microclusters, Shannon entropy and Shannon evenness.

Variety (number of microclusters)	**2001-2006**	**2007-2012**	**2013-2019**
Research unit 1	185	232	288
Research unit 2	81	133	186
Research unit 3	311	404	412
Shannon entropy			
Research unit 1	4.21	4.53	4.50
Research unit 2	3.24	3.86	4.11
Research unit 3	4.87	5.29	5.23
Shannon evenness			
Research unit 1	0.81	0.83	0.79
Research unit 2	0.74	0.79	0.79
Research unit 3	0.85	0.88	0.87

Hypothesis 2: Cognitive similarity between units
In order to estimate the similarity in the research content across the three research units, we compare the distribution of their publications across the microclusters. The analysis shows (table 2) that there is an increasing degree of similarity between the three units in terms of microclusters. This result is confirmed using references as units for comparison (table 3). This suggests that the strategic goal to increase integration between research units has been successful. But what mechanism might have been used to foster integration?

Table 2. Cognitive similarity according to micro cluster distribution

All publications in units	**2001-2006**	**2007-2012**	**2013-2019**
Research units 1-2	0.05	0.07	0.13
Research units 1-3	0.12	0.21	0.25
Research units 2-3	0.07	0.21	0.24
Without collaborations between units			
Research units 1-2	0.04	0.03	0.08
Research units 1-3	0.11	0.09	0.08
Research units 2-3	0.07	0.09	0.10
Relative similarity due to collaborations			
Research units 1-2	10%	61%	36%
Research units 1-3	9%	55%	70%
Research units 2-3	5%	57%	56%

One possible explanation is increased collaboration, in terms of co-authorship, between research units. Co-authorships between units increase from 2% of the total in the first period to 18% in the second period to 23% in the third period. Publications shared between units increase similarity of the research profile of the three units. In table 2 and 3 we have included the same measures of cognitive similarity taking out all papers that were collaboration betweens research units (and thus present in as publications in both sets of publications). We also measure the ratio to which cognitive similarity can be ascribed to these collaborations. This shows that in the second and third period a large part of cognitive similarity, especially when measured through reference similarity, can be assigned to collaborations. Looking at microclusters a large part of cognitive similarity is also due to collaboration but overall 40% or more percent cannot be attributed to collaboration. Using these two indicators for cognitive similarity shows that while the point in the same direction, they measure cognitive similarity in a slightly different way.

Table 3. Cognitive similarity according to references

All publications in units	**2001-2006**	**2007-2012**	**2013-2019**
Research units 1-2	0.028	0.067	0.121
Research units 1-3	0.062	0.157	0.218
Research units 2-3	0.041	0.205	0.226
Without collaborations between units			
Research units 1-2	0.021	0.009	0.037
Research units 1-3	0.050	0.041	0.050
Research units 2-3	0.037	0.047	0.053
Relative similarity due to collaborations			
Research units 1-2	25%	87%	70%
Research units 1-3	18%	74%	77%
Research units 2-3	9%	77%	77%

Conclusion

This proceeding aims to illustrate how bibliometrics can show the epistemic changes produced by strategic decisions in research management with an example from a biomedical school. These initial results point to collaboration in publications as an important mechanism for increased knowledge integration in the research school. We will therefore extent our analysis of collaboration, using both qualitative and quantitative data and methods to understand who is collaborating with whom and why these researchers are more prone to collaborate in period 2 and 3.

Using Citation Bias to Guide Better Sampling of Scientific Literature

Yuanxi Fu, Jasmine Yuan and Jodi Schneider

University of Illinois at Urbana-Champaign, School of Information Sciences, 501 E Daniel St, Champaign, IL 61820 (USA)

Abstract

It is rarely possible to cite every relevant work on a topic. When controversy exists in a field, work holding the same opinion as the citing paper (i.e., homophily) is more likely to be cited. Thus, readers may inadvertently select a non-representative sample of articles to read. Here, we begin to develop a method that guides better sampling of scientific literature by designing and testing two new network metrics. The first metric, the ratio between real and expected citation counts, guides users to papers that were cited many fewer times than expected and may represent marginalized findings. The second metric, the relative evidence coupling strength, guides users to papers that may present a unique view of the field. We test our metrics on a known case of citation bias: a network of 73 papers about whether stress is a risk factor for depression. Our metrics select a cross-section of 21 papers. The intersection of the two metrics selects 3 papers that represent all 3 positions of this claim network. In future work we will test our metrics on more datasets, and we will partner with domain experts to verify whether our metrics do identify a diverse sample of research articles.

Introduction

Authors must make choices when citing related work: it is rarely possible to cite every relevant article on a topic, and sometimes even identifying all relevant work is difficult. However, citation bias arises when "data critical of or refuting claims are systematically uncited in favour of data supporting a claim" (Greenberg, 2009). Studies have found that cited articles are more likely to report statistically significant results (Urlings, Duyx, Swaen, Bouter, & Zeegers, 2019b), outlier studies (Schrag, Mueller, Oyoyo, Smith, & Kirsch, 2011), or conclusions supportive of a hypothesis (Duyx, Urlings, Swaen, Bouter, & Zeegers, 2017; Urlings, Duyx, Swaen, Bouter, & Zeegers, 2019a). When controversy exists in a field, preference was given to articles holding the same opinion as the citing paper (i.e., homophily) (Trinquart, Johns, & Galea, 2016). Citation bias benefits authors by bolstering grants and papers, making them more easily accepted. However, it creates a "filter bubble" (Pariser, 2011) for people who want to use scientific literature as impartial evidence. For example, busy decision-makers only have time to read a few articles. They may end up inadvertently choosing articles belonging to a group of papers that reach the same findings. This selection of the literature gives the impression that there are no controversies on the given topic and that the evidence is well supported by many other papers.

This paper addresses an important challenge facing many literature users: how to sample diverse research articles. In this paper we propose a new sampling method, which uses insights from citation bias studies to design new network structure metrics to guide better sampling of the literature. First, we need to identify papers that get far fewer citations than chance permits, in case they are marginalized due to contradicting the dominant view of a field. Second, we need to identify papers that do not belong to any homophily group(s), because they may hold unique views towards the scientific question. Furthermore, the method should be accessible and intuitive, so that it can easily be adopted by a wide range of users. This paper reports our work in progress on developing such a method. First, we explain our current method, along with the design of two network structure metrics. Then we apply our method to a citation network. And finally, we discuss our plans for future work.

Data

To answer a specific scientific question, decision makers gather a body of literature relevant to some topic. This set of papers (nodes) and the citation relationships among them (directed edges) form a "claim-specific network," following Greenberg (2011). A claim-specific network is a subgraph of the entire citation network, since we omit all papers that do not concern a given topic (Greenberg, 2011). Thus, the papers (nodes) in a claim-specific network all address a single research question, for example, whether reducing salt intake brings health benefit at the population level, or whether stress is a risk factor for depression. Such a network captures the communication of ideas and the establishment of belief regarding a specific scientific question (Greenberg, 2011).

The dataset used here comes from a paper that analyzed citation bias in favor of positive findings (de Vries, Roest, Franzen, Munafò, & Bastiaansen, 2016). That study constructed a claim-specific citation network between 73 primary studies, all concerning risks of developing depression after stressful life events, associated with a gene known as 5-HTTLPR. Based on the outcome each primary study reported, 24 studies were coded as "Positive", 38 studies as "Negative", and 11 studies as "Unclear." The "Positive" articles received more citations than the "Negative" articles (de Vries et al., 2016).

Metrics

In this pilot study, we will use two metrics. The first metric is the **ratio between the real and expected citation count**, which measures whether a paper is sufficiently cited. Currently, we define the expected citation count as the number of citations a paper would receive if all papers in the network published *two years or more later* cited it. This ratio is designed to select papers that would be less prominent in a purely citation-based heuristic.

To compute the ratio between the real and expected citation count for the 5-HTTLPR claim-specific citation network, we constructed two networks. First, we reconstructed the real claim-specific citation network from the published dataset (de Vries & Munafò, 2016), which has 73 nodes and 488 edges. Second, we constructed a new, simulated network, in which the nodes are identical to those in the real network, while the edges are determined by the gap between the publication years of the two articles. To be more specific, if two papers are two or more years apart, we add a directional edge from the younger paper to the older paper. The resulting simulated network has 73 nodes and 1799 edges. Currently, we compute the expected citation count of a node as its in-degree in this simulated network.

The second metric resembles the relative bibliographic coupling strength (Sen & Gan, 1983; Shen, Zhu, Rousseau, Su, & Wang, 2019). The difference is that we limit to the items within the claim-specific network, rather than the whole bibliography: thus, in the name we replace "bibliographic" with "evidence". Specifically, we define the **"relative evidence coupling strength"** as

$$\text{RECS(X,Y)} = \frac{|E_X \cap E_Y|}{|E_X \cup E_Y|}$$

where E_X and E_Y represent the set of references for X and for Y in the claim-specific network. In other words, this metric characterizes the percentage of overlapping items (i.e., $E_X \cap E_Y$) in the collective evidence set (i.e., $E_X \cup E_Y$) between the pair of nodes. This metric is inspired by an observation we made in a study of disagreement between systematic reviews, in which we found that systematic reviews that synthesized different evidence sets reached different conclusions (Hsiao, Fu, & Schneider, 2020).

Although our two metrics were inspired by studies of citation bias, their ultimate utility is to help literature users sample a diversity of research articles. Users do not need to know whether a claim-specific network is biased or to what extent to make use of them.

Our script to construct the networks and compute the network metrics can be found in GitHub (https://github.com/infoqualitylab/citation_bias_study/tree/master/ISSI_2021).

Results

Figure 1(a) shows the distribution of our first metric, the ratio between the real and expected citation counts. Citations are quite unequal among those 73 papers. One paper, Caspi 2003, received 97% of its expected citation counts, whereas 16 papers (22%) (colored in pink in Figure 2) received less than 10% of their expected citation counts. Since they were cited many fewer times than expected, those 16 papers need more attention from readers, in case they represent a marginalized view of the topic. Also, 18 papers were published in the last two years covered in the datasets (2011 and 2012), and under our current construction, their expected citation counts are zero, and therefore do not have a value for this metric. Those papers are colored white in Figure 2.

We computed the relative evidence coupling strength for each of the 2628 pairs. Figure 1(b) shows the distribution of this metric. Forty-nine pairs (1.9%) shared more than 90% of their collective evidence set and 818 pairs (31%) shared less than 10% of their collective evidence set. Since a single paper can be involved in 72 pairs, it is quite common for a paper to find another paper in the dataset with which its relative evidence coupling strength is small. What we need to pay attention to are papers that *always* have a small relative evidence coupling strength with other papers. Those are what we call "unique" papers, as they may represent unique views of the field (i.e., looking at a different set of evidence). Currently, we set an arbitrary threshold of 0.3 and found 8 papers that never participated in any pair with relative evidence coupling strength more than 0.3. Those papers are colored in pink in Figure 3 and they should be sampled too.

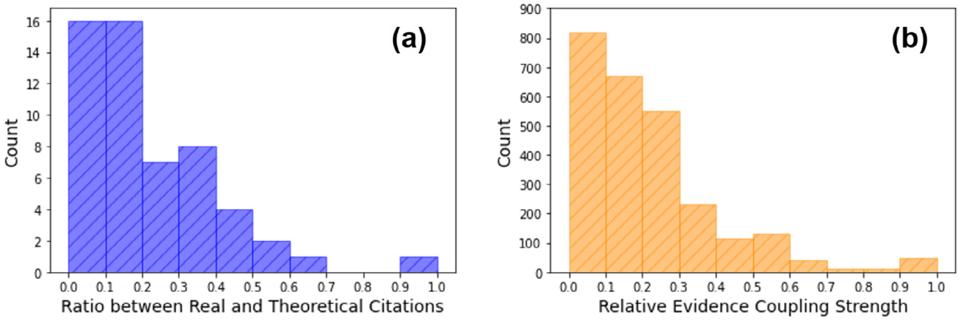

Figure 1. The distribution of the ratio between (a) the real and expected citation counts and (b) the relative evidence coupling strength for the 5-HTTLPR network

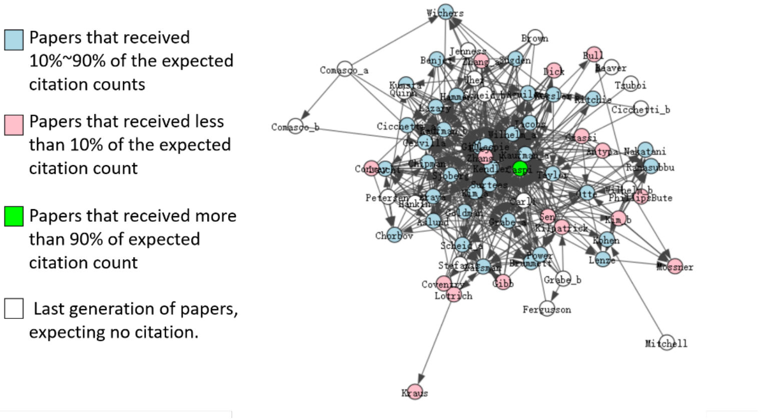

Figure 2. The ratio between real and expected citation count applied to the HTTLPR-5 network

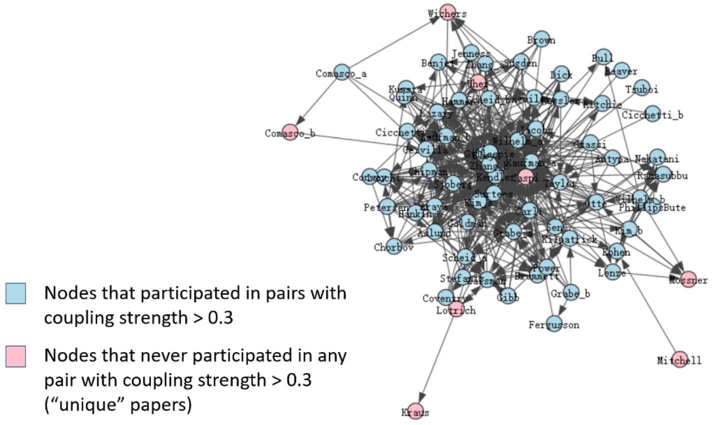

Figure 3. Relative evidence coupling strength applied to the HTTLPR-5 network

Our two metrics select different articles. As shown in Table 1, there are just 3 overlaps. Interestingly, each group selects papers with all 3 available outcomes (Positive, Negative, Unclear) – and the group selected by the intersection of the two metrics does this in just 3 papers, the minimum possible. Notably, there is only a 16.1% chance for a randomly selected set of three papers to cover all three outcomes. This finding suggests that these metrics are promising for further exploration, because the intersection included three papers with different outcomes, meeting our intention to select a diverse set of papers for readers to read.

Table 1. Papers selected by the two network metrics

Conclusions and Future Works

In conclusion, we proposed a method that may help users who need to select diverse papers to read to assist in their decision making. We designed two metrics inspired by previous studies of citation bias: First, the ratio between the real and expected citations identifies papers that received far fewer citations than expected, which may represent marginalized views. Second, the relative evidence coupling strength identifies papers with unique views towards a topic. We applied these metrics to a previously citation network of 73 research articles studying whether a gene increases the risk of depression after stressful events. Our sampling method resulted in partitioning the network into two groups: 21 papers that readers need to pay particular attention to, and 52 articles from which readers can choose a few to read.

Our current method has known limitations and needs evaluation and improvement in the future. First, the current expected citation count is in effect a maximum citation count (assuming a delay between publication and citation). Some of the later published papers were expected to cite as many as 55 papers, which is unrealistic and inflated the expected citation counts for other papers. Second, the relative evidence coupling strength also has low values among paper pairs whose publication years are far apart, and the method we are using now (i.e., selecting nodes that never participated in any pair with relative evidence coupling strength above a threshold value) over-selects early papers, which have a diminished chance to share reference items with papers published later.

For future work, our priority is to find domain experts to evaluate the two sets of papers and see whether the selected papers fit our expectations. Second, we need to evolve the metrics. We plan to create better algorithms to for computing more realistic expected citation counts. And we will also filter out papers selected purely due to their age. The visualization should be improved too, making it more interactive and informative. We envision an interface that allows users to zoom into one part of the network and click on a node to find information about a paper (e.g., title, DOI). Finally, the utility of our methods will need to be verified with larger-scale studies. We plan to use both published claim-specific networks (e.g., Duyx et al., 2019; Trinquart et al., 2016; Urlings et al., 2019a; Urlings et al., 2019b) as well as our own datasets constructed in collaboration with domain experts. We are currenting working with a kinesiology and community health expert and have constructed a claim-specific citation network with 439 articles relating to the effectiveness of exercise therapy for treating depression. This is larger than any claim-specific citation network that we are aware of. Those datasets will provide a larger testbed for verifying whether our method is effective in helping readers obtain a diverse sample of research articles.

Acknowledgments

This research is supported by the Campus Research Board of the University of Illinois at Urbana-Champaign Grant RB21012. We acknowledge Dr. Ymkje Anna de Vries and Prof. Marcus Munafò for making their dataset available under the Non-Commercial Government Licence v2.0 and Zhonghe Wan for her assistance in statistical calculations.

Abstract

This paper presents a two-dimensional graphical mapping for institutional profiles of higher education entities (such as colleges and universities) in research, teaching, technology transfer, or internationalization. For the sake of simplicity, our illustrations focus on research profiles only. The new graphs embrace both the organizational field level and the organizational level. We illustrate how the new graphical representation improves existing ones, using examples from the German public university system.

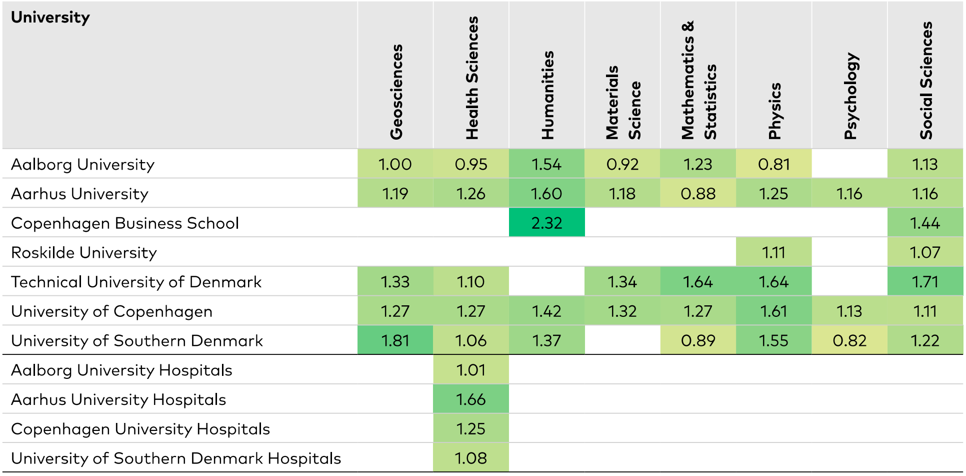
Introduction

Mapping profiles in higher education, especially with regard to research and teaching, has proliferated in recent years. Such mapping is done in the context of an increased attention to large-scale visualization of science and technology (Borner, Bueckle, & Ginda, 2019; Fortunato et al., 2018). One focus in this literature have been comparisons at the system level (van Vught, 2009). An example is Huisman, Lepori, Seeber, Frölich, and Scordato (2015) who classify 24 national higher education systems in Europe with regard to their degree of horizontal differentiation in research, teaching, technology transfer, and internationalization. Another example is Harzing and Giroud (2014) who identify top-3/bottom-3 research areas in 34 national higher education systems using the *Revealed Comparative Advantage (RCA)* measure. At the country level, Teixeira, Rocha, Biscaia, and Cardoso (2012) found for Portugal that private higher education entities have research profiles complementary to those of public entities, using the *Relative Specialization Index (RSI)*.

A second focus in the literature is on organizational fields in higher education (Brint et al., 2011; Ruef & Nag, 2015). A well-known comprehensive mapping of bibliometric profiles has been done for the Nordic universities (Piro et al. 2017; 2014). Here, the *RSI* is used for the comparison of field-related publication and citation percentages with respective global field percentages, highlighting those colleges and universities with either below-average, average, or above-average contributions. In addition, Bonaccorsi, Colombo, Guerini, and Rossi-Lamastra (2013), by means of the *Activity Index (AI)*, show for Italy that universities specialized in applied fields and engineering have a positive impact on start-ups in their region, especially in the service industries. In contrast, universities with a profile in basic science fields are related to a greater number of start-ups in manufacturing. More recently, teaching and research profiles of public universities in Germany were mapped, using both the *RSI* and a modified version of it, the *RESP* (details below), with longitudinal data on scientific staff, funding, bibliometric indicators, and student enrolment (Heinze, Tunger, Fuchs, Jappe, & Eberhardt, 2019).

Mapping institutional profiles typically involves graphical representations, often *heatmaps*, that are meant to display degrees of specialization. Consider the example in Figure 1. Such heatmaps depict specializations with a color-spectrum ranging from yellow to green (Piro et al. 2017; 2014). Although such heatmaps show whether a university has either a below-average or above-average profile in a research field, they do not display the size of the respective field in the university under consideration. In other words: although a university might be specialized in a particular field, such as Aarhus University in “humanities” (Figure 1), the heatmap does not provide information with respect to the size of the humanities compared to the 7 other fields in

Aarhus. Of course, this information could be provided in a separate table or graph, but this would make comparisons of large numbers of higher education entities rather complex.



University	Geosciences	Health Sciences	Humanities	Materials Science	Mathematics & Statistics	Physics	Psychology	Social Sciences
Aalborg University	1.00	0.95	1.54	0.92	1.23	0.81		1.13
Aarhus University	1.19	1.26	1.60	1.18	0.88	1.25	1.16	1.16
Copenhagen Business School			2.32					1.44
Roskilde University						1.11		1.07
Technical University of Denmark	1.33	1.10		1.34	1.64	1.64		1.71
University of Copenhagen	1.27	1.27	1.42	1.32	1.27	1.61	1.13	1.11
University of Southern Denmark	1.81	1.06	1.37		0.89	1.55	0.82	1.22
Aalborg University Hospitals		1.01						
Aarhus University Hospitals		1.66						
Copenhagen University Hospitals		1.25						
University of Southern Denmark Hospitals		1.08

Source: RSI scores for citation rates (2011-2014), Piro et al. (2017, p. 82).

This paper provides a new graphical representation that depicts both the specialization of a given higher education entity in a particular academic discipline (relative to all other relevant higher education entities) and its size within that entity. This new representation displays two types of information simultaneously. First, it shows whether a college or university either has a below-average, average, or above-average profile in a given research field. Second, it shows whether the research field is big, mid-size, or small compared to all other fields within that higher education entity. We provide examples from the German public university system, illustrating how the new graphical representation improves the existing one.

Data and Method

Our analysis builds on a dataset of 68 public universities in Germany, with information on scientific staff, basic funding, grant funding, publications, citations, and enrolment available for the years 1992-2018 (for details see Heinze et al., 2019). Based on these data, we calculated and then visualized institutional profiles, using both the RSI and the RESP. Results are available on the following website: https://fachprofile.uni-wuppertal.de/en.html. Both RSI and RESP are based on the aforementioned *Activity Index* (Narin, Carpenter, & Woolf, 1987). The *AI* captures the extent to which certain entities are specialized in certain activities (Formula 1). *AI* values lower 1.0 indicate a negative specialization (below-average scores), *AI* values greater 1.0 indicate a positive specialization (above-average).

Formula 1: General formula of the Activity Index (AI)

$$AI_{ij} := \frac{N_{ij}/\sum_i N_{ij}}{\sum_j N_{ij}/\sum_{ij} N_{ij}}$$

The AI's value range of [0.0,+∞] lacks an upper limit. Therefore, interpreting the RSI is easier than the AI due to its symmetrical value range of [−1.0,+1.0]: values lower 0.0 indicate negative specialization; values greater 0.0 indicate positive specialization. We use a modified version of the RSI that was introduced by (Grupp 1994; 1998). Its value range is [-100.0, +100.0] with an expected value of zero (Formula 2). We call this index RESP (for "Index of Relative Specialization"). It is based on the *hyperbolic tangent.* Consequently, its curve is steeper and reaches the upper limits of its value range more quickly than RSI.

Formula 2: Relative Specialization (RESP)

$$\mathrm{RESP} := 100\,\frac{\mathrm{AI}^2 - 1}{\mathrm{AI}^2 + 1}$$

Note: The subindices i and j of the AI are omitted for the sake of simplicity.

Consider Figure 2 as an example that displays RESP scores for Web of Science publications of the University of Aachen from 1995-2018. At least three results can be inferred from the heat-map. *First*, Aachen has an above-average publication profile in psychology in all years. *Second*, Aachen's publication profile in economics has shifted from above-average to below-average. *Third*, Aachen's publication profile in chemistry has changed from below-average to average. As mentioned above, Figure 2 does not display the size of disciplines at the University of Aachen: the color bars of psychology, economics, chemistry are all of the same size. However, in reality, the three disciplines have very different publication outputs – and this is true also for other indicators, such as professorial staff or funding. As shown in Figure 3, Aachen's largest discipline in terms of publications is physics/astronomy ("Physik, Astronomie"), its bar has maximum size. All other disciplines are measured relative to it. For example, chemistry is smaller than physics/ astronomy but larger than psychology or economics. In other words: specialization in psychology requires a much smaller number of publications compared to physics/astronomy. As Figure 3 shows, physics/astronomy has most publications in Aachen, but their number is not as high as to constitute a particularly strong specialization in this discipline: its scores are yellow, meaning Aachen's number of physics publications are on average, compared to all other (here: technical) universities with publications in this discipline. The different bar sizes of disciplines in Figure 3 are based on Formula 3 for a given year. A university's largest discipline has bar size =1, because the enumerator equals the denominator, whereas all other disciplines have a bar size relative to the largest discipline. In Aachen, as mentioned, the largest discipline with regard to publications is physics/astronomy. The three other above-mentioned disciplines have the following bar sizes [min, max] between 1995 and 2018: chemistry [0,367; 0,830]; psychology [0,024; 0,140]; economics [0,010; 0,032]. All annual values are placed in the middle of the bar, and adjacent bars are connected using a natural cubic spline interpolation which has the effect of smoothening the bar graph.

Formula 3: Bar size calculation in Figures 3-5

$$\text{Bar size} := \frac{\text{Publications of University i in Discipline j}}{max_j\ \text{(Publications of University i in Discipline j)}}$$

Results

Figure 3 constitutes an improvement compared to Figure 2 because it allows to simultaneously evaluate both disciplinary specialization (measured at the organizational field level) and size of disciplines (measured at the organizational level). What are possible conclusions? *First*, Figure 3 depicts disciplines that have been for a long time below-average (geosciences) or have become so (economics, mathematics). *Second*, these three disciplines are marginal in terms of overall publication output; here four disciplines dominate: physics/astronomy, chemistry, mechanical and process engineering, and biology. *Third*, Aachen's increasing specialization in chemistry has been the result of a considerable growth in publications, relative to the discipline with most publications over time (physics/astronomy).

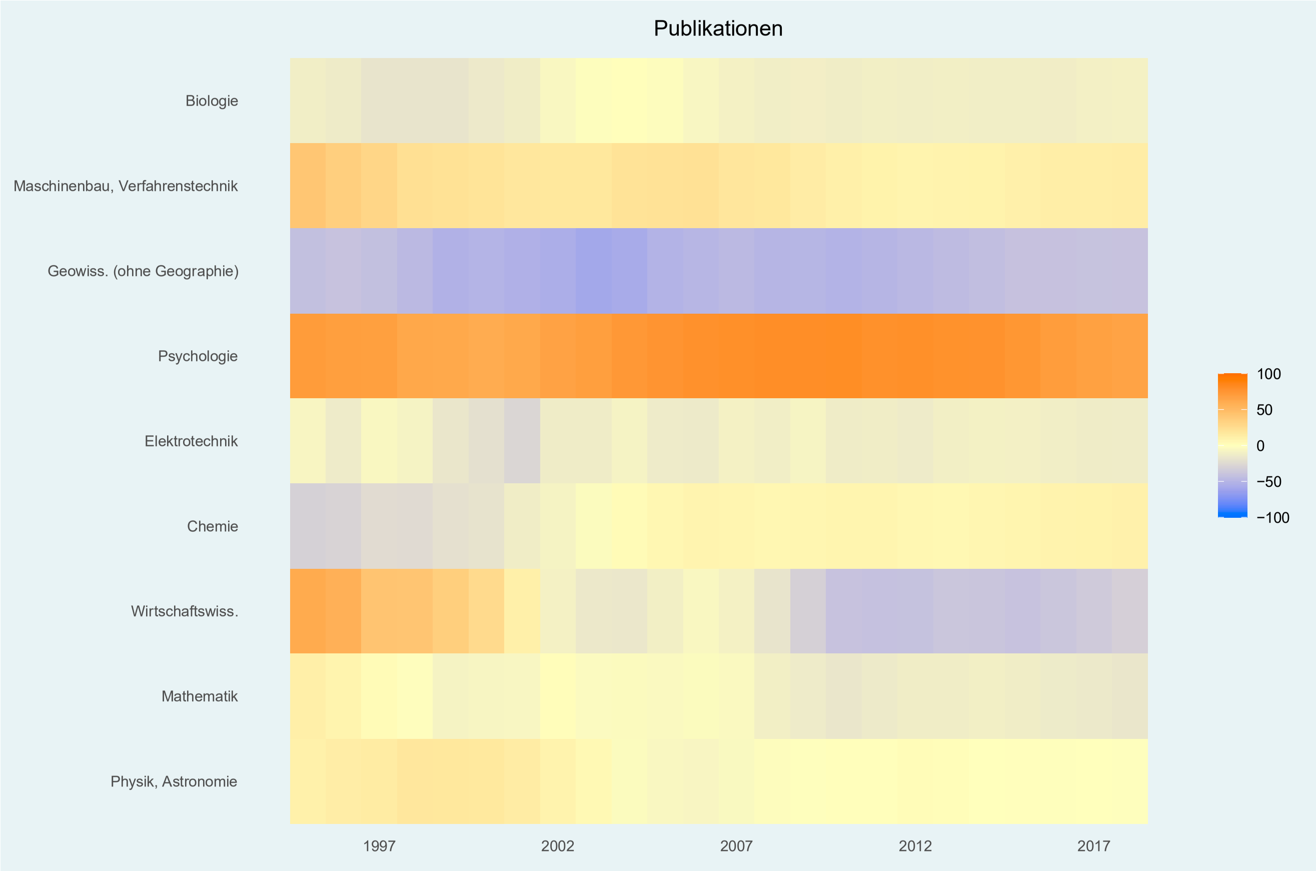

Figure 2. One-dimensional heatmap, Web of Science publications (Univ. of Aachen)
Source: RESP scores for WoS publications, available at: https://fachprofile.uni-wuppertal.de/en.html.

This interpretation for Aachen's publication profile can be squared with other indicators, such as scientific staff. Consider Figure 4 that captures Aachen's development of professorial staff. The overall picture looks quite different from that of publications in that almost all disciplines have grown relative to the discipline with most professors (mechanical/ process engineering). Two conclusions seem warranted regarding the comparison of Figures 3 and 4. *First*, in some disciplines, we observe double growth in input (professorial staff) and output (publication output) that leads to a stronger disciplinary profile (e.g., chemistry, physics/astronomy). *Second*, in other disciplines, input and output are decoupled, and there seems to be no coherent institutional profile (e.g., economics, geosciences, mathematics).

Another functionality of the new graphical representation is that it documents the connection between changes both in funding structure and research profiles. For example, consider the University of Wuppertal where grant funding has considerably changed since the late 1990s (Figure 5). In particular, the growth of externally funded research projects in mathematics moves the university's research profile in this discipline from below-average (blue) to above-average (orange) within a few years. Note that mathematics is deeply orange although its grant funding is only a fraction of the largest discipline (electrical engineering). In contrast, chemistry takes almost the opposite route: within ten years only, the university switches its research profile in this discipline from above-average to below-average. Here, the decrease in grant funding occurs simultaneously: both on the organizational field level (other universities) and on the organizational level (grant funding, Wuppertal).

Discussion

We introduce a two-dimensional graphical mapping, with emphasis on research profiles of public universities. The new graphical representation can be applied to other dimensions, such as teaching, technology transfer, or internationalization as well. The key difference compared to existing *heatmaps* is that our new graphs capture comparisons on both the organizational field level (here: other universities) and the organizational level (university). In this way, we make a first step in better understanding the interplay between both levels. We are aware that our contribution is descriptive, and that further statistical analyses regarding the two levels and their function for both building and maintaining institutional profiles are necessary.

Regarding the graphical representation in Fig. 3–5, one might wonder about other technical possibilities, such as Sankey diagrams, stack area charts, or stream graphs (Wickham, 2016). Although it would be possible, for example, to stack the heat bars, and thus arrive at stack area charts, we decided not to do this. First, our prime motivation is to improve existing (and widely used) heat maps (as discussed above). Therefore, we used existing heat maps available for German public universities (https://fachprofile.uni-wuppertal.de). By adding one additional slice of information (here: the share of a field in comparison to all fields at one university), we wanted the new graphs to be as similar as possible to the existing ones, resulting in variable heights of the heat bars without stacking. Second, when using stack area charts or stream graphs, every research field would get their own color (so fields can be identified). But this is not our aim. In our graphs, colors represent RESP values. Consequently, different fields are displayed by the same color. In contrast, stalking the field would lead to a much more complex color spectrum in the graph, and thus counteract our main purpose: the production of intuitively understandable graphical representations that capture both the field and organizational levels.

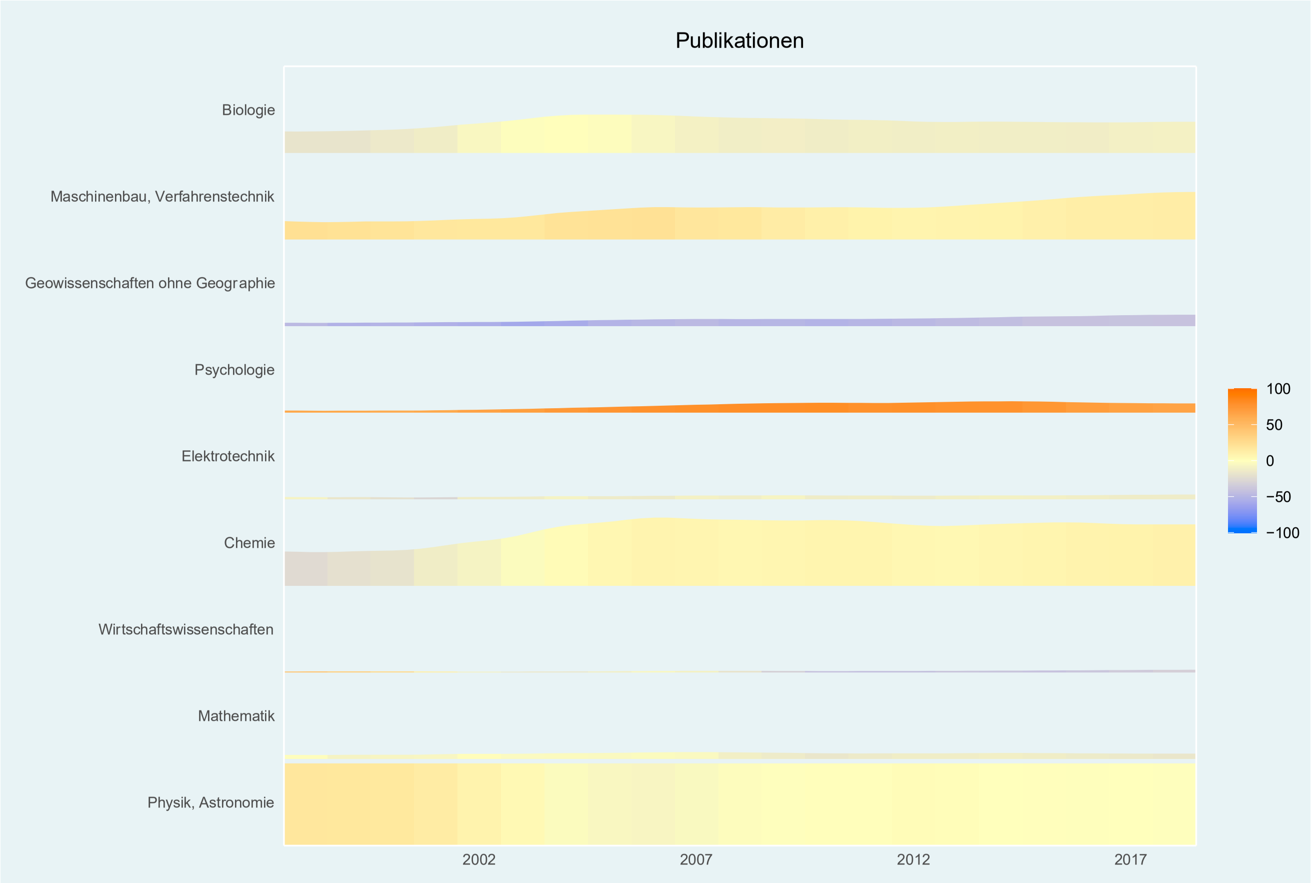

Figure 3. Two-dimensional heatmap, Web of Science publications (Univ. of Aachen)
Source: RESP scores for WoS publications plus respective size of disciplines.

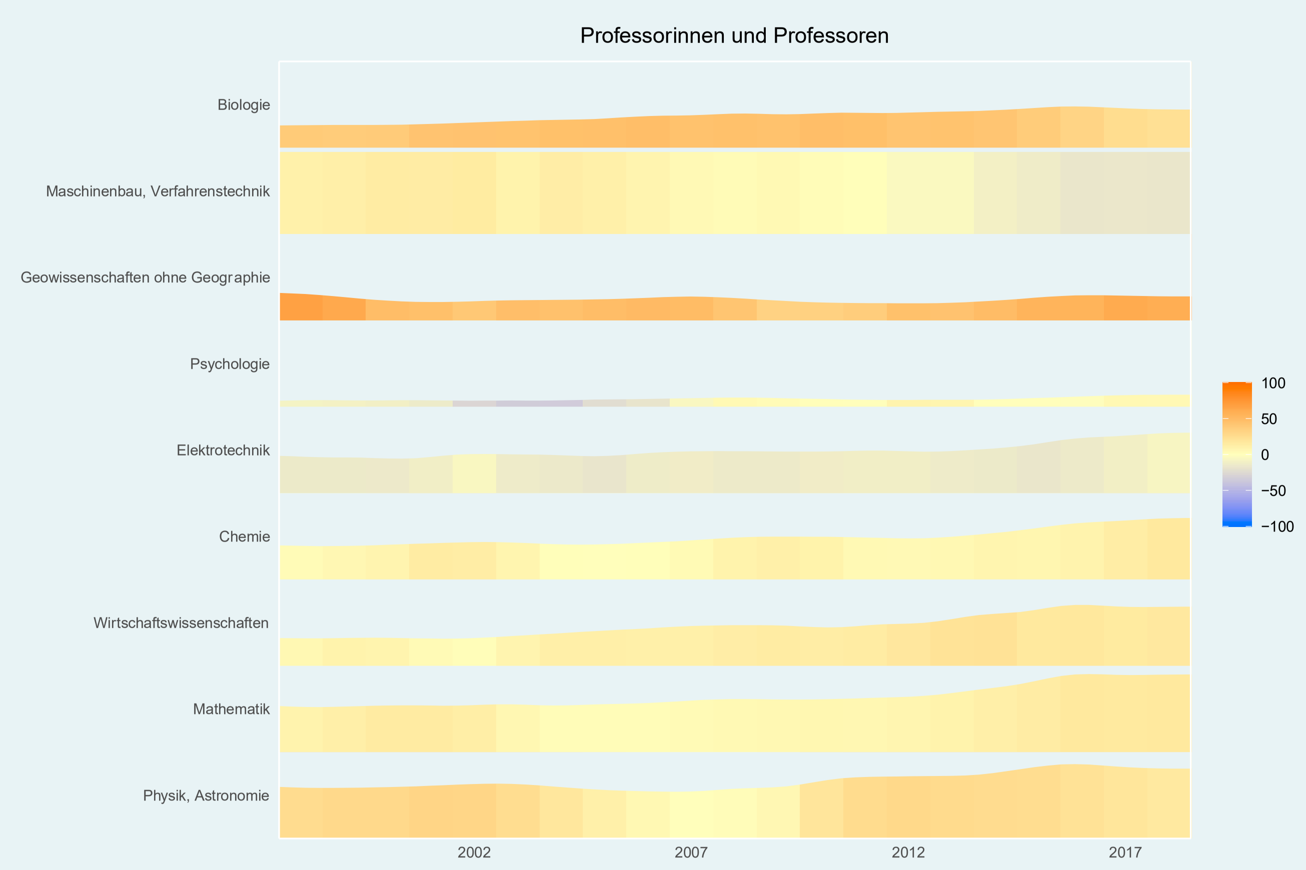

Figure 4. Two-dimensional heatmap, professorial staff (Univ. of Aachen)
Source: RESP scores for professorial staff plus respective size of disciplines.

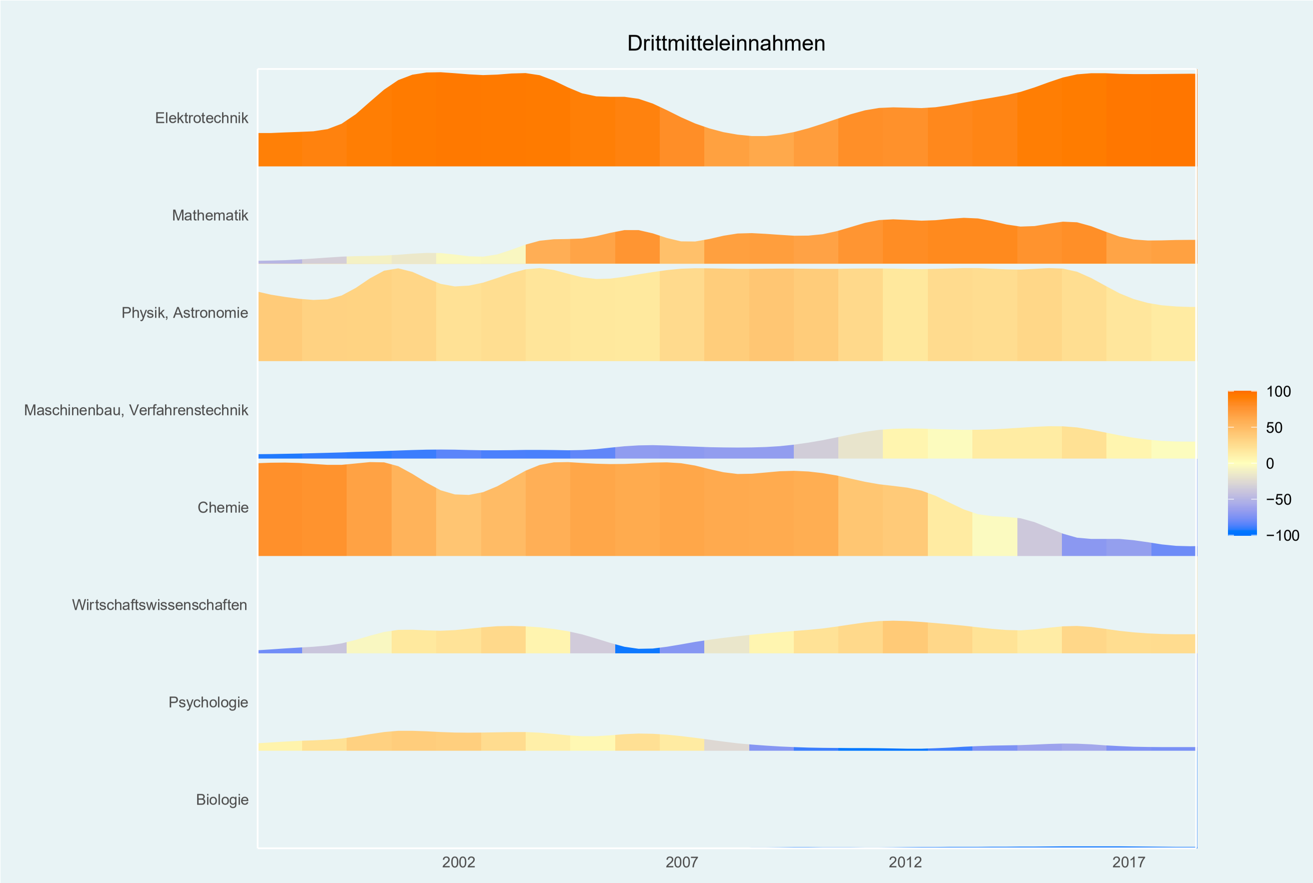

Figure 5. Two-dimensional heatmap, grant funding (Univ. of Wuppertal)
Source: RESP scores for grant funding plus respective size of disciplines.

Notes

All graphs can be found and used under the CC-BY-NC-ND-4.0 international license at https://fachprofile.uni-wuppertal.de/conferences/issi2021.html. Analysis was conducted in R (R Core Team, 2020) with data.table (Dowle & Srinivasan, 2019) and figures were produced using ggplot2 (Wickham, 2016). For smoothing the heat bars, the packages stats (R Core Team, 2020) and splines (ibid.) were used. The pseudo code for smoothing is (as geometric part of the ggplot command): stat_smooth(method = 'glm', method.args = list(family = gaussian), formula = y ~ splines::ns(x,df = years - 1), se = FALSE, geom = "ribbon", span = 1).

Abstract

Studies that have examined organizations' productivity and their leaders have found a rather weak relationship between a leader's personal characteristics and organizational output. In this study, I take a theoretical approach to quantify the effects of top leadership on university research performance. I assume that top leaders may influence university research productivity, but this influence should be visible. I theorize two types of university leader: the "strategic manager" who seeks to reallocate resources to make it of use for the whole university and the "politician" who reallocates resources to benefit certain research areas, especially the one they specialize in. Using an extensive sample of Russian universities, I demonstrate that while there is no observable relationship between overall university research productivity and the university leader's academic excellence, there is a positive influence by university leader's academic productivity on the research performance of his/her specific research field.

Introduction

How important is leadership for how organizations perform? Organizational scientists in general believe that institutional leaders are in a strategic position to influence the implementation of organizational goals (Thornton and Ocasio 1999; Pfeffer 1981; Yielder and Codling 2004; Kraatz and Moore 2002; Henkel 2002; Hambrick and Mason 1984; Fligstein 1987). Good leaders make organizations more consistent and stable while also enabling them to achieve certain goals and be more effective. Leaders function as key actors that provide a link between the organization and its environment based on their reading of the environment and they use resources and power to initiate new actions (Fligstein 1987). However, in professional organizations, leaders' potential to influence institutional courses of action can be restricted (Birnbaum 1989; Cohen and March 1974). Recent studies on academic leadership demonstrate that the question is not whether there is a link between leadership and organizational performance, but what type of leaders or under what conditions leaders are in a position to influence university performance. This study, based on extensive data from Russian universities, joins other attempts (Goodall 2005; 2009; Goodall, McDowell, and Singell 2017) to analyze the impact of academic leaders on organizational performance.

Who is best prepared to govern academic institutions in the most effective way? Conventional assumptions suggest that the best leader combines academic background and managerial experience (Etzioni 1959). However, since the recent managerial revolution, traditional academic experience has begun to be perceived as less important than the managerial background necessary to turn universities into effective organizations (Breakwell and Tytherleigh 2008; Engwall 2014; Musselin 2007). The empirical research suggests that the academic excellence of university leaders is statistically significant for the research quality of the university they lead (Goodall 2005; 2009; Goodall, McDowell, and Singell 2017). However, Breakwell and Tytherleigh (2010) studied a broad sample of UK universities and found that variability in the performance of a university is explained by non-leadership factors. In this study, I raise the same question and ask whether the research performance of an academic leader influences the institutional performance of the organization they lead. Contrary to previous empirical studies, I focus on the leaders' research field specialization. The results demonstrate that a leader's academic performance effect is more profound in the areas of research in which the leader specializes. The findings thus support the argument for the importance of expert specialization.

This paper looks specifically into the relationship between a university leader's individual academic performance and the university's research performance. Research question is thus: "How does university productivity change if the university leader is a top scholar?". In contrast to the largely untheoretical approaches of previous studies exploring the same question, I consider two major theories to help explain the existence—or its absence—of a relationship between a university research performance and its leader's academic achievements. One is the managerial model which assumes that university leaders act as a fair resource reallocator to boost the university performance in general because s/he is deeply invested in the university and plans either to work in the same position at other institutions or to retire as university leader. The second is the political model which assumes that a university leader will favor the department of his/her research specialization to boost its performance by providing scarce resources especially if s/he was previously affiliated with a particular department or plans to work there after the term as leader is over.

This study doesn't seek to forecast future performance, but rather to establish correlation between the variables of interest. For this study, I use Russian Index of Scientific Citation (hereafter RISC) as main data source. I collected individual research performance and university research performance information for 915 universities and 949 rectors. First, I analyze whether there is a correlation between university performance in general and whether the university's rector is a leading scholar is his or her field. Second, I look at how research the various academic fields perform academically at the university and inquire whether the fact that the university leader is a specialist in a specific field is statistically related to it. The models are tested using panel data.

Theoretical framework

The question of the president's influence on university performance was raised in a pioneering paper by Amanda Goodall (2006). In this paper, she analyzed top research universities and found a positive correlation between a leader's academic achievements—measured by citation count—and the research university's international ranking. Breakwell and Tytherleigh's (2010) study of British universities' KPIs and leader's background, shows somewhat different results than Goodall's. They find that university leaders' characteristics as well as leadership change have no observable influence on university performance. These conflicting findings suggest that the effect of top leadership may not be necessarily visible for the university in general. So far, the possibility of rector having an effect on research area's academic performance hasn't been studied while rectors are closely attached to their background areas. Present study fills this gap by exploring the effect of top leadership on the research performance of the different research areas. I do this by positing two theoretical types of leaders. The first type relies on a New Public Management (hereafter NPM) studies according to which university leaders are strategic managers seeking to reallocate resources for the betterment of the whole university. The second type takes its bearing from the political model of organizational governance. This model argues that leaders are politicians who reallocate resources to benefit particular constituencies or research fields.

From a NPM perspective, a university leader should be someone who seeks to balance the competing forces within the university and avoid conflict while also effectively delivering for the betterment of the whole university. This logic sees university leaders as strategic managers setting the rules of the game for all university departments regardless of their own departmental specialization. This quality of benefiting all university departments equally is considered a crucial feature for successful university leaders following the principles of objectivity in decision-making (Julius, Baldridge, and Pfeffer 1999). Based on the mentioned above research literature on the effect of top researchers on the organizational performance (Goodall 2009; Goodall, McDowell, and Singell 2017), I suggest that an academic success of university leaders might have an influence on the research output of universities. This allows to formulate the first hypothesis.

H1a: There is a positive relationship between the academic success of a university leader and the future research performance of university in general.

I further propose to examine whether the academic success of new leadership is more strongly related to university performance for externally recruited leaders rather than from within. In contrast to leaders selected from within an organization, new leaders brought from the outside might be less bound by implicit contracts and internal coalitions (Cannella Jr and Lubatkin 1993; Staw 1980). In addition, outsider hires can be perceived as more capable than insiders to initiate and implement strategic changes (Zhang and Rajagopalan 2004; Helmich 1975; Cannella Jr and Lubatkin 1993). Thus, I propose:

H1b: A positive relationship between the academic success of a university leader and the future research performance of university in general will be found only for externally recruited leaders.

The second leadership type I consider is the "political model." This model was developed largely as a contrast to the bureaucratic model which assumed that formal authority is limited by power blocs and interest groups internal to the organization (Baldridge 1971). A number of studies argue that most organizations are of political in nature this sense and universities are not an exception (Salancik and Pfeffer 1974; Pfeffer and Moore 1980). Drawing on this type, I suggest that the power that a university leader possesses may come not only from his/her formal position, but also from intra-organization interest groups located at the subunit level (Pfeffer and Salancik 1974; Salancik and Pfeffer 1974). I expect university leader to act more as a politician deliberately reallocating resources in favor of certain university departments with which s/he is affiliated especially if the leader is an internal candidate. Those university leaders who had previously worked at the university and/or specialized in a specific research area are part of a tight intra-organizational network and are expected to favor these networks while in office. Based on this, I propose the second hypothesis.

H2a: There is a positive relationship between the academic success of a university leader and the future research performance of the field in which the leader specialized or previously worked.

H2b: The effect of the relationship between the academic success of a university leader and the future research performance of the field in which the leader specialized will be stronger for internally recruited leaders.

Data and methods

University academic productivity can be measured in different ways. For example, it can be measured as the university's position in international rankings (Goodall 2005) or in national ratings (Goodall 2009), as a share of the total country-wide weighted publications (Goodall, McDowell, and Singell 2017). For this study we use the Comprehensive Publishing Performance Score (CPPS) as a measure of university performance and a key dependent variable. The CPPS (*Kompleksnyj ball publikacionnoj rezul'tativnosti*) is a numerical measure of research productivity introduced by the Russian Ministry of Education and Science and is based on university research performance reports, WoS data, and Ministry data. RISC uses the methodology of CPPS calculation and publishes it. As RISC is a national bibliometric database and covers a large amount of bibliometric data (Sīle et al. 2018) across the Russian academy in comparison to WoS and Scopus, I consider CPPS to be a more reliable measure of university research productivity in Russia. RISC provides the opportunity to count CPPS separately for research fields (life sciences, social sciences, humanities, etc.). While it is possible to use administrative data about the research performance of Russian universities as others have demonstrated (Dyachenko and Mironenko 2019), the bibliometric data provided by RISC core is more reliable as it is independently collected.

Although I acknowledge some difficulties that may arise from using citations as an individual research output measure (Goodall 2005, 390–91), citations are important for understanding academic achievements. A number of studies use citations to assess academic output and productivity (Bornmann et al. 2008; Bayers 2005; Taylor 2011; Goodall 2005; Goodall, McDowell, and Singell 2017; Goodall 2009). I consider two variables that determine a rector's academic achievement measure, i.e., a binary variable *top 10% scientist* and a continuous *p-score*. The *p-score* as a key measure of a rector's academic achievement was calculated using Goodall's (2005) approach. Moreover, since disciplines differ in their patterns of academic citations, I calculated citation thresholds for each discipline using RISC lists to create a list of the *top 10%* best researchers in each field. A rector's p-score thus equals the rector's citation number divided by a threshold. While a binary *top rector* variable equals 1 if the rector is among the top 10% most cited academics in his/her research area according to RISC lists for core RISC and RISC in general. As both measures showed virtually the same results in the preliminary phase of the analysis, I choose the p-score as a more sensitive measure of change in individual rectors' performances. In addition, I gathered biographical data of university leaders from official university websites and government portals as well as the leaders' personal web pages.

Table 1. Summary statistics for key variables (restricted sample).

VARIABLES	LABELS	N	mean	sd	min	max	median
year_founded	Year university was founded in	705	1959	45.05	1712	2016	1968
sex	Rector's sex (1-male, 0 - female)	705	0.79	0.41	0	1	1
year_pub	Year of rector's first publication	705	1993	14.85	1955	2017	1996
project5100	University-participant of the project (1-yes,0-no)	705	0.03	0.17	0	1	0
top10_yes	Top rector (1-yes, 0-no)	705	0.34	0.47	0	1	0
N_authors	Number of authors at the university	705	1005.6	1887.51	0	30293	455
cat_rector	Rector's specialization (area of expertise), encoded	705	29.1	13.3	1	49	25
term	Rector's term length in years	571	12.3	7.15	4	41	10
category_uni_encoded	University type, encoded	705	26.8	11.41	1	42	30
internal_rector	Rector is an internal candidate (1-yes,0-no)	556	0.68	0.47	0	1	1
external_rector	Rector is an external candidate (1-yes,0-no)	556	0.32	0.47	0	1	0
p-score	Rector's p-score 2010-2019	7.830	1.41	7.20	0.00	148.90	0.27
year	Year of observation	7.050	2014.5	2.872465	2010	2019	2014.5
CPPSALL	Overall CPPS 2010-2019	7.024	185.4	589.29	0.00	14310.7	54.8

Note: The last three variables are variables in a panel format.

Control variables are essential for reliable results. Control choice has been driven by several factors. It is necessary to account for individual and institutional factors that may have an influence on university research productivity. For instance, as some universities are the participants of the Russian Excellence Initiative (project 5-100), they may have better chances at scoring higher in research productivity variables than non-participants due to additional resources provided by the state. At the same time, younger universities may be less responsive to a rector's research activity in contrast to older institutions as others have demonstrated

(Engwall 2014). Importantly, university size may also contribute significantly to research productivity because in contrast to smaller universities, bigger ones have more resources to hire qualified employees who produce more academic output (Breakwell and Tytherleigh 2010; Goodall 2009).

Because not all rectors and universities have profiles in RISC, the initial sample that contained 951 universities (both public and private) and 949 rectors needed to be cut in size. The sample was also restricted to organizations in which the rector has been in office for no less than four years. As rectors' term of office in Russia is set at five years, I consider four years to be the minimum number of years needed to observe the effect of a leader on university performance. Since the main dependent variable covers the period from 2010 to 2019 (no prior data is available), I assumed that rectors who retired prior to 2007 could not affect the outcome variable. The result was 705 universities and 783 rectors (Table 1).

Results

First model results: overall university performance and top leadership

The first model seeks to test the hypothesis that there is a statistical relationship between Russian rectors' academic achievement and overall university research performance. The outcome variable is *overall CPPS 2010-2019* variable; the key independent variable is a continuous *p-score 2010-2019.* The data consists of a panel of 574 universities observed over 10 years (4,068 observations). Panel data analysis isolates individual effects for each university before estimating the coefficients of the explanatory variables, some of which vary over time. It also controls at the entity level for time-invariant omitted variables. Random effects method is chosen because the variation and differences across entities/universities, i.e., unique university characteristics are assumed to be random because they might have some influence on dependent variable. Fixed effects cannot be implemented because of the lack of variation in dummy independent variables. In the fixed effects model these variables are absorbed by the intercept. In addition, I performed a Sargan-Hansen test, which revealed that a RE estimator would have been a better choice than a FE.

The estimated panel regression equation is as follows:

$$Y_{it} = \alpha + \beta X_{it} + Z_i + u_{it} \text{ , where}$$

Y_{it}: overall university CPPS for university i in year t;
X_{it}: p-score for university i in year t, continuous;
Z_i: controls;
u_{it}: error term.

This formula allowed to answer the question of whether there a significant relationship between Russian university research productivity and the fact that its leader is a top scholar. To more fully answer this question, I interpret the results of panel regression analysis shown in Table 2 below.

Having controlled for the rector's sociodemographic characteristics, his/her experience, specialization, and term length, as well as university size, age, and participation in the 5-100 project, I found *no significant positive relationship between the variables of interest (column 1).* Basic models without controls (not reported here) demonstrate that there is a positive significant relationship between university productivity and the leader's prominence, but I have found that this relationship is *not* statistically significant when university size and the rector's specialization are controlled. This may be because these variables explain some variation in university productivity.

Table 2. Model 1. Panel regression results. Column 1: overall CPPS of the university 2010-2019 regressed on whether rector is a top scholar (measured by leader's p-score); Column 2: overall CPPS of the university 2010-2019 regressed on whether rector is a top scholar controlling for whether rector is an external candidate (dummy variable).

VARIABLES	*(1)*	*(2)*

Number of universities	574	552
Controls for rector's specialization	YES	YES

Standard errors in parentheses
*** p<0.01, ** p<0.05, * p<0.1

Notes: Output for rector's specialization area is not included; model was tested on panel data using random effects.

Notably, participation in the 5-100 Project increases CPPS by more than 100 points, which can be evidence that research universities have a higher research productivity rate than the rest of the sample. The models control for the fact that university is a 5-100 project participant to get more reliable results. I've run a regression with an interaction between 5-100 Project universities and rector's p-score values which showed statistically significant and positive results (not reported here). Additionally, I've run a separate regression for 5-100 Project universities only meaning that there is a significant correlation between university research productivity and whether the university is a 5-100 Project participant. The Project created a competitive environment for university participants to score better in research in Russia and internationally. Average CPPS among 5-100 Project participants is 1473 in contrast to non-participants which equals 175. This means that research universities score 8 times higher in research than non-research. The results also demonstrate that term length is positively associated with overall CPPS. This may be because a longer term allows for the stability needed to achieve the results required for the university to be effective in research.

Column 2 in Table 2 presents panel regression results that examine the relationship between top leadership and overall university performance controlling for rector type. Internal rectors are those who have worked at the university prior to an appointment while external rectors are those who have not. It is of interest that the average CPPS for universities led by external rectors in the sample is 214.6 while for universities with internal rectors it equals 232.3. I found no observable relationship between overall university research performance and whether or not the rector is an external candidate. While external rector control is not statistically significant, the coefficients remain stable. These results do *not* support the posed hypotheses H1a and H1b. Firstly, there is no significant positive relationship between the academic success of a rector and the future research performance of the university in general. Secondly, a positive relationship between the academic success of a rector and the future research performance of the university in general for externally recruited leaders was *not* found.

Second model results: university research areas' productivity and top leadership

The second model seeks to examine whether the interaction between a rector's academic achievement and his/her specialization has an effect on that university research field's productivity. The model deals with various dependent variables, i.e., *CPPS for specific research fields* at the university (CPPS in mathematics, physics, etc.). These dependent variables were regressed on an interaction between *p-score* and whether the rector specializes in this particular area of research since I assumed that top leadership adds to research productivity. Importantly, the model requires that I consider all universities that have different departments and produce academic output for these fields, i.e., universities in the sample have multiple faculties, not only mathematics, physics, etc. Controls are the same as before, except for the *rector's specialization area* control, which was excluded as I use instead the rector's specialization dummy in the interaction. However, the *university type* dummy has been included instead to control for this.

The regression equation is as follows:

$$Y_{it} = \alpha + \beta_1 X1_{it} + \beta_2 X2_{it} + \beta_3 X1 * X2_{it} + \beta_4 Z + u_{it} + \varepsilon_{it} \text{ , where}$$

Y_{it}: CPPS for specific research fields, e.g., mathematics, for university i in year t;

$X1$: p-score, continuous;

$X2$: rector's specialization area, binary, for example, mathematics;

$X1*X2_{it}$: interaction between X1 p-score (continuous) and X2 (rector's specialization area, binary, e.g., mathematics)

Z: controls;

u_{it}: between entity error;

ε_{it}: within-entity error.

Table 3 shows the effects of the interaction between a rector's specialization and whether the rector is a top researcher for each research field. The results show that interactions between the two *is statistically significant for the research fields of physics, technical sciences, medicine, agricultural, and social sciences.* For instance, in the field of technical sciences, 7.7 is the change in CPPS if the rector is a technical sciences specialist and a top scholar in contrast to a vice versa situation. The interaction seems to bring about a greater change for the CPPS in medicine in comparison to other research areas. For every 1-unit increase in p-score, the CPPS in medicine should be expected to decrease by 21 points if the rector is not a specialist in the area, while otherwise it is expected to add an additional 321 points to the CPPS. On the other hand, I found that the interaction is *not significant for computer science, chemistry, earth sciences, humanities, and biology.* This may be related to the fact that some research fields lack data in general. Yet it can be confidently said that when rector is a specialist in the area of mathematics, computer, technical and social sciences there is a positive influence in the CPPS of this respective field. Moreover, I found that the longer a rector serves as rector is important for the CPPS in mathematics, physics, chemistry, earth sciences, and biology. All findings also suggest that larger universities tend to have higher CPPSs in all research fields.

I then run a three-way interaction to test whether there is an effect on the CPPS in research fields depending on whether rector is internal. Table 4 demonstrates that the CPPS in physics, agriculture, medicine, technical, and social sciences remains statistically related to an interaction between p-score and the rector's specialization controlling for whether the rector is an internal candidate. The statistically significant coefficients remain largely unaffected. These results partially support hypotheses H2a and H2b. Indeed, I find that for some research areas there is a positive relationship between the academic success of a rector and the university performance in the field in which the leader specializes. Likewise, the result stays significant when I add internal rector variable to an interaction.

Discussion

The results demonstrate that if a university leader is a successful academic, then s/he will positively influence university productivity only in specific research areas depending on his/her area of specialization. While the analysis did not support the hypotheses originating in NPM theory, I did find some evidence supporting the "political model" of leadership which states that politics is effective in enhancing research performance in particular research fields the rector is closest to. Paradoxically, a rector who does *not* prioritize overall university performance above department performance seems to be a more productive strategist in increasing productivity than the NPM strategic thinker who reallocates scarce resources within the university in a fair manner.

While the results shed some light on the nature of the relationship between university productivity and top leadership, we can also think about other possible explanations. For instance, universities might be considered as loosely coupled organizations since academic organizations embark on weak linkages between professionals in different areas rather than a tightly linked groups of professionals (Weick 1976). Universities embrace various disciplines so the content within the organization differs widely especially since these disciplines are weakly related to each other. In other words, universities differ in their internal organization compared to the typical organization as studied by NPM. This supports the finding that internal candidates can be better leaders (at least at some university types) since they possess incentives to benefit their respective subunits in comparison to external appointees. Hence, better connection to a discipline may be a reason why there is a relationship between top leadership and university productivity in certain areas.

In general, the results raise questions about the effectiveness of the NPM narrative, which has been influential in many countries that have sought to increase government efficiency. While NPM pretends to be the dominant policy in HE, it is also debated whether it is an effective one. The Russian case and several other empirical cases allow to conclude that universities—as specific organization type—require a special type of professional leadership (Goodall 2009; Engwall, Levay, and Lidman 1999). Academic excellence is the prerequisite for improving institutional performance in universities. Leaders with excellent academic records influence the academic performance in the research fields that are closest to. Nevertheless, there is a positive relationship between academic excellence in leadership and university performance.

Abstract

This study examines how international development and gender equality reinforce one another through the introduction and implementation of mechanisms to (1) promote women's engagement in scientific and technological advancements that hold potent promises for developing countries and the attainment of United Nation's (UN) sustainable development goals (SDGs), and to (2) orient more scientific activities toward promoting gender equality (SDG5). It addresses these two dimensions and answers three main questions: (1) to what extent scientific efforts are aligned with the achievement SDGs, (2) where SDG5 (Gender equality) stands in these scientific efforts, and finally (3) who is involved in the scientific advancements that contribute to the success of SDGs and SDG5, in terms of disciplines, countries, economies, and gender. The findings call for the need to support more research in relation to SDGs, particularly SDG5, which could potentially reinforce the engagement of more women in science from both developing and developed nations. The results of this study thus have great implications for both developed and developing nations and underpin the importance of cross-dimensional analysis, which is often overlooked in retention and inclusion policies of women in S&T.

Introduction

Gender inequality prevails in science. Women comprise fewer than 30% of scientific authorship, and their publications receive lower citation rates (Larivière et al. 2013). That is largely perpetuated by the lack of women in science, technology, engineering, and mathematics (STEM) fields. However, this explanation is only partial. Other factors are (but not limited to): under-recognition of women's contributions to science in the receipt of prestigious awards and grants (Lincoln et al. 2012), gender biases in perceptions of publication quality and collaboration interest (Knobloch-Westerwick et al. 2013), persistent gender biases in evaluations of research work (Murray et al. 2019). Yet, the reward system of science revolves around scientific productivity, which coupled with citation measures could reinforce biases in resource distribution and salary (Hilmer et al. 2015), hiring, appointment, tenure, and promotion (Holden et al. 2005), and potentially leave women disadvantaged and underprivileged. This not only has consequences for gender equality but also for research outcomes. That is, the dearth of women in science could also be reflected in the lack of attention to gender-related factors in research and scientific discoveries (Nielsen et al. 2017)—also known as gendered innovation (Schiebinger 2014), which could potentially circumscribe research agendas and priorities.

In response to the growing concern on the dearth of women in science, science and technology policies largely focus on either increase in participation of women or on affirmative action practices to remedy the attrition of women from the science pipeline. However, these efforts could be futile, unless coupled with systematic efforts to alleviate inequalities in other dimensions that are likely to hinder social inclusion and cohesion (Cozzens et al. 2007). One primary implication is to promote international development through the introduction and implementation of mechanisms to (1) promote women's engagement in scientific and technological advancements that hold potent promises for developing countries and the attainment of United Nation's (UN) sustainable development goals (SDGs), and to (2) orient more scientific activities toward promoting gender equality (SDG5).

This study seeks to address these two priority dimensions, and answers three main questions: (1) to what extent scientific efforts are aligned with the achievement SDGs, (2) where SDG5 (Gender equality) stands in these scientific efforts, and finally (3) who is involved in the scientific advancements that contribute to the success of SDGs and SDG5, in terms of disciplines, countries, economies (world bank classification), and gender. The results of this study help underpin the need for the incorporation of cross-dimensional analysis into gender-related science and technology policies.

Methods

Data is extracted from the Web of Science (WoS) from the years 2008-2018. SDG-related papers—i.e., papers that are in line with the SDGs—are identified using the list of WoS keyword queries developed by the IRDG Office at the University of Toronto (University of Toronto 2020, p. 42). This list entails a set of detailed queries designed and developed for each goal for the analysis of research papers. 388,334 papers are identified over the years 2008-2018 that are associated with the SDGs. Each paper is assigned to only one discipline based on National Science Foundation's (NSF) journal classification. Citation measures (both citations and journal impact factor) are normalized by field and year of publication. Countries of affiliations are further classified into high income, upper-middle-income, lower-middle-income and low-income economies based on World Bank (WB) country classifications by income level (2018-2019). Gender of authors is assigned in a similar approach as in Larivière et al. (2013) by using universal and country-specific existing name and gender databases. The proportion of the scientific output of authors of each gender is defined as a fractional count of papers, according to which each author is given a 1/x count of authorships. This study considers first and corresponding authors as a proxy for lead authors who make the main contributions to a scientific paper (Larivière et al. 2016; Mattsson et al. 2011). Accordingly, when the *first and the corresponding authors* of a paper are of the *same gender, or of the same country, or of the same economy (WB country classification)*, this study considers that the main contributions to that paper are made by that gender, that country, or that economy. Table 1 shows the number of SDG-related papers by gender, country of affiliation, and WB country categories of the lead authors.

Table 1- Number of SDG-related papers by gender, country, and WB country categories of the lead author(s)

Gender	*# of papers*	*Top countries*	*# of papers*	*WB category*	*# of papers*	*Discipline*	*# of papers*
Female	92009	*USA*	112835	*High-income*	252,926	*Arts and humanities (AH)*	886
		China	57104	*Upper middle-income*	88,635	*Natural sciences & engineering (NSE)*	218949
Male	148621	*UK*	36956	*Lower middle-income*	17,391	*Biomedical research*	92099
		Australia	25133	*Low income*	1,583	*Social Sciences*	76400

Results

Our findings reveal a continuous increase in the share of SDG-related papers (as of the total number of papers published) over the period 2008-2018 (Figure 1). Overall, SDG-related papers form 2.73% of total publications in years 2008-2018, which accounts for 1.5%, 2.8%, and 4.6% of total papers published in the fields of biomedical research, natural sciences and engineering (NSE), and social sciences, respectively. The share of SDG-related papers in 2008-2018 follows a linear trend line, which shows that the increase in this share has been steady over the years and that the introduction of SDGs in 2015 did not provide an upsurge in research associated with the SDGs.

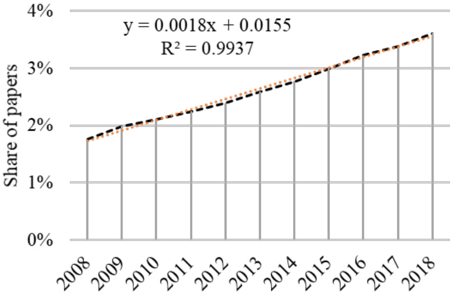

Figure 1. Share of SDG-related publications over years.

While examining SDG-related publications, our results show that clean water and sanitation (SDG6), climate action (SDG13), good health and well-being (SDG3), and life on land (SDG15) were among the top focus areas of SDG-related articles. Gender equality (SDG5) accounts for only 5% of SDG-related publications and falls into the 6th area of focus of SDG-related publications (Figure 2).

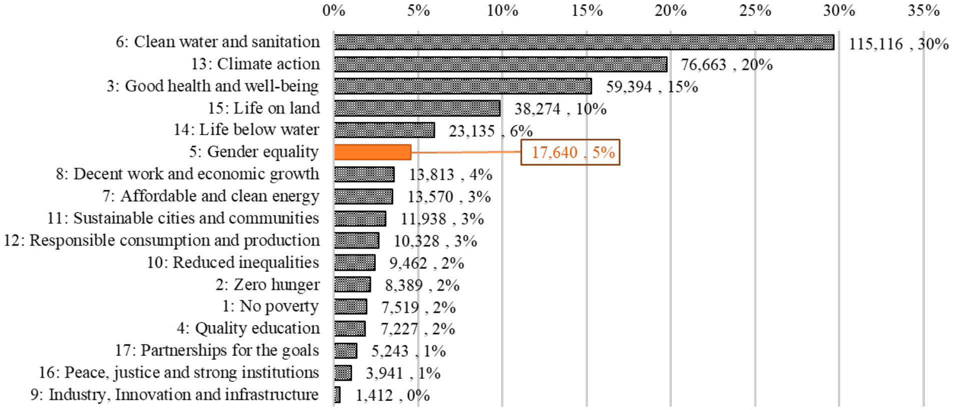

Figure 2. Number of and share of papers related to each SDG (to all SDG-related papers).

Our results highlight that among SDG-related papers, there has been a substantial increase in areas associated with climate change (SDG13) (increased from 13% in 2008 to 23% in 2018), and affordable and clean energy (SDG7) (increased from 1% in 2008 to 5% in 2018), and decrease in research focus areas associated with good health and well-being (19% in 2008 to 12% in 2018) (Figure 3). The share of papers associated with SDG5 (gender equality) stayed the same over the 11-years period. Our findings also show that the area of focus among SDG-related papers varies by country and economy (Figure 4a and 4b). The main focus of SDG-related papers published by high-income countries is on clean water and sanitation (SDG6, 24% of their SDG-related publications) and climate change (SDG13, 22% of their SDG-related publications), while for upper- and lower-middle-income countries is clean water and sanitation (SDG6, 43% of their SDG-related publications), and for low-income countries is good health and well-being (SDG3, 36% of their SDG-related publications). When looking into SDG5, our analysis reveals that the majority of SDG5-related papers are written by researchers from the US, the UK and Canada (Figure 4a) and that a higher proportion of SDG-related papers published by high income and low income countries is dedicated to SDG5 (Figure 4b).

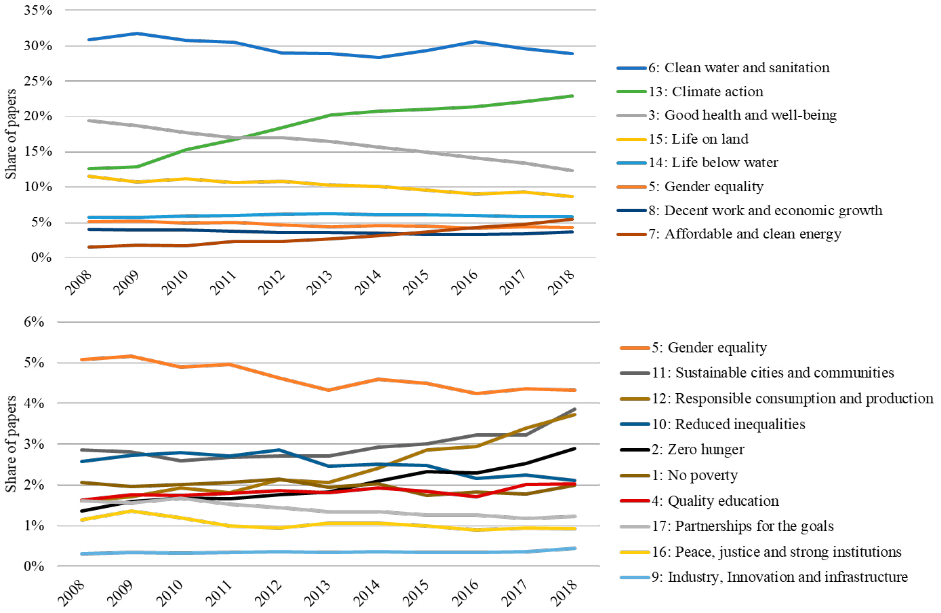

Figure 3. Share of papers related to each SDG (to all SDG-related papers) by publication year.

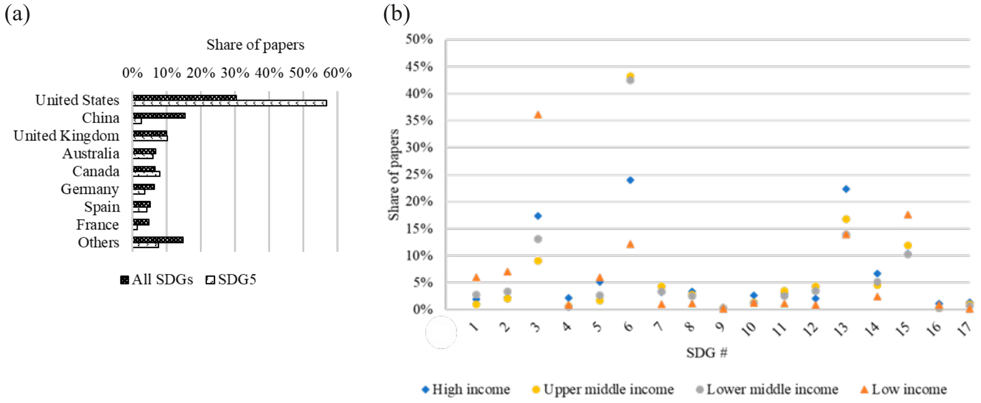

Figure 4. (a) Share of top prolific countries in papers related to all SDGs and SDG5 (left); and (b) Share of papers related to each SDG (to all SDG-related papers) by WB country classification (right).

Women account for 36.5% of total SDG-related authorship. The representation of women is more conspicuous in goals: gender equality (SDG5), and quality education (SDG4) (Figure 5). Moreover, women are highly represented in scientific activities related to SDG5 in all low, middle, and high-income countries (Figure 6a). However, despite women's higher representation, those papers that are led by women received lower citations and were published in lower impact factor journals (Figure 6b).

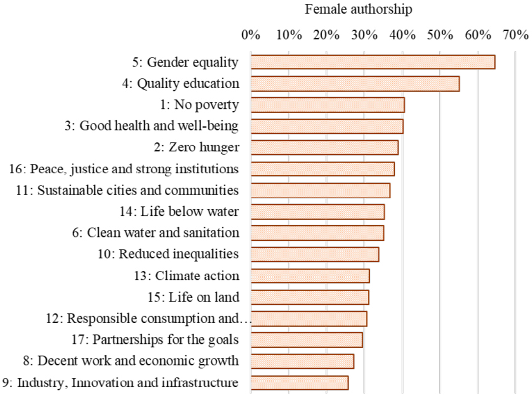

Figure 5. Share of female authorship by SDG.

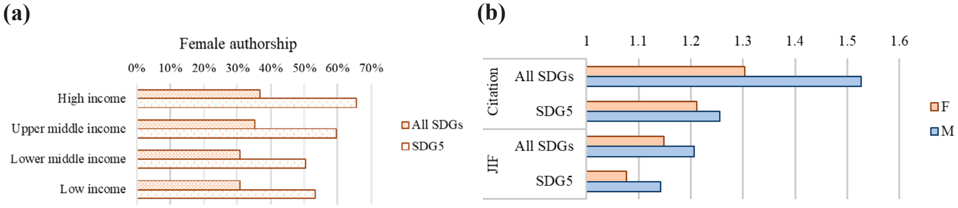

Figure 6. (a) share of female authorship in SDG-related papers and SDG5 by WB country classification; (b) relative citations received by papers led by women and men and the relative impact factor of the journals they are published in.

Conclusion

This study examines scientific publications that contribute to the attainment of SDGs and determines which goals are of primary importance to these scientific activities globally. It also identifies the relationship between lead authors' characteristics (gender, country, and economy of affiliation) with scientific efforts associated with each SDG. It also pays particular attention to SDG5 (gender equality) and maps to what extent these publications are led by women.

Our results show that the top focus areas of SDG-related research are different by the level of income of countries. High-income countries pay more attention to clean water and sanitation (SDG6) and climate change (SDG13), while upper-and-lower middle-income countries focus more on clean water and sanitation (SDG6), and low-income countries focus highly on good health and well-being (SDG3). The majority of SDG5-related papers are published by researchers from the US, the UK and Canada. China is an active player in SDG-related publications, but not in SDG5.Women represent 36% of total SDG-related authorship, which is higher than the representation of women in scientific authorship across all disciplines (i.e., 30% (Larivière et al. 2013). Women are highly represented in the scientific research related to

SDG5 (gender equality) regardless of their WB country classification. However, their publications are published in journals with lower impact factors and receive lower citation rates. Finally, our study shows that there has been no substantial increase in the share of papers related to SDG5 over eleven years (even after the proposition of SDGs in 2015).

These findings call for the need to support more research in relation to SDGs, particularly SDG5, which could positively reinforce the engagement of more women in science from both developing and developed nations. The results of this study thus have great implications for both developed and developing countries and underpin the importance of cross-dimensional analysis (looking at equity in terms of participation and outcomes of science), which is often overlooked in retention and inclusion policies of women in S&T. This study can advise on international development policies, including (1) encouraging women's participation in scientific research and promoting collaboration with women, and (2) providing opportunities for women to stay active in research and facilitating their ascent to the scientific eminence.

Abstract

Studies of interdisciplinarity research (IDR) poses severe challenges to bibliometricians. These challenges range from conceptualisation of IDR, over the definition of disciplines and the way of how research can be assigned to those, to finding the particular methods for quantifying and measuring the peculiarities of IDR. One of the key issues is the determination of granularity. This issue is twofold: The conceptional consideration should clarify the question the level at which IDR would be studied, namely as topic, subject or field interdisciplinarity, and this needs to be supported by quantitative results. The second key issue concerns the way of the assignment of the subjects that are integrated in the research, once the granularity level has been chosen. These two questions are tackled in the present paper, which is closely linked to further studies by the authors on the knowledge diffusion impact of IDR, on different implementations of similarity for the measurement of disparity and variety, and on the effect of similarity measurement approaches on indicators (see references below). The present study proposes a multiple-generation reference model and gives solutions for individual-document based subject assignment and the calculation of cognitive distances between disciplines needed for the determination of disparity measures.

Introduction

As science increasingly deals with boundary-spanning problems, important research ideas often transcend the scope of a single discipline or program. Thus, building sustainable bridges between two or more disciplines is valuable for pushing academic capability forward and for accelerating scientific discovery. Despite the growing attention interdisciplinary research (IDR) has received, there is a lack of consensus in the literature as to the definition of "interdisciplinary" (Huutoniemi et al., 2010). The definition of a "discipline" and discussions of the varieties of interdisciplinary, multidisciplinary, and transdisciplinary research have occupied much scholarly debate (NSF, 2004).

As a multi-faceted concept, IDR can mean different things to different people. One of the most broadly-accepted definitions of IDR is set forth in a National Academies' report (COSEPUP, 2004):

> *"a mode of research by teams or individuals that integrates information, data, techniques, tools, perspectives, concepts and/or theories from two or more disciplines or bodies of specialized knowledge to advance fundamental understanding or to solve problems whose solutions are beyond the scope of a single discipline or area of research practice."*

Derived from the above definitions, knowledge integration is the essence of IDR. According to Porter et al., (2008), the knowledge to be integrated can be of various forms: ideas (such as concepts and theories), methods (techniques and tools), or data from various fields of knowledge. The research on interdisciplinarity can be approached from several different perspectives. From a conceptual viewpoint, there are two main perspectives of studying interdisciplinarity, namely the cognitive perspective on the basis of information flows across disciplines and the organisational approach on the basis of co-authors' professional skills and/or affiliation. The cognitive approach can be implemented by using two different methods that can actually be combined into a hybrid methodology: Since abstract and citation databases provide the necessary link and textual information on citation flows and document topics, respectively, on the large scale even providing the basis of benchmarking, the cognitive approach can be considered the first option. By contrast, useful large-scale information on skills or affiliation needed for the organisational approach is only covered partially (Zhang et al., 2018). On the other hand, subject classification schemes provided with the databases or based on journal assignment and fail in the context of interdisciplinarity whenever journals have a general or even multidisciplinary scope. In order to gain reliable information on the subject of individual documents indexed in the database, a document-based improvement of the subject assignment is needed. The question arises of whether such an assignment with appropriate granularity is feasible on the large scale. We propose a parameterized rule-based model, implement different versions and study the effect of altering parameter settings. The assignment of a publication is based on the most dominant subfield(s) in the aggregated set of cited references where not only the references in the publication are taken into consideration but also those included in the cited publications.

Conceptual considerations and research design

The two central concepts related to IDR are “diversity” and “coherence” (cf. Rafols and Meyer, 2010). While Stirling (1994) distinguished has three components of diversity *variety*, *balance*, and *disparity*, Rafols (2014) proposed to subdivide the notion of coherence into the three aspects *density*, *intensity* and *disparity*. In either component, but most notably in the context of variety and disparity, the correctness and the granularity of topic identification is crucial.

The first aim of the present study is therefore twofold, on the one hand, we attempt to choose a granularity level at which the identification of IDR has still a nuts-and-bolts use and interpretation (biomedical engineering or urbanism certainly represents a different level of IDR than stochastic geometry), secondly, we try to extend existing journal-based subject classification schemes towards the individual document-level assignment. In order to achieve this objective, we will first summarise the effect of granularity on subject disparity on the basis of literature cited by articles indexed in the 2018 volume of the Web of Science Core Collection. We have applied three scientometric link-based methods to measure similarity, bibliographic coupling, co-citation and cross-citation links.

In this context we note that in the present paper we just summarise the major outcomes of these two objectives, while we have devoted three separate studies to the knowledge diffusion impact of IDR (Huang et al., 2021a), the effect of the choice of the particular scientometric method (coupling, co- and cross-citation) on the definition of the (dis-)similarity measures (Thijs et al., 2021) and the analysis of the granularity level in the context of IDR (Huang et al., 2021b). We decided to publish these two important aspects in separate papers as the exhausting investigation would require more space than available in this paper. The main focus of the present study is actually laid on the assignment of individual documents to disciplines, as the journal-based assignment used by the database providers proved too unspecific and thus, at least in the case of more general and multidisciplinary journals, impractical for our purpose. Nonetheless, the choices of both granularity level and link-analysis are indispensable steps in quantification and measurement of IDR and need to be decided upon before (interlinked) document are properly assigned to subjects. We decided therefore, not to remove these steps but to report them giving additional examples to those already given in the two other studies by the authors.

The following sections describe the experiment and the major outcomes.

Data sources and data processing

All documents indexed as articles in the three journal editions (SCIE, SSCI, A&HCI) of the 2018 volume of the Web of Science (WoS) Core Collection have been extracted from the database. For evolutionary and robustness analyses the previous volumes covering the period

1999–2018 have been inclued. For the analysis of cited references, all items that are indexed in *any* WoS database are taken into consideration. As the cognitive subject scheme underlying this study, the adjusted Leuven-Budapest classification with 16 major and 74 sub-fields (disciplines) building upon the WoS Subject Categories (Glänzel et al., 2016) has been used. Figure 1 shows the subject structure of the Leuven-Budapest scheme at the sub-field level.

Methods and results

Determining the granularity level

The basic methodological idea was to conduct the research in several consecutive steps. The first one concerned the granularity proceeding from the assumption that the discriminative power of the level would not dramatically change when we adjust the journal-based assignment by an article-based version using the same hierarchic structure. We applied three scientometric methods based on bibliographic coupling (BC), co-citation (CO) and cross-citation (CC). Again, a systematic investigation of the appropriate methodology for link-based similarity measures has been conducted by Thijs et al. (2021). We here give an example to quantitatively underpin the choice of the granularity level, which, in turn, is necessary for the implementation of individual subject assignment. This, again, shows the interweaving of the tree aspects.

Since co-citations need an appropriate citation window, we have used the five-year window 2010–2014 in this case. Since we are proceeding from a vector-space model, a cosine measure was applied to determine the similarity of subjects. The cosine similarity is defined as the cosine of the angle between two vectors representing the respective documents, i.e., ratio of their scalar product and the product of their lengths. In the case of a Boolean vector space as, for instance, in the case of BC and CO, this reduces to Salton's measure, i.e., the ratio of the number of jointly cited/citing items and the geometric mean of the number of all cited/citing items. To cross-citations, we have used formula used by Zhang et al. (2010) in Eq. (1) and later applied in the context of IDR as well (cf. Zhang et al., 2016). Dissimilarities can readily be derived from the cosine measure by elementary arithmetic manipulation.

This step is required to select both the granularity level and the methodological basis for measuring the disparity aspect of subjects in possible IDR indicators. The correlation across granularity levels is strong (≥ 0.92 for major fields and disciplines and ≥ 0.82 for the subject categories and disciplines) but the slopes reveal systematic trends. These are also reflected by the means. Table 1 gives the *mean* and *minimum mean* similarity with other subjects according to the three approaches. BC provides in general stronger similarity than CC and CO at all three levels. Although the minima for the individual scientometric link-analyses are taken by different subjects, the deviation is not large because the values of G (Geo & space sciences) and L (Social sciences II), K6 (literature) and H2 (pure mathematics), and UT (poetry) and EO (classics), respectively are of similar order (EO = 0.018 in BC, H2 = 0.051 in CC and G = 0.216 in CO, which do, however, not appear in Table 1).

Table 1. Empirical similarity statistics at three granularity levels

	BC		**CC**		**CO**	
	Mean	*Minimum*	*Mean*	*Minimum*	*Mean*	*Minimum*
Major Field	0.364	0.248 (G)	0.326	0.180 (G)	0.314	0.208 (L)
Discipline	0.228	0.064 (H2)	0.180	0.038 (K6)	0.163	0.051 (H2)
Subject Category	0.139	0.007 (UT)	0.090	0.015 (EO)	0.071	0.006 (EO)

Data sourced from Clarivate Analytics Web of Science Core Collection

This confirms previous findings by Glänzel et al. (2009) concerning subject-normalised citation indicators according to which major fields proved too coarse and the lowest level, (subject categories) provide a fine-grained but very fuzzy subject assignment. Subfields could therefore serve as the favoured reference level for disciplines. This gives also some quantitative evidence to support the decision of not to go for kind of "topic interdisciplinarity" as sketched in the preliminary and more conceptual considerations above.

Figure 1. The cross-citation based structure of the Leuven-Budapest scheme (1999–2018) based on major fields (top) and subfields (bottom)

Data sourced from Clarivate Analytics Web of Science Core Collection

Figure 1 shows the disciplinary structure of the WoS at the broad field level (15 major fields) and subfield level (74 disciplines). The detailed scheme for these hierarchic levels is given in the Appendix.

Individual document based subject assignment

The next step towards creating the groundwork of variety and disparity measurement concerns the individual subject assignment of articles and their cited references. Variety (and balance) is based on the number and distribution of disciplines the knowledge of which is integrated in published research results, whereas disparity takes also their dissimilarity into account. While the first aspect can be studied by analysing, e.g., the disciplines to which the cited references belong, the later aspect requires the knowledge of the disciplinary structure of the complete database (cf. Figure 1). Because of the strong correlation and robustness of all three methods, any of those are suitable for the creation of a 'global' (dis-)similarity matrix. We decided to choose BC, since this does not require any particular citation window and most documents have sufficiently long reference lists. At this point, we have to make a distinction between the reference items used for BC, the particular topics of which are not relevant for the link analysis, and those used to improve subject assignment and to detect topics of knowledge integration in IDR. This forms a straight continuation and update of the idea proposed by Glänzel et al., (1999) and Glänzel & Schubert (2003) in connections with the creation of cognitive but bibliometrics-aided subject classification scheme. The proposed iterative algorithm is suited to assign documents to subjects at different levels of granularity, of course, with different precision. In this context we mention that Milojevič (2020) has recently developed a citation-based algorithm for to reclassify Web of Science articles at two different aggregation levels, to subject categories and broad disciplines.

Since many cited documents are published in general journals such as *Physical Review Letters* in physics, *JACS* or *Angewandte Chemie* in chemistry or even multidisciplinary journals like *Science*, *Nature*, *PNAS US* or *PLoS One* with no specific subject profile, we have to detect the topic of those items by analysing their own references. Therefore, we introduce the multiple-generation reference model to classify individual scientific publications. In this step, we adopt a full-counting method for the assignment classification system and we track the relationship between the original publication and the cited references' sub-fields (1st generation), but also the cited reference's sub-fields of those cited references (2nd generation) and so on (3rd generation).

The classification model we propose is a parameterized rule-based model. This approach allows us to implement different versions and study the effect of altering parameter settings. In short, a publication is assigned to the most dominant subfield(s) in the aggregated set of cited references. Cited subfields are ranked based on the normalized share they take in the total set across multiple generations. The selection of the most dominant subfields can be based on a particular threshold or a combination of rules or judgements.

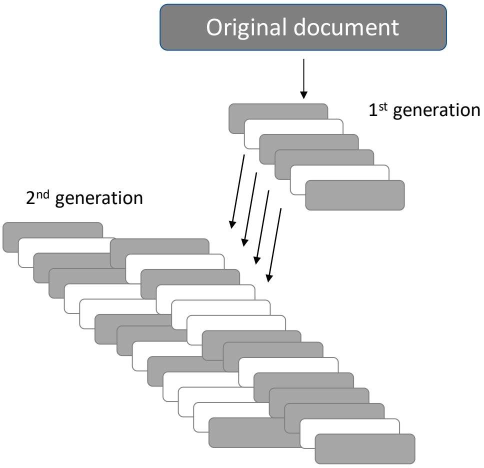

Figure 2. The multi-generation reference model supporting individual document subject-assignment based on two generations with 'active' (dark) and 'non-source' items (light).

Figure 2 illustrates the 2-generation approach. The grey-shaded references symbolise the "active" references, i.e. those that are indexed in the database, the white one stand for non-source references the assignment of which is often unclear and which are therefore ignored. Of course, each additional generation can increase the number of disciplines contributing to the integration of knowledge but could weaken their direct influences and thus increases fuzziness. Table 2 shows the distribution within the major fields of the similarity between the discipline profiles of the first two generations of cited references, where the share of the records within a certain similarity range in all records belonging to the corresponding field is calculated. According to the results, in some fields there is less integration of knowledge from other disciplines over reference generations than in other fields. The corresponding field codes can be found in the Appendix. The more skewed the distribution, the lower is the fuzziness and vice versa. Therefore, lower weights can be given to 'indirect' references, which are represented by higher generations and the precision of which in terms of the assignment of the original document decreases with the order of the generation.

Table 2. The distribution of discipline similarity between 1st and 2nd generation references by major fields, with a colour gradient from red (strong similarity) over white to blue (weak)

Field	[.95,1]	[.9, .95)	[.85, .9)	[.8, .85)	[.75, .8)	[.7, .75)	[.65, .7)	[.6, .65)	.55, 1.6)	[.5, .55)	[.0, .5)

Data sourced from Clarivate Analytics Web of Science Core Collection

The general formula of normalizing the share of a research field or discipline in our multiple-generation model is as follows:

$$\mathrm{NFS}^{(n)}{}_i = w_1\,\mathrm{FS}^{(1)}{}_i + w_2\,\mathrm{FS}^{(2)}{}_i + \ldots + w_{\mathrm{n}}\,\mathrm{FS}^{(n)}{}_i,$$

with

- n is the number of cited reference generations considered.
- $\mathrm{NFS}^{(n)}{}_i$ denotes the normalized share of category i aggregated over n generation.
- $\mathrm{FS}^{(k)}{}_i$ denotes the share of cited category i in the total number of cited categories at generation k.

- w_k refers to the normalizing factor or weight attributed to generation k. it takes a value between 0 and 1.
- $w_1 + w_2 + \ldots + w_n = 1$.

Based on the values that are assigned to the normalizing factors or weights special cases can be identified:

- If w_k=1 for any value of k where $1 \leqslant k \leqslant n$, only the k^{th} generation is taken into consideration.
- If w_k = 1/n for any value of k where $1 \leqslant k \leqslant n$, every generation is taken into consideration and treated equally.
- If $w_k = w_1/k$, for any value of k where $1 \leqslant k \leqslant n$, every generation is taken into consideration and the k^{th} generation has the $1/k$ times of share compared to the 1^{st} generation.
- If $w_k = w_1^k$, for any value of k where $1 \leqslant k \leqslant n$, each generation is taken into consideration and the factor for each additional generation is multiplied by w_1.

Next, the cited categories or fields are ranked in descending order based on their normalized shares. Finally, the highest ranked category or categories are attributed to the publication after the application of judgement rules. The normalized share for the highest ranked subfield is given by $\text{NFS}^{(n)}_{r=1}$

In this study, we consider only the first two generations and report on three weight-allocation schemes (or models) as shown in Table 3. References to *multi-disciplinary journals* in the last considered generation were ignored as being unspecific. The weights and their ratios have been determined on an empirical basis and simple arithmetic, where, for instance, M3 takes the potentiating number of references into account.

Table 3. The weight-allocation model for normalising the share of research fields

Wight model	Formula	w_1	w_2
M1	$w_1 = 1$	1.000	0.000
M2	$w_2 = 1$	0.000	1.000
M3	$w_2 = w_1^2$	0.618	0.382

For the assignment of the sub-fields to individual papers, we have implemented these selection rules:

- The individual assignment to a paper is limited to three sub-fields (i.e., disciplines) according to their frequency ranks i = 1, 2, 3.
- A publication can be uniquely assigned to discipline a only if none of the higher ranked subfields has a normalized share which is at most 0.67 times the subsequent one.
- Assignment of additional disciplines is done, if the above share is larger than 0.67 following the same algorithm.
- The procedure is to be stopped after at most three fields have been assigned. Otherwise, assignment is stopped by the procedure whenever $\text{NFS}^{(2)}_{r=i+1}/\text{NFS}^{(2)}_{r=i} \leqslant 2/3$ for any $i \leq 3$.
- Unassigned documents can still be assigned manually, but are very likely to be truly interdisciplinary themselves. These cased proved to be rather rare.

Table 4 provides a concise formalised view of the complete procedure of subfield assignment to individual papers.

We add a sample of the identified papers published in Nature to illustrate the procedure of assigning the field, shown in Table 5. Note, that the weight type here is M1, i.e., only considering the first-generation reference. As our purpose is to allocate up to three fields to the individual scientific publication, the fields labeled "Multidisciplinary Sciences (X0)" should be removed.

Table 4. Overview of the complete procedure of subfield assignment to individual papers

1st round judgement	2nd round judgement	3rd round judgement	Assignment
$NFS^{(2)}_{r=2}/NFS^{(2)}_{r=1} \leqslant 2/3$			Field 1
$2/3 < NFS^{(2)}_{r=2}/NFS^{(2)}_{r=1} \leqslant 1$	$NFS^{(2)}_{r=3}/NFS^{(2)}_{r=2} \leqslant 2/3$		Field 1 Field 2
$2/3 < NFS^{(2)}_{r=2}/NFS^{(2)}_{r=1} \leqslant 1$	$2/3 < NFS^{(2)}_{r=3}/NFS^{(2)}_{r=2} \leqslant 1$	$NFS^{(2)}_{r=4}/NFS^{(2)}_{r=3} \leqslant 2/3$	Field 1 Field 2 Field 3
$2/3 < NFS^{(2)}_{r=2}/NFS^{(2)}_{r=1} \leqslant 1$	$2/3 < NFS^{(2)}_{r=3}/NFS^{(2)}_{r=2} \leqslant 1$	$2/3 < NFS^{(2)}_{r=4}/NFS^{(2)}_{r=3} \leqslant 1$	Unassigned

Table 5. The sample to illustrate the procedure of assigning the field

ISI	Total Refs.	WoS Refs.	Field 1	Field 2	Field 3	Field 4	Assigned Field(s)
000419769300025	71	59	G2 (0.389)	X0 (0.254)	G4 (0.152)	G3 (0.085)	G2

Remove X0 after original result	M1	-	-	0.232	B2	0.214	B1	0.107	B3	B2; B1
	M2	0.238	B2	-	-	0.211	B1	0.107	I4	B2; B1
	M3	0.247	B2	0.206	B1	-	-	0.135	I4	B2; B1
Remove X0 before calculating shares	M1	0.317	B2	0.293	B1	0.146	B3	0.122	I4	B2; B1
	M2	0.306	B2	0.272	B1	0.135	I4	0.125	B3	B2; B1
	M3	0.287	B2	0.239	B1	0.156	I4	0.09	B3	B2; B1
Remove X0 after calculating shares	M1	0.232	B2	0.214	B1	0.107	B3	0.089	I4	B2; B1
	M2	0.238	B2	0.211	B1	0.107	I4	0.096	B3	B2; B1
	M3	0.247	B2	0.206	B1	0.135	I4	0.077	B3	B2; B1

Data sourced from Clarivate Analytics Web of Science Core Collection

Table 7 gives an impression on the effect of the chosen formula and weight scheme on the share of possible individual assignment for four selected journals. Using the M2 and M3 alone usually resulted in lower shares, for instance, of about 0.87 for the journals *Nature*, *Science* and *PNAS*, only the combination of M1, M2 and M3 resulted in significant improvement of the share. The same applied to the general journals like JACS in chemistry but even in the more specific journals with already high w_1 scores, the (M1 + M2 + M3) combination resulted in further improvement (cf. JASIST in information and library science).

Table 7. Overview of the complete procedure of subfield assignment to individual papers

Our approach yields a similar precision as that proposed by Milojevič (2020): In fact, about 5% of articles published in general and multi-disciplinary journals could not be assigned individually. These papers proved highly interdisciplinary, mostly with no dominant discipline in the cited information sources so that the procedure, which was originally designed to be used in the context of IDR studies, helps directly identify interdisciplinary research quasi as by-product. Below we list four documents published in PLoS ONE and Nature just as typical examples of such research. Neither the cited references nor titles/abstracts and the authors' affiliations point to one specific discipline but immediately reveal the interdisciplinary nature of the underlying research:

- WOS:000383255900083 – Abundant topological outliers in social media data and their effect on spatial analysis (PLOS ONE)
- WOS:000391217400045 – Narrative style influences citation frequency in climate change science (PLOS ONE)
- WOS:000268938300034 – Dense packings of the Platonic and Archimedean solids (Nature)

- WOS:000376883000004 – The Kinome of pacific oyster Crassostrea Gigas, its expression during development and in response to environmental factors (PLOS ONE)

Figure 6 finally shows the subject profiles after individual subject assignment on the basis of the described iterative process of reference analysis. Above all, the three big multi-disciplinary journals reflect a large spectrum of (unequally distributed) disciplines. With the application of the models and methods described above, we have all prerequisites for the creation of the tools to measure the main aspects of IDR, most notably variety and disparity of integrated knowledge. However, this will be part of a separate study.

Summary of main findings and conclusions

The experiment has provided three major results, firstly, bibliographic coupling, cross-citation and co-citations provided similar results in the analysis of subject (dis-)similarity of the WoS documents space, where BC proved a suitable and robust methodological basis at all granularity levels. Secondly, the granularity sub-field level with 74 disciplines in the sciences, socials sciences and humanities proved most suited for the large-scale analysis of IDR of individual documents and provides quantitative support to the conceptual consideration on what level the integration of knowledge may be studied. Thirdly and finally, the iterative process of weighted multi-generation reference analysis resulted in the applicability of the journals-based ECOOM classification scheme to individual-document assignment for ≥ 95% of documents. Recalling the objective of this study, namely improving the precision of disparity measurement in studies of interdisciplinary research, the achieved level of about 95% is sufficient: On the one hand, the method helps build reliable (dis-)similarity matrices for providing the basis for developing disparity measures and essentially improves the accuracy of the subject assignment of cited references (on the basis of the 2nd reference generation) for the measurement of variety but can, on the other hand, also be used to assign the documents themselves to a number of particular subjects. The remaining documents proved to be truly interdisciplinary and require further (qualitative) investigation of knowledge integration. This could be done on the basis of cited literature standing for knowledge that has become integrated into the research in question in conjunction with text analysis using the title, abstracts and keywords or, whenever available, the full texts of the documents. The results of this study form the groundwork for important future tasks: The main future objective is, of course, the creation of measures of variety and disparity with full implementation of the methodology described in the present study. This will be achieved in a separate paper on the different implementations of similarity for disparity and variety measures (Thijs et al., 2021). A secondary task is the individual subject assignment of all papers indexed in the WoS to disciplines according to the ECOOM classification scheme with the possibility of supplementary attribution of IDR labels to documents for policy-relevant applications.

Measuring the excellence contribution at the journal level: An alternative to Garfield's impact factor

Abstract

The aim of this study is to analyze to which extent the JIF reflects the amount of excellent publications contained in a journal in the corresponding subject category. Therefore, we are introducing two percentile-based indicators in order to measure the excellence contribution at journal level. Calculations of these indicators have been carried out for five different JCR subject categories to investigate the correlation with Garfield's Journal Impact Factor. Differences in the ranking according to all three indicators especially in Quartile 1 of each category are shown and discussed. We have also studied the effect of multidisciplinary journals to the excellence contribution at category level and observed considerable differences between the five categories. In the hard sciences, their omission would lead to neglect a large part of excellent publications. Furthermore, our results hint to the fact that the introduced excellence indicators are very robust considering the types of documents considered for their calculation.

This pilot study shows that the introduction of journal excellence indicators will provide a complete and more accurate picture of the citation impact of a journal than the JIF, because they are informing directly about the total and normalized excellence contribution of each journal to the corresponding subject category.

Introduction

Since its introduction by Garfield in the 1960s (first mention in 1963, Garfield and Sher,1963; Garfield 1972, 1976), the Journal Impact Factor (JIF) is still one of the most common bibliometric indicators when it comes to measuring journal impact (Archambault & Larivière, 2009). Its popularity is unbroken, and not only because its introduction meant a revolution for the scientific community (Lariviere & Sugimoto, 2019). The simple fact that, despite the development of a multitude of new indicators, none of the alternatives has prevailed testifies to the high acceptance of the IF when it is used reasonably (Garfield, 2005; Gorraiz et al., 2020). The past has clearly shown that the JIF is not an all-in-one solution for various issues, which has led to controversial discussions and justified criticism (Todorov & Glänzel, 1988; Moed & van Leeuwen, 1995; Glänzel & Moed, 2002; Moed, 2002; Alberts, 2013; Gorraiz et al., 2012a). In response, several manifestos and statements were published especially due to the increasingly frequent misuse in research-assessment practices (San Francisco Declaration on Research Assessment, ASCB, 2012).

The first edition of the Journal Citation Reports (JCR) – including for the first time the Journal Impact Factor - was launched in 1975 and was based on the fundamental understanding that citations can be used as valuable criterion for the assessment of scientific journals (Garfield, 1976). The more frequently a journal is cited, the higher the recognition of its importance and prestige as information channel in the respective research field.

Researchers started to use the JIF in order to identify adequate publication venues and to optimize their publication strategies. As of its introduction editors and publishers rely on the

JIF in order to estimate the reputation, prestige and market value of their journal portfolio. Furthermore, the JIF opened up a new support tool for librarians to back up decisions about subscriptions, to guarantee the presence of indispensable journals in their collections and to optimize their acquisition strategy. Finally, policy makers have thus gained a quantitative indicator for evaluation purposes, which additionally drove the expansion from its use for scientific information to application in evaluative contexts (cf. Glänzel, 2006).

The JIF has been further developed and improved over the years (extension of the citation window to five years, consideration of the journal self-citations, etc.) and nowadays a number of alternative journal citation-indicators are available such as the h-index for journals (Braun et al., 2006), eigenfactor metrics (Bergstrom et al., 2008; West et al., 2010), SJR (González-Pereira et al., 2010; Guerrero-Bote & Moya- Anegón, 2012), the SNIP indicator (Moed, 2010 a&b) or the CiteScore (cf. van Noorden, 2016). Nevertheless, the new edition of the JCR is eagerly expected each year, which shows the continuing importance of this analytical tool for the scholarly community and for research assessment.

Research assessment exercises are often performed for recent time periods. In these cases, impact analyses relying on citations are not very useful, because in many disciplines the citation window is practically too short for retrieving significant citation numbers.

Although it is not the appropriate indicator to measure the impact of a publication (Waltman & Traag, 2017), the JIF does provide a quick information on the impact and prestige of the journals in which the researcher, group or institution has been able to publish. Being published in journals with high JIF is much more difficult (higher rejection quotes), and successful publication in these journals needs recognition. JIF also helps to identify the top journals in each field according to their impact or prestige. This is why the Journal Impact Factor plays such a key role.

The competition to be included in the Web of science Core Collection and to be indexed as a Q1 journal or to publish in one continues unabated (Osterloh, & Frey, 2014) and is inextricably linked to the question of how the citation impact and prestige of a journal is measured.

However, since the introduction of the IF, many analytical tools have been developed and are available, enabling a very quick and automatic calculation of the percentiles of the most cited publications for each publication year and each subject category (Lozano et al., 2012)..

Nowadays the normalized citation counts like Category Normalized Citation Impact CNCI and the number and percentage of Top 10% and Top 1% most cited publications are essential indicators in citation analyses (Adams et al., 2007; Gorraiz et al., 2012b; Gorraiz & Gumpenberger, 2015).). Top 10% is usually considered as a measure of "excellence".

Therefore, it can be quite interesting to use these normalized indicators as an alternative to the JIF. Does the JIF reflect the amount of excellent publications contained in a journal or in a subject category? Are there other approaches to paint a more precise picture of journal excellence? This is the subject of our study.

Research questions

In order to achieve our objectives to measure the excellence contribution at the journal level, we will answer the following research questions.

1. Can the Journal Impact Factor (JIF) designed to provide a robust and size-independent journal performance measure be supplemented by an indicator of excellence based on the high-end of a journal's publications? Could a proper percentile-based approach result in an improved assessment of the citation impact of a journal?
2. How does the Impact Factor correlate with the proposed percentile-based indicators?
3. Which high-impact journals from the last ten years do not appear in Quartile 1 (Q1/WoS)? What could be the reasons for this?
4. How do multidisciplinary journals affect the indicators?

5. How sensitive are these indicators to the choice of document types, particularly of the so-called ‘citable items’ (i.e., research articles and reviews) instead of all documents types?

Methodology

All documents assigned to the WoS Subject Categories “Virology“ (VIR), “Physics, Condensed Matter” (PHCM), “Economics” (ECO), “Information & Library Science” (ILS) and “History” (HIS) published of the years between 2009 and 2018 were selected and subsequently analyzed in InCites at the journal level.

In this study, we are considering only journals with an Impact Factor, and we are performing the analyses for two different groups: 1) only journals assigned to each WoS subject category according to Journal Citation Reports (“JCR Cat.”), and 2) including all multidisciplinary journals that, according to InCites, have likewise contributed to this category (“JCR Cat. + Multidisciplinary”).

For each journal, we list:

- Number of publications published in this journal in JCR Cat.: p(J)
- Number of excellent publications published in this journal in JCR Cat.: x(J)

For each category we list:

- Total number of publications in JCR Cat: p(T)
- Total number of excellent publications in JCR Cat.: x(T)

In this study the term “excellent publications” or “excellence” is used as synonym for publications belonging to the Top 10% most cited documents in the same JCR Category, publication year and document type.

Beside the Journal Impact Factor retrieved from the JCR Edition 2020, we have calculated the following indicators for each journal:

1. Journal Percentage of Excellent Publications (JPEP) = (x(J)/p(J)) = Number of excellent publications published in this journal in the PY=2009-2018 in this WoS Category / Total number of publications published in this journal in the PY=2009-2018 in this WoS Category
2. Journal Contribution to the Excellence of the Category (JCEC) = (x(J)/x(T)) = Number of excellent publications published in this journal in the PY=2009-2018 in this WoS Category / Total number of excellent publications published in the PY=2009-2018 in this WoS Category.

Both indicators are size dependent: The first one (JPEP) can reach very high values for journals with just few publications in the category, and the second one (JCEC) benefits journals with a large number of publications. Therefore, we have also calculated two further indicators:

3. Journal Brute Excellence (JBE) = JPEP * JCEC = $x^2(J)/(p(J)*x(T))$.
4. Journal Normalized Excellence (JNE) = (x(J)/x(T))/(p(J)/p(T)) = Journal Contribution to the Excellence (JCEC) / Journal Contribution to the Category

The first one reflects the total brute excellence force or brute contribution of the journal to the category. The second one provides the normalized excellence contribution of the journal to the category. Both together provide a more complete picture of the journal excellence.

We are using the JNE especially for the analysis limited to the journals assigned to the JCR Category under study (“JCR Cat.”), because the number of publications of these journals is significant, resulting in relevant JNE values. Note that JNE is inspired by the “Attractivity Index” by Schubert and Braun (1996), which is, in turn, defined based on the model of the Activity Index introduced into Scientometrics by Frame (1977). Both indicators have been used since the late 1980s to reflect a country’s, region’s or other unit’s relative contribution to research productivity and citation impact in given subject fields (cf. Schubert et al., 1989). JNE here expresses a journal’s contribution to the excellence in a given subject. As such JNE, analogously to the above-mentioned indicators by the Hungarian research group, is a balance measure with neutral value 1, i.e. a journal contributes relatively more (less) to the subject's excellence according as JNE > (<) 1. It is not contributing at all, if JNE = 0. The only conceptual deviation of JNE from activity/attractivity is that the balance in not considered across subjects but across units (i.e., journals). A consequence of the "balance" property of this concept is that not all journals can contribute relatively more (less) than expected – some journals assigned to the subject category reflect relatively more excellence than the subject standards, others contribute to subject excellence to a lesser extent.

When analyzing the effect of the multidisciplinary journals, we use the JBE. Multidisciplinary journals contributing rather few publications to the category yield high JNE values, but according to the JBE no significant contributions are achieved.

Pearson Correlations were then performed for the JIF, JPEP, JCEC, JBE and JNE for each of the five categories considering only journals assigned to the subject category ("JCR Cat.") and including also multidisciplinary journals ("JCR Cat. + Multidisciplinary").

In addition, the Gini coefficient has been calculated for all five categories.

Furthermore, we have compared the Q1 journals assigned to each category according JCR (2020) with the Top Journals according to the two new indicators JNE ("JCR Cat."), and JBE ("JCR Cat. + Multidisciplinary").

In order to address research question #4, we have analyzed and discussed the contribution of other journals not directly assigned to the corresponding category, like e.g. the multidisciplinary journals, to the excellence of the category. For this purpose, we have introduced two more indicators:

5. Category Percentage of Multidisciplinarity (CPM) = Number of publications added by multidisciplinary journals not directly assigned to this category according to the JCR (e.g. Nature, Science, PLOS, etc.) / Total number of publications in the category.
6. Category Excellence Degree Multidisciplinarity (CEDM) = Number of excellent publications added by journals not directly assigned to this category according to the JCR (e.g. Nature, Science, PLOS, etc.) / Total number of excellent publications in the category.

Last but not least, we have also performed our analysis not only for the document types articles and reviews, but also for all document types in order to address research question 5.

Results

General Overview

Table 1 gives an overview of the number of journals, publications and excellent publications for each category considered in this study.

Table 1. Overview of the five categories (PY= 2009-2018)

		JCR Category			JCR Cat. + Multidisciplinary			Multidisciplinarity	
Categories	**Document Types**	**Nr Journals**	**Nr Pubs**	**Nr Excellent Pubs**	**Nr Journals**	**Nr Pubs**	**Nr Excellent Pubs**	**Percentage CPM**	**Degree CEDM**
Economy	All types	351	242.035	29987	433	246764	30481	1.92%	1.62%
	Art. / Rev.	343	181852	26332	424	187937	26694	3.24%	1.36%
History	All types	99	82575	8983	126	88258	9902	6.44%	9.28%
	Art. / Rev.	99	25443	7371	119	27992	8157	9.11%	9.64%
Information & Library S	All types	79	92657	7077	144	95329	7213	2.80%	1.89%
	Art. / Rev.	73	33745	5850	131	37828	5950	10.79%	1.68%
Physics High Condensed M	All types	63	285812	29762	100	289678	29934	1.33%	0.58%
	Art. / Rev.	62	278819	29145	98	283149	29307	1.53%	0.55%
Virology	All types	35	83006	7269	145	89138	8248	6.88%	11.87%
	Art. / Rev.	34	65277	6258	140	71280	7174	8.42%	12.77%

Furthermore, it provides information about the differences between document types – all document types (All types) versus Article and Reviews (Art. /Rev.) –, the "Category Percentage of Multidisciplinarity" (CPM) and the "Category Excellence Degree Multidisciplinarity (CEDM)" (see section Methodology). The results show that articles and reviews are mostly responsible for the number of excellent publications in all categories. This is even true for the three categories related to the Social Sciences where big differences between the total number of all document types compared to articles and reviews can be observed.

The lowest percentage of articles and reviews within the excellent publications is observed for "Information & Library Science" (ILS) and "History" (HI) with 82%, followed by "Virology" and "Economics" with around 88% and the highest in "Physics, Condensed Matter" (PCM) with almost 98%. In this study, we are focusing on the document types Articles (Art,) and Reviews (Rev.). In Section 5, the effect of the document types will be further analyzed and discussed.

Table 1 also shows that the category percentage and degree of multidisciplinarity are different according to the subject categories. For the category "Virology" (VIR) it is even more significant when considering the contribution to excellence (CEDM). More than 12% of the excellent publications are published in multidisciplinary journals in the category of "Virology" and around 10% in the category "History". In "Physics, Condensed Matter" (PCM) the effect of the multidisciplinary journals is almost inexistent, and in Economics (ECO) very low. In "Information & Library Science" (ILS) the effect is much higher in the total number of publications (CPM) than in the number of excellent publications (CEDM) as well as for articles and reviews in comparison to all document types.

Showcase Results for the category "Information & Library Science" (ILS)

Table 2 provides an example of the results obtained for the category "Information & Library Science" (ILS) and includes all the indicators mentioned in the methodology.

Table 2. Excerpt of the data retrieved for the category ILS, only Q1 journals according to the JIF 2019 (Article & Reviews, PY=2009-2018)

						Final Indicators

It shows the Q1 journals according to the Journal Impact Factor[1].

Figure 1 shows the correlation between the IF and the two new indicators for all journals of the JCR Category "Information & Library Science" (ILS). The correlation is rather moderate (JBE; r = 0.763, see Table 3), most notably for the normalized JNE (*r* = 0.906, see Table 3), but some of the journals change their position, if a normalized and size-independent indicator (JNE) is used (e.g., JASIST and Scientometrics).

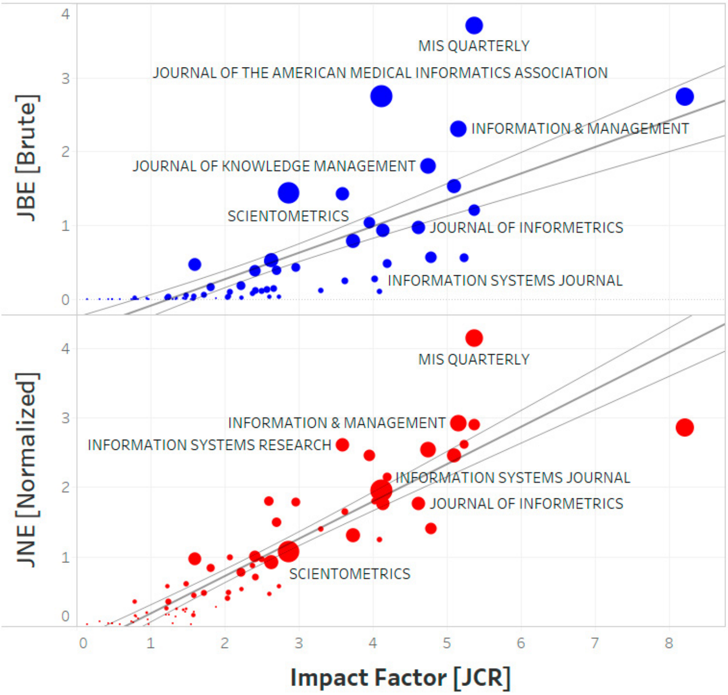

Figure 1. Correlations of the Impact factor with the JBE and JNE in the category Information Library & Science

Table 3 shows the Pearson correlations between all five indicators: JPEP, JCEC, Journal Impact Factor (JIF), JBE and JNE for the category "Information & Library Science" (ILS) for a) only articles and reviews (lower left triangle) b) for all the document types (upper right triangle).

Table 3. Pearson correlations between all measures and indicators for all JCR journals of the category ILS (lower left triangle: Articles & Reviews; upper right triangle: all document types; PY=2009-2018)

A+R vs. all	Pubs	Exc. Pubs	JIF	JPEP	JCEC	JBE	JNE
Pubs	-----	0.077	-0.136	-0.107	0.077	-0.107	-0.029

In Table 4, journals in the category ILS are listed. It shows the changes in ranking position, which is traditionally based on the Journal Impact Factor, when applying the Excellence Indicators JBE and JNE. Values in green indicate a higher ranking position compared to the JIF, values in red indicate a lower position.

Portal: *Libraries and the Academy* and *Journal of Health Communication* are the journals that improve their rank position the most due to the excellence indicators. *Malaysian Journal of Library & Information Science* and *Information Technology for Development* are the ones decreasing the most in the brute and normalized excellence rankings.

Comparisons between the five categories analyzed

Table 5 shows the results of the correlation between the Impact Factor and the two Excellence Indicators for all the categories considered in our study: "Information & Library Science" (ILS), “Economics” (ECO), “History” (HIS), “Physics, Condensed Matter” (PHCM) and “Virology“ (VIR).

Table 5. Correlations between JIF, JBE and JNE for the five subject categories analyzed (Article & Reviews, PY=2009-2018)

ILS	JIF	JBE	JNE
JIF	1.000		
JBE	0.763	1.000	
JNE	0.906	0.836	1.000

ECO	JIF	JBE	JNE
JIF	1.000		
JBE	0.544	1.000	
JNE	0.909	0.620	1.000

HIS	JIF	JBE	JNE
JIF	1.000		
JBE	0.624	1.000	
JNE	0.784	0.836	1.000

PHCM	JIF	JBE	JNE
JIF	1.000		
JBE	0.691	1.000	
JNE	0.941	0.799	1.000

VIR	JIF	JBE	JNE
JIF	1.000		
JBE	0.758	1.000	
JNE	0.956	0.867	1.000

The results show that the correlation between the Journal Impact Factor (JIF) and the JNE is higher than between JIF and the JBE. This is expected because JIF and JNE are both size independent.

The correlation between the JIF and the JNE is very high for the JCR Categories “Virology“ (VIR) and “Physics, Condensed Matter” (PHCM) (around 0.95), good for “Economics” (ECO) and “Information & Library Science” (ILS) (around 0.9) and lower for
“History” (HIS) (0.784).

Effect of the multidisciplinarity

Table 6 illustrates strong differences in the effects of the “multidisciplinary journals” in the five selected categories. Categories related to the life sciences and natural sciences show strong influences of such journals compared with the Social Science that are less affected. Of course, we have to keep in mind that humanities and most fields in the social sciences have a lesser weight in the big multidisciplinary journals. In particular, virology (VIR) is the category with the highest presence in multidisciplinary journals. Five multidisciplinary journals are responsible for the largest brute excellence contribution and can be considered as “Q1 journals” in this category according to this indicator. In Economics, four multidisciplinary journals appear among the journals with high contribution to the brute excellence, but not on the top. Also four journals are listed for “Physics, Condensed Matter” (PHCM) with comparably lower ranking positions.

The only multidisciplinary journal ascending to the first quartile in “Information & Library Science” (ILS) is PLOS ONE. As it is well-known, PLOS ONE has a special section for Research assessment and Bibliometrics. However, according to its size, its excellence contribution is not as high as expected (see also Table 1).

Table 6. Effect of the multidisciplinary journals in the JBE Ranking for the journals of the five subject categories (Article & Reviews, PY=2009-2018)

			Contributions		Brute		
Category	Journal	PUBs	JPEP	JCEC	JBE	Rank JBE	Percentile
VIR	PNAS	650	49.38%	4.47%	2.210	4	8
VIR	SCIENCE	118	98.30%	1.61%	1.590	5	10
VIR	NATURE	100	97%	1.35%	1.312	6	12
VIR	NATURE COMMUNICATIONS	176	58.52%	1.43%	0.840	7	14
VIR	NEW ENGLAND JOURNAL OF MEDICINE	15	73.33%	0.15%	0.112	12	24
PHCM	SCIENCE	30	93.33%	0.09%	0.089	11	15
PHCM	NATURE COMMUNICATIONS	178	34.27%	0.20%	0.071	13	18
PHCM	NATURE	26	84.61%	0.07%	0.064	14	20
PHCM	PNAS	84	30.92%	0.08%	0.027	16	23

HIS	JOURNAL OF ECONOMIC HISTORY	323	74.30%	2.94%	2.186	2	2
ECO	PNAS	248	56.04%	0.52%	0.292	24	7
ECO	SCIENCE	62	85.48%	0.19%	0.170	37	10
ECO	PLOS ONE	726	11.98%	0.32%	0.039	88	24
ECO	NATURE	10	100%	0.03%	0.037	92	25

Effect of the document types

Finally, we analyzed the effect of considering all types of documents instead of only articles and reviews. As it is common knowledge that there is an asymmetry in the calculation of the Journal Impact Factor. In the numerator, the citations to all types of documents are summed up, while in the denominator only research articles and reviews are considered[2]. In Section 1 we have already analyzed the document types in each category and their contribution to the Excellence (see Table 1). The results corroborate that in the subject categories related to the social sciences (ILS and HIS), other document types than articles and reviews might play a significant role accounting for around 18% of the category excellence.

Furthermore, the two new excellence indicators have been also calculated for all document types and for articles and reviews only (see Table 3). The results underline the role of research articles and reviews in scientific journals. Any reasonable correlation of the number of documents with excellence measure is absent, even slightly negative. Thus it is plausible that the observed Pearson correlation between JIF and JNE is distinctly higher for articles and reviews than for all document types (0.906 versus 0.755), while it is just the opposite for the brute excellence contribution (JBE), where the total number of publication in the category plays a role (0.763 versus 0.897).

Figure 2 shows the correlation of the Journal Impact Factor, and the two excellence indicators (JBE and JNE) for the Q1 journals of the category ILS when considering only articles and reviews (column 2 and 3) and all document types (column 4 and 5), respectively. The results show that, even if the actual indicator values are changing, the distribution of the JBE or JNE as such is not much affected by the considering all document types instead of only 'citable items'. This hints to the fact that our excellence indicators are quite robust or less sensitive to the types of documents considered. In particular, the correlations are very strong, e.g. 0.986 for the Journal Normalized Excellence (JNE), and 0.99 for the Journal Brute

[2] Originally, Garfield used the document types, articles and reviews, also called "citable items" in the JCR Edition. Nowadays, all the proceedings papers published in journals are also considered articles in the Core Collection with the effect of double assignment.

Excellence (JBE), and they corroborate the robustness of both indicators concerning the document types used in their calculation. One possible reason is that the normalizations performed for defining excellent publications are also done by document type (= Top 10% most cited publications of the same document type and publication year in the same category year).

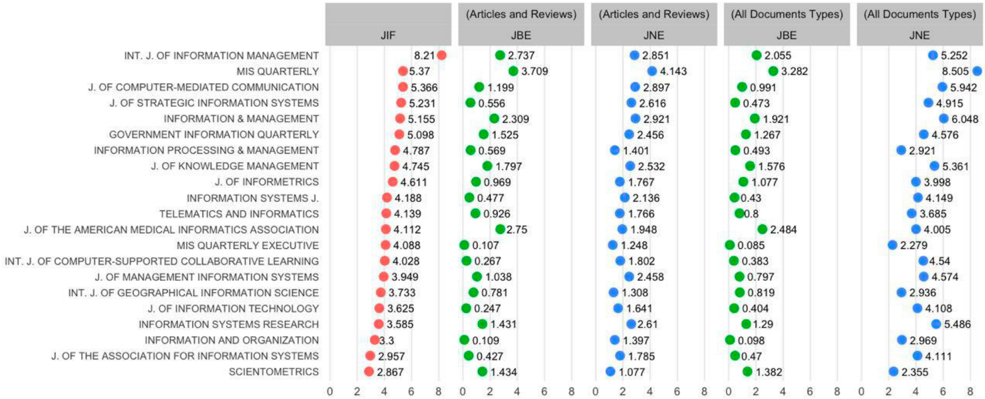

Figure 2. Distribution of JIF, JBE and JNE for all Q1 journals of the category ILS for only Articles and Reviews (2nd and 3rd columns 2 and 3) and all document types (columns 4 and 5).

Conclusions

Due to the precariousness and long half-lives of the citations, the identification of the top journals in each discipline is one of the most requested and used tools in academic evaluation exercises focusing on the assessment of the research performance of the most recent years.

The Journal Impact Factor has established itself as one of the most consolidated instruments for assessing the impact and prestige of the journals where the scientists, research groups, organizations and countries have published in.

To provide a broader view of each journal's contribution to the excellence in each category or field, we have introduced two new indicators, which ideally complement the JIF. The first one, the Journal Normalized Excellence (JNE) measures the normalized excellence contribution of a journal to its subject category. A journal contributes relatively more (less) to the subject's excellence according as JNE > (<) 1.

On the other side, it is also interesting to know the total contribution of a journal to the category excellence, independently of its size. The Journal Brute Excellence (JBE) reflects the total brute excellence force or brute contribution of the journal to the category. It also plays a crucial role in order to estimate the effect of multidisciplinary journals in the category and especially their contribution to the excellence in the category.

This study also reveals that the effect of the multidisciplinary journals is very different according to the category and it is generally stronger in the hard sciences.

In this pilot study, which was restricted to five subject categories, our excellence indicators have shown a robustness concerning the consideration of all types of documents instead of only articles and reviews. Therefore, they provide an amelioration of the inherent asymmetry reflected in the definition and calculation of Garfield's Impact Factor.

Another advantage of our excellence indicators relies on the practical aspect for the measurement of the visibility of publications. When using the Impact Factor for this purpose, there is always a controversial decision: what JCR Edition should be used? There are three possibilities: a) using JIF values of the last JCR-edition for all publications independently of their publication year; b) Using the JCR-edition corresponding to the publication year of each publication; and c) using the mean value of the last *x* years according to the time period under study. Anyone of them is completely satisfactory (Glänzel et al., 2016). Our excellence indicators circumvent this problem because they are based on accumulated measures including the last ten complete publication years and are not restricted to two years or a selected JCR edition.

One of the possible applications of our study is to prevent the use of JCR Categories for the delineation of scientific areas, as has been done in many previous bibliometric studies. Our study warns of serious consequences of this approach, as contributions from multidisciplinary journals are not considered in some categories. For example, reducing the study to only journals of the category in Virology or PHM would mean missing a large part of the scientific breakthroughs and excellent publications, which are regularly published in multidisciplinary journals. In economics, however, this contribution is not notable, and in LIS or HIS, only sporadic contributions can be observed.

Although it is well known that journal impact measures do not work well in the Arts and Humanities and can lead to false interpretations (Repiso et al., 2019), we have also considered the category "History" in an exploratory way. However, in these disciplines it will be crucial to determine which types of publications contribute most to excellence, and this will be part of our future studies.

Future analyses could also be extended to include the effect of interdisciplinarity. Unfortunately, InCites does not offer the possibility to measure this effect, because the subject classification is made on journal level, except for the multidisciplinary journals (on publication level). The recent introduction of the publication based "Citation Topics" may be an improvement in InCites. This topic will also be part of our future analyses.

Abstract

Literature obsolescence has been widely studied in scientometrics. Yet, most existing research has studied a set of publications (e.g., those in a certain discipline or a certain journal; the macro-level analyses) instead of each individual publication (e.g., the micro-level analyses). Among micro-level analyses, Bailón-Moreno et al. (2005) proposed a model by dividing the citation "life cycle" into four periods. Yet, their model remains on a conceptualisation level. To this end, the current paper shows a feasible way of operationalising their model and of implementing a set of cross-discipline publications in the Web of Science database to test its performance. In the operationalisation, we are particularly interested in two stages of literature ageing, namely the sleeping period (SP) and the recognition period (RP). We find that 50% publications in *Arts & Humanities* almost receive no citations in the first five years after their publication; and the distribution of SP and RP varies a lot in different disciplines. Obsolescence differences among publications could shed light on many useful political implications.

Background and Research Objective

Literature obsolescence refers to the phenomenon that the content/value of literatures is increasingly out of date and is utilised less as time goes by (Gupta, 1990). For decades, indicators and mathematical models have been proposed, such as the length of half-life (Tsay, 1998) and the Price index (Egghe, 2010). These pioneer studies have painted a macro-level picture of the publication ageing issue and have shed light on science policy decision-making and library information resource services (Clermont, Krolak & Tunger, 2020; Kinney, 2007; Perrault et al., 1999; Petersen et al., 2014). However, although having shown universal patterns of literature obsolescence, most of the existing studies did not study details of the obsolescence process for *each individual paper*, i.e., a micro-level exploration. We believe that investigating individual paper-level obsolescence helps understand the laws in this citation dynamics more deeply and will guide practices in research evaluation.

As an important contribution to studying individual publications' obsolescence, Bailó n-Moreno et al. (2005) proposed a generalised model for studying individual publications' ageing process (the GMAV model). Their proposed model conceptually partitioned the period after a paper was published into four periods according to its citation rate:

Period X (Period I): the publication has low transition capacity, and it will not be cited;

Period P (Period II): the publication has high transition capacity to influence other literatures;

Period C (Period III): the publication is being cited currently, and it could maintain this period in the future. However, it has a trend of moving to Period N; and

Period N (Period IV): the publication has been cited, but its citation rate has declined currently. It is likely that the publication will transition to Period C, but such a probability will diminish with time.

Nonetheless, Bailón-Moreno and colleagues' work remains at a conceptualisation level without presenting detailed operationalisations, which hinders future bibliometricians from widely adopting their model in practice. To this end, **the research objective of the current paper** is to offer a feasible operationalisation of Bailón-Moreno et al.'s (2005) GMAV model. The operationalisation is based on the annual citation time series of a given publication. We showcase the usage of our operationalisation by particularly focusing on the lengths of Period I (sleeping period, abbreviated as SP) and Periods II+III+IV (recognition period, abbreviated as RP). In the empirical study, we adopt all publications in 1985 in the Web of Science database, which covers papers in all disciplines, and implement a cross-discipline analysis. Our dataset covers at least a 30-year-long time window after they were published to guarantee that the citation window is of sufficient length empirically.

Yet, to quantify the length of Periods I-IV, we also need to empirically define Period V (the period after Period IV), in which publications do not receive citations (no longer being "adopted"). This is necessary when people calculate the length of RP (or Periods II+III+IV). In this paper, our operationalisation also highlights this new contribution.

The rest of this paper is organised as follows. We first present previous related papers on literature obsolescence. We then detail how we operationalise the model. Next, we introduce our dataset and show the empirical results based on all publications and those in different disciplines. We also showcase a mini case study to illustrate more details in our operationalisation. Finally, we discuss potential implications, both methodologically and politically, and suggest future work.

Related Work

Literature obsolescence has been widely studied in scientometrics and bibliometrics since the 1940s (Glänzel & Schoepflin, 1995; Sengupta, 1992). Extant related work can be summarised as two different levels (**macro** and **micro** levels), which differ from each other in terms of their research object – the former focuses on *a set of* publications (e.g., those in a certain discipline) while the latter focuses on individual publications.

On the macro level, half-life is an important indicator for measuring obsolescence. Yet, there are two ways of calculating half-life, namely diachronic and synchronic strategies. Generally, both strategies are equally feasible to measure literature obsolescence, but different results would be obtained with the two strategies when considering other factors such as the growth of literatures (Egghe, Rao, & Rousseau, 1995). The diachronic strategy first selects a set of publications and collect their citations' data in the following several years (after their publication); as for the synchronic strategy, we select a particular year and examines all past publications cited by the publications in this particular year. For example, the half-life proposed by Bernal (1958) is diachronic. Later, another concept of half-life based on the synchronic method was proposed by Burton and Kebler (1960), and this is defined as the publication interval of the 50% recently published literature cited by a certain current publication (of a journal or a discipline), which is also called median citation age. Although different, both strategies have been widely used in the calculation of the degree of literature obsolescence. For example, the Journal Citation Report (JCR) adopts both concepts and offers two indicators for journals, namely cited and citing half-life: the former equals the interval of the 1/2 new citing papers of a journal while the latter is the interval of the 1/2 new references of this journal. While the value of the half-life indicator may vary in different years and disciplines, the average value among years is generally used to describe the degree of obsolescence. In addition to the half-life indicator, people also adopt the Price Index to characterise obsolescence, calculated by dividing the number of references published in the previous five years by the total number of references published in the current year. Egghe (1997) proposed the N-year Price Index to supplement the original Price Index by extending five-year-long time-window of this indicator to any integer, N. He pointed out that there exists a certain relationship between Price Index and half-life indicator. Additionally, on a more theoretical yet crucial level, some research has also been devoted to exploring the law of obsolescence and to constructing some literature obsolescence models (e.g., Avramescu, 2007; Burton & Kebler, 1960).

Compared with macro-level studies, the number of micro-level approaches is much smaller, but it offers more details on the process of publication ageing. For example, Wei and Qian (2005) pointed out that every measurement of obsolescence was an estimation in statistics, and the half-life indicator or Price Index of literature could be regarded as point estimation while micro-level approaches could be seen as interval estimation. In other words, micro-perspective research could calculate the probability that the true value falls into this interval, which outperforms macro-level studies. Zhang and Glänzel (2017) found that it might be extremely different in the distribution of Price Index of individual papers that were published in two journals with a similar Journal Price Index. For example, supposing there are two journals, one is composed of 50% small Price Index papers and 50% large Price Index papers, and the other is completely composed of papers with medium Price Index papers. This would result in a similar macroscopic Price Index (journal's Price Index), yet the microscopic Price Index (paper's Price Index) would be quite different, as aforementioned. As a pioneer, Price (1963, 1976) first linked micro-level studies with the half-life indicator. He extended the concept of half-life, and proposed that the half-life value of an individual publication equals the interval of publication of its new 50% citing papers. Price (1963) indicated that the half-life of a paper was about 1.5 years, which meant that half literatures which cite this literature were published within 1.5 years after the publication of this literature.

Model Operationalisation

In his model, Bailón-Moreno (2005) proposed three transitions based upon the aforementioned four periods: the transitions from period *P* to *C*, from *C* to *N* and from *N* to *C*. These transitions represent an increase or decrease of the literatures' citations in different ageing stages. While Bailón-Moreno's model remains at the conceptualisation level, we operationalise the model in a doable way (and adopt a numbered naming strategy for simplicity):

Period X (Period I): the publication's citation count conforms to a zero-growth model, and the number of citations is equal to or is approximately equal to zero;

Period P (Period II): the publication's citation conforms to an exponential model, and its citation count has an accelerating growth;

Period C (Period III): the publication's citation conforms to a linear model, and its citation count grows at a smooth speed;

Period N (Period IV): the publication's citation conforms to the deceleration stage of a logistic model, and its citation count decreases over the years.

This operationalisation indicates a temporal-based ageing process of an individual paper by examining the temporal change of its annual number of citations. Generally, one paper will have a *Period I* after its publication, then its citations may grow quickly in *Period II*. Later, the growth rate decreases and its citations maintain a slow growth, i.e., *Period III*. It then comes to *Period IV* and decays. Finally, the publication will not be cited and adopted anymore (*Period V*). Note that Period V was not mentioned in Bailón-Moreno et al.'s model. Yet, to operationalise Periods I to IV (especially their lengths), we have to define this period when there are no additional citations received. It is worth noting that some publications will not experience all these periods, e.g., "uncited papers" only have *Period I*. The process is illustrated in Figure 1.

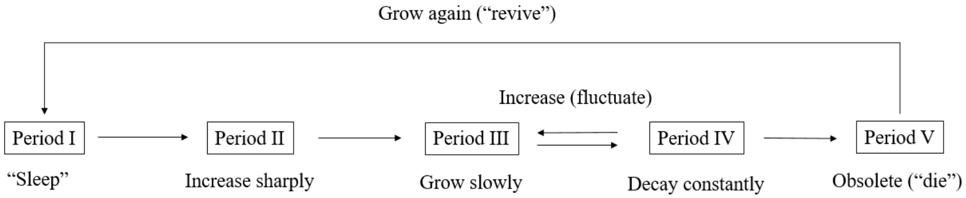

Figure 1. Annotation of the publication obsolescence process.

We then further stipulate the rules of operationalisation as per Raan (2004) by examining the annual number of citations of a publication in each year after it was published:

a) If the number of citations of a specific paper in the first year after its publication is fewer than 2, its state in the first year is *I*; otherwise, the state in the first year is *II*.

b) Given a particular year, if the state of a specific paper in the previous year is *I*, and the number of citations in this year is fewer than 2, the state in this year is *I*; if the number of citations is equal to or greater than 2, the state in this year is *II*.

c) Given a particular year, if the state of a specific paper in the previous year is *II*, and the number of citations in this year is 20% greater than that of previous year, the state is *II* in this year; otherwise, the state is *III*.

d) Given a particular year, if the state of a specific paper in the previous year is *III*, and the number of citations in this year is equal to zero or is 10% smaller than that of previous year, the state in this year is *IV*; otherwise, the state is *III*.

e) Given a particular year, if the state of a specific paper in the previous year is *IV*, and the number of citations in this year is 10% greater than that of previous year, the state in this year is *III*; if the number is not 10% higher than that of previous year and it is fewer than 2, the state in this year is *V*. If either of the two conditions is satisfied, the state in this year is still *IV*.

We adopt iterative check to reduce the volatility as: if the state of the publication in the previous year is the same as that in the following year, the state in the current year would be adjusted to the same period. With this definition, the transitions between states in our new model, shown in Figure 1, and their indications are:

I to II: the literature's citing papers are not subject to their publishing delay (or other unknown factors) and are published successfully, so the literature starts to receive citations.

II to III: the growth of citations has gradually slowed down. For example, prior to this transition, the literature's citations grow rapidly as it is spreading to the author's peers; now, nearly all colleagues are aware of it, so it keeps citation counts at a high level but the growth slows down.

III to IV: the number of citations starts to decrease; knowledge in this literature seems out of date gradually.

IV to III: the transition from Periods IV to III represents the fluctuation of citation counts. For example, the number of citations was decreasing over time, but it increases later as, for instance, some new studies start to discover and cite the literature more frequently.

IV to V: the literature is "dead" and it will not be cited to a large extent.

Experiment

Data

The dataset used in the current study comes from Indiana University Network Science Institute (IUNI) in-house version Web of Science (WoS). It contains the bibliographic data of high-quality journals, conference articles and monographs. Although the WoS is not exempt from limitations on its coverage (Mongeon & Paul-Haus, 2016; Moya et al., 2007), there are at least two reasons why we choose this dataset for our search. On the one hand, the WoS covers a variety of disciplines and a large amount of data at the international level; on the other hand, the journals it covers is selected by experts. We select all WoS papers published in 1985, and set their citation window as 30 years[1].

Table 1. Number of publications in each discipline.

Discipline	# pubs (%)
Arts & Humanities	111,338 (12.46%)
Clinical, Pre-Clinical & Health	253,723 (28.39%)
Engineering & Technology	121,392 (13.58%)
Life Sciences	216,489 (24.23%)
Physical Sciences	179,562 (20.09%)
Social Sciences	100,314 (11.23%)

Specifically, our dataset includes 893,647 distinct publications; these publications have been cited 12,804,905 times. These publications are labelled as *one or more* fields from 250+ subject categories from the classification system of Clarivate[2]. All of these 250+ subject categories are categorised into six disciplines, namely *Arts & Humanities*, *Clinical, Pre-clinical & Health*, *Engineering & Technology*, *Life Sciences, Physical Sciences*, and *Social Sciences*. The numbers of publications under these six disciplines are shown in Table 1. Figure 2 shows the citation distribution of the publications in our dataset.

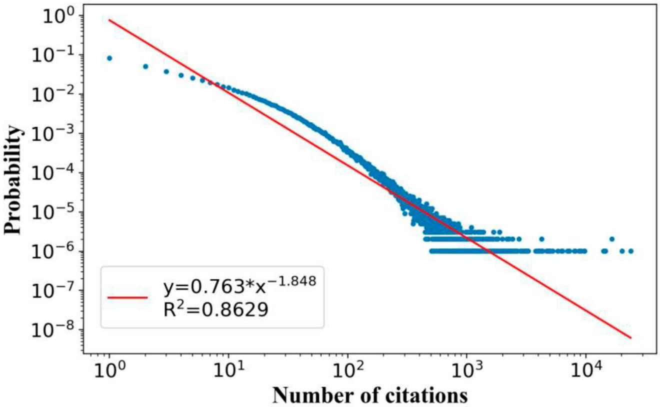

Figure 2. Density distribution of publications' number of citations

Results

For the five-period framework as aforementioned, *Period I* represents the state when a paper has no or a few citations (the annual citation counts should be fewer than 2), and the following three periods (a.k.a., *Periods II+III+IV*) indicate that the paper starts to receive citations, regardless of its trends – increasing or decreasing. To this end, we particularly focus

[1] Some papers were published in January and some papers were published at the end of 1985. Thus, we select the data from 1985 to 2015 (including 2015) to ensure the citation window is not shorter than 30 years, so some papers' citation window will be close to 31 years. But, compared to the citation window, the nuance is so insignificant that we can ignore it.

[2] http://help.prod-incites.com/inCites2Live/indicatorsGroup/aboutHandbook/appendix/mappingTable.html.

on the below two partitions, namely the lengths of *Period I* (sleeping period, annotated as SP) and of *Periods II+III+IV* (recognition period, annotated as RP). Figures 3a and 3b present the distribution of length of SP and RP, respectively.[3]

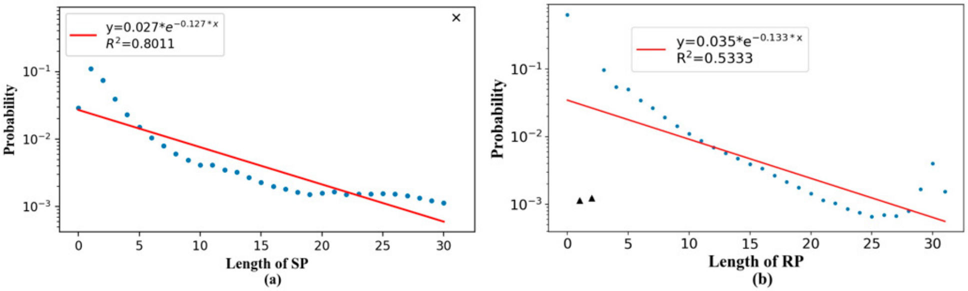

Figure 3. Distribution of the lengths of SP (a) and RP (b).

The black cross ("x") in Figure 3(a) (top-right of the subfigure) represents papers which are always in *Period I* without entering the following period(s). Researchers call them "uncited papers" and they will not be included in the following analyses[4]. The round dots ("·") represent the "cited papers" as they would experience other periods besides *Period I*. By fitting the distribution of SP length for the round dots, we find that the distribution of SP conforms to negative exponential distribution. It suggests that, for the "cited papers", many of them have a short SP, and with prolongation of SP, the number of papers decreases exponentially.

Similarly, we use several functions to fit the distribution of RP and obtain the fitting effect, as Figure 3(b) shows. The distribution of RP also conforms to negative exponential distribution and it shows that most literatures have a short RP. It is worth noting that the fitting effect (R^2) in Figure 3(b) is worse than that in Figure 3(a). By analysing Figure 3(b), we find that the difference mainly comes from the special dots (two black triangles, left-bottom in Figure 3(b)). It can be considered that these triangles represent a special kind of literature called "early rise, rapid decline" (Aversa, 1985) which receives many citations rapidly after its publication and declines quickly after reaching its peak. There are only a limited number of "early rise, rapid decline" papers, and they tend to have a short RP, so the R^2 in Figure 3b is not as good as that in Figure 3(a).

Regarding discipline-wise results, the basic descriptive statistics are shown in Tables 2 and 3. For example, the mean of SP for *Clinical, Pre-Clinical & Health* is 3.98 and that of the RP is 6.96, which illustrates that, on average, the papers belonging to this discipline receive virtually no citations in the first four years after their publication and will tend to be cited in the following seven years (years 5 to 11). After that, the popularity of these papers drops down dramatically and will tend to receive very few citations.

[3] The year of publication is stipulated as 0 instead of 1, and this is also applied for all the following analyses.

[4] The triangle represents the papers that are always in *Period I*; it should be the long-tailed distribution. But we set it as 31 in the X-axis and it is beyond the confines of our citation window (30 years), so our following analyses will not contain these papers (this triangle).

Table 2. SP length of publications in different disciplines.

ID	*Discipline*	*Mean*	*Q1*	*Q2*	*Q3*	*# pubs.*
1	Arts & Humanities	9.92	2	5	19	3952
2	Clinical, Pre-Clinical & Health	3.98	1	2	4	98679
3	Engineering & Technology	5.5	1	3	6	33351
4	Life Sciences	3.62	1	2	4	109039
5	Physical Sciences	3.87	1	2	4	91980
6	Social Sciences	5.98	2	3	7	21310

Note: Publications that only have *Period I* are not included; the same below.

Table 3. RP length of publications in different disciplines.

ID	*Discipline*	*Mean*	*Q1*	*Q2*	*Q3*	*# pubs.*
1	Arts & Humanities	4.66	3	3	5	3952
2	Clinical, Pre-Clinical & Health	6.96	3	5	8	98679
3	Engineering & Technology	6.04	3	4	7	33351
4	Life Sciences	7.36	4	5	9	109039
5	Physical Sciences	6.59	3	5	7	91980
6	Social Sciences	6.79	3	5	8	21310

We can see that some disciplines' SP and RP are similar, such as the *Clinical, Pre-clinical & Health* and *Physical Sciences*, and both their mean values of SP are close to 4. We also observe some differences between the two average values, such as the *Arts & Humanities* (RP mean = 4.66) and *Clinical, Pre-clinical & Health* (RP mean = 6.96). To further explore inter-discipline differences of SP and RP, we employ the Kruskal-Wallis test (KW-test) to test the significance of their difference. KW-test is a nonparametric test for multiple samples. It could be used in the analysis when the distribution of the sample is unknown, so it has a good applicability without limitation of distribution of samples. The distribution of data, SP and RP, does not conform to normal distribution; this is the main reason why we choose the KW-test. SPSS 25.0 is adopted to implement these analyses.

We present the KW-test from two perspectives, namely the whole samples without considering two specific disciplines' statistical differences (Table 4), and for all discipline pairs (Table 5). We can see that there are significant differences in the distributions of SP and RP lengths between disciplines. However, the result in Table 4 is only true for the whole disciplines, and we do not know the significance of difference for two specific disciplines. Therefore, we need to further analyse the test result. The results in Table 5 show that the difference of distribution of SP length is significant and it exists in any two disciplines, which is also the case for the distribution of RP length.

Table 4. KW-test for the whole disciplines. Two stars (**) represent $p < 0.01$.

Test	***Sig.***
KW-test for SP length	.000**
KW-test for RP length	.000**

Table 5. KW-test (*test statistic*) results of SP (bottom-left) and RP (top-right) lengths for discipline pairs.

Discipline	AH	CPH	ET	LS	PS	SS
AH	-	-66341.7**	-42062.5**	-73832.9**	-57364.4**	-52464.3**
CPH	65338.7**	-	24279.2**	-7491.2**	8977.3**	13877.4**
ET	42155.7**	-23183.1**	-	-31770.5**	-15302.0**	-10401.8**
LS	80215.1**	14876.4**	38059.5**	-	16468.5**	21368.6**
PS	74864.1**	9525.4**	32708.4**	-5351.0**	-	4900.1**
SS	26098.9**	-39239.9**	-16056.8**	-54116.3**	-48765.2**	-

Note: (1) Significance: *: p<0.05; **: p<0.01. (2) Abbreviations: Arts & Humanities (AH); Clinical, Pre-Clinical & Health (CPH); Engineering & Technology (ET); Life Sciences (LS); Physical Sciences (PS); and Social Sciences (SS).

Based on these analyses, we find that the mean of SP length of *Arts & Humanities* is the longest and its mean of RP length is the shortest. In contrast, the mean of SP length of *Life Sciences* is the shortest and its mean of RP length is the longest. There exist significant differences in the distribution of SP and RP lengths between any two disciplines, which indicates that the differences of obsolescence processes between science disciplines exist objectively.

A case study

To depict more nuances for the SP and RP of literatures, we select several cases according to the lengths of SP and RP from *information science & library science*. The first case (Paper A) has a short SP and RP. The second case (Paper B) has a short SP but a long RP. The third case (Paper C) has a long SP and RP. As the paper with a long SP but a short RP is so special, it needs to have some characteristics of two kinds of literatures – the literature we called "sleeping beauties" (van Raan, 2004) and the literature we called "early rise, rapid decline" (Aversa, 1985). As this kind of paper is too rare to carry out a case study, the analysis in this subsection does not include such a case. The bibliographic information of the cases is shown in Table 6. Their numbers of citations in each year are illustrated in Figure 4. Again, the citation window is from 1985 to 2015.

Table 6. Bibliographic information of the three cases. All three papers were published in 1985.

	Title	***Author***	***# cits***	***# refs***	***Journal***
A	Critical Thresholds in Co-Citation Graphs	Shaw, W. M.	18	30	*Journal of the American Society for Information Science*
B	Alternative Measures of System Effectiveness - Associations and Implications	Srinivasan, A.	218	29	*MIS Quarterly*
C	Finding Minimal Enclosing Boxes	O'Rourke, J.	41	11	*International Journal of Computer & Information Sciences*

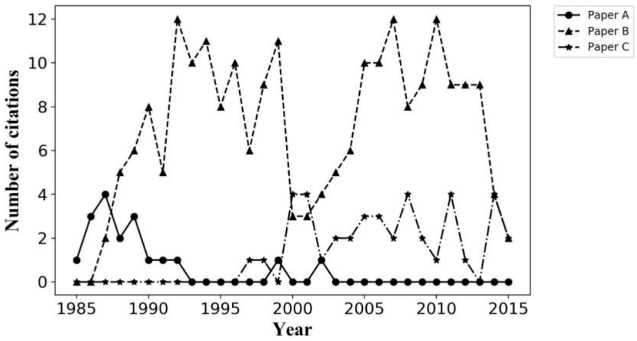

Figure 4. Annual number of citations over the years for the three selected cases.

Paper A (Shaw, 1985) discussed the threshold of co-citation graphs. We can see from Figure 4 that this publication only received one citation exactly in the year when it was published. In the second year after publication (i.e., 1987), it had a short RP and reached its citation peak. After that, its number of citations decreased, and around 1991, it had been obsolescent and had no or few citations in the following two decades. By analysing those citing papers of Paper A, we find that the first citation of Paper A is a self-citation and that its first non-self-citation appeared in 1986.

Paper B (Srinivasan, 1985) studied the effectiveness of Management Information Systems (MIS). Compared with Paper A, Paper B's topic is more concerned with many active scholars – the author researched users' behaviours and system utility and proposed a standard for system evaluation. This research was quite innovative, which was reflected in its early citing papers. Some scholars (Zahedi, 1987) mainly focused on the difference between Paper B and previous empirical studies, while other scholars (Montazemi, 1988) mainly concentrated on the measurement indicators and methods mentioned in Paper B. The great contribution of this publication might be the reason for its long RP. Furthermore, the citing papers of Paper B might improve its popularity further. The mean number of citations of its first 10 citing papers is 845 as there is a "super" citing paper with 7849 citations. Even if that paper is excluded, the mean of citation counts of its first nine papers is 60. These citing papers may improve the citation-based impact of Paper B implicitly.

Paper C studied the minimal volume box for a set of 3-D points (O'Rourke, 1985). In this publication, the author proposed a new algorithm which could find all minimal volume boxes for a set of n-points with the complexity of $O(n^3)$. From Figure 4, we can see that Paper C had a long SP of 15 years. However, the academic contribution of Paper C exists objectively, which is reflected by its long RP. Thus, its long SP might be affected by some external factors, such as the author's career stage and the research topics.

Discussion

This paper operationalises a conceptual model of studying the obsolescence of scientific publications. The operationalisation has three **highlights**. Firstly, we operationalise the model by purely using the annual number of citations of publications, which is feasible for many future bibliometricians. Secondly, the operationalisation contains a new period (Period V) compared with Bailón-Moreno et al.'s (2005) model. The new period captures the "death" state of a publication, indicating that the article will not be cited (to a large extent). The new period helps quantify the length of Period IV in a more accurate way. Finally, our study emphasizes a complex feature of citation dynamics and provides empirical evidences against the use of short-term citation on metrics in research assessment exercises.

We do not quantify the length of Periods I to IV one by one in our empirical study. More particularly, we are interested in two periods in publications' citation life cycle, namely the sleeping period (SP) and recognition period (RP). We find a significant difference regarding the ageing patterns in various domains. For example, we see that 50% of publications belonging to *Clinical, Pre-Clinical & Health* have no or very few citations (annual citation counts equal 0 or 1) during the first two years after their publication (see Table 2). In addition, the case study indicates that there are many complex, external factors (e.g., self-citations, author's career stage, etc.) that may affect SP and RP lengths.

For future bibliometricians, there are two ways of applying our operationalisation. On the one hand, as shown in the current paper, they can purely characterise the lengths of SP (Period I) and RP (Periods II+III+IV) as an easier strategy; this strategy particularly functions when the number of focal publications is great. On the other hand, as citations are at the basis of several quantitative measures increasingly used in evaluation criteria aimed at evaluating career trajectories of scholars (Edwards & Roy, 2017) and research performance of institutions (Bornmann, Haunschild, & Mutzm, 2020), bibliometricians and research evaluators could quantify the lengths of each individual period one by one and present a more nuanced picture of each obsolescence process. That will show more accurate details in research evaluation.

Regardless of which strategy is utilised, our operationalisation offers many interesting and useful implications for science policy makers and funding providers. From tables 2 and 3, we observe quite different patterns for various domains. For example, *Arts & Humanities* has a mean value of 9.92 in terms of SP (~2.5 times that of *Physical Sciences*) but a mean value of 4.66 for RP (the shortest). This indicates to funding providers that they should establish a different rule/criterion to evaluate scholars/works in *Arts & Humanities*. Specifically, these works should be given a longer time to be discovered compared with other domains; more detailedly, the mid-term examination of scholars in this discipline may need to be softened.

Limitations and future work

This pilot study has many limitations. From the perspective of operationalisation, the lengths of Periods II, III, IV, and V are not considered separately in our empirical study. We, therefore, are going to implement more detailed analyses of these periods with more sophisticated strategies, such as advanced time series analysis and parameter settings in operationalisation. Additionally, we observe a special but crucial phenomenon from the citation curves of the publications – the "revival" – and these special publications will experience another *Period II* after *Period V*. This indicates that, although a certain publication has been "dead" (receiving no citations) for quite a long period, sometime it is cited again by a very recent publication. In the future, we are also going to explore this phenomenon by extending the current operationalisation framework.

Abstract

The purpose of this study is to assess the validity of citation metrics based on disciplinary representative surveys. The present project fills the gap by comparing citation rankings for individual scientists with expert judgements collected through a survey of 3,689 Russian sociologists. We used scientometric indicators not limited only to traditional metrics (Hirsch index and Impact Factor), but also special indicators developed by the Russian Index of Science Citation. We conclude that scientometric indicators predict the names of the most influential sociologists with significant accuracy. Citation metrics and survey results converge to a large extent, at least with regard to the goal of identifying the disciplinary elite. We found two types of deviations—false positive and false negative identifications. False positive identifications (high results in scientometrics, but low in the survey) are explained by specialization in writing textbooks and the explicit gaming of metrics, which can, however, be identified.

Introduction

The issue of validity of citation metrics was raised with the launching of the first citation index by Eugene Garfield in the early 1960s. The idea behind the Science Citation Index was to create the infrastructure to enable effective searching of scientific information. However, citation metrics had begun to be considered as a way to measure academic recognition very soon after the launching of the index (Cole & Cole, 1967). The interest in citation rankings was boosted by the expansion of quantitative indicators for research assessment of individual academics, departments, and disciplines. Many countries have launched performance-based research funding systems in which citation metrics are an integral part (Hicks, 2012). Besides the use of scientomentics at the national level, the phenomenon of 'citizen bibliometrics' has come into existence—citation metrics are used by groups, other than professional, including scientists and administrators in everyday evaluation of individuals practitioners (Hammarfelt & Rushforth, 2017). The reliance on quantitative indicators of research productivity was perhaps the most important recent transformation of academic institutions (Auranen & Nieminen, 2010; Espeland, Sauder & Espeland, 2016; Muller, 2018). As a result, the issue of the validity of citation rankings has been discussed widely based on empirical attempts to demonstrate whether citation data are a valid means of measuring scientific performance.

One way to assess the validity of metrics is by studying the degree of their correspondence with expert judgements (So, 1998; Serenko & Dohan, 2011). Researchers conduct academic reputation surveys, in which specialists in a discipline evaluate journals, institutions, individuals, or texts. Disciplinary surveys are considered a reliable way to measure academic quality—recognition or impact—directly, rather than by a proxy through citations. A review of various studies on the validity of citation metrics demonstrates that not much research has been conducted with a focus on individual scholars. While this can be explained by the fact that individual scholars are seldom evaluated in the course of national evaluations (So, 1998), they are nevertheless assessed in the context of faculty hiring, tenure, or promotion. In addition, establishing validity using survey data is less common due to the complexity of organizing a large-scale disciplinary survey. Our research strives to solve the classic problem of assessing the validity of citation metrics by comparing citation rankings for individual scientists and expert judgements collected through a survey of Russian sociologists.

Literature review

The most common method of estimating the validity of citation rankings is to compare expert judgements and citation metrics; high correlation suggests that the validity of bibliometrics has been established (So, 1998). This validation relies on the idea that peer review is the gold standard for scientist evaluation (Wainer & Vieira, 2013; Aksnes & Taxt, 2004). Peer reviewers are considered to be capable of conducting both objective and nuanced evaluation. The advantage of peer-based rankings is their suitability for the development of national and regional rankings for which citation data are not always relevant (Mahmood, 2017) as global citation databases represent mainly English-language journals (Mongeon & Paul-Hus, 2016). During recent decades a number of studies have examined how citation indicators can be correlated with the results of peer reviews. The studies focus on different types of research outputs from entire nations down to individual researchers.

The first way to obtain peer review results is to use evaluations conducted in the course of national evaluation exercises. Governments provide data to researchers to assess the correspondence between peer review scores and citation metrics. Aksnes and Taxt (2004) examined how the outcome of the evaluations conducted by the Research Council of Norway correlated with various citation metrics. In a study of the natural sciences, they found weak positive correlations for all indicators: for the three citation-based metrics the correlation coefficient varied between 0.24 and 0.46 (Aksnes & Taxt, 2004). Wainer and Vieira (2013) conducted research to determine the correlation of various bibliometric measures to peer judgements of scientists working in 55 different scientific fields. They used the evaluation system in Brazil as their source of data. Peers evaluated the scholarship level for individual scholars, and the change in a scientist's level might be considered as the result of the peer evaluation.

The second method of gathering peer judgements is conducting surveys among active researchers in the field for their opinion on the importance of individuals, departments, or journals. More recent studies attempt to establish the validity of citation rankings using journals as an object. Serenko and Dohan (2011) examined whether expert judgements and journal impact measures generate consistent ranking lists in the field of artificial intelligence. Ellis and Durden (1991) studied journals in the field of economics and found that journal reputation is a reflection of the scientific impact measured through citation metrics, although for some journals the correspondence is not large. They found that highly ranked journals tend to have better reputations than their citation impact would predict, and that lower-ranked journals tend to have poorer reputations than their impact would justify (Ellis & Durden, 1991).

So (1998) noted that comparisons between citation metrics and peer evaluation seldom rely on individual scholars as a source of data, compared to journals, research articles, or institutions. We review further the main studies that use individuals as the subject to compare citation metrics and expert opinions. Norris and Oppenheim (2010) conducted a survey of library and information science academics to examine how the results of peer review can be correlated with the h-index. The survey was designed to collect data on the perceived quality of the world's leading academics. The result was a correlation between 0.397 and 0.518 for the h-index, depending on the citation database, which is considered to be medium or large effects (Norris & Oppenheim, 2010). Li et al. (2010) extended the analysis of Norris and Oppenheim (2010) by examining how the peer judgments correlate with citation metrics from different databases, not only from WoS. They confirmed the results of the previous study by discovering strong significant correlations of citation metrics with the expert judgments of 42 LIS experts. However, they were cautious of using citation-based indicators as a cost-effective alternative to the use of experts as the strongest correlation was only 0.552.

Roettger (1978) pioneered an attempt to determine the elite system of a discipline over time. He found agreement on the top ten contributors in political science, but there is less agreement down the ranking as well as diminishing agreement over time. Robey (2012) compared the reputational ranking of political scientists with the ranking by citation and found that the reputational method produces a different list of prominent scholars from the results of citation metrics. He concludes that the reputational method probably includes a number of ways to contribute to the field, while the citation method identifies a more specific type of contribution. So (1998) compared the citation method with peer review judgements in the evaluation of individual scholars in the field of communication by asking respondents to rank the 10 selected scholars in their respected field. He intended to find out how the size of the research specialty and scholar prominence matter for these evaluation methods. So (1998) found results suggesting that the citation method and the peer review provide basically the same outcomes: only a few evaluated scholars are "misplaced" in the peer review method. He also found that correspondence between citation evaluation and peer review is more stable for smaller research specialties which provide more stable results. So (1998) demonstrates the validity of the citation method and concludes that citation data might be used as an alternative and even a substitute for peer review in evaluation of research performance. All these studies point to the necessity of conducting surveys on large samples that guarantee a range of research interests.

To conclude, numerous studies demonstrate mixed results: "whereas several investigations conclude that both methods may be used as substitutes, others report negligible or even negative correlations between the obtained journal scores" (Serenko & Dohan, 2011). Wainer and Vieira (2013) found that the strength of the effect depends on the academic discipline, which prevents generalizing from previous research in peer judgement correlations in one discipline to other research fields. It is also important to conduct studies for each national context.

Methods

The Russian Index of Science Citation (RISC), launched in 2005, is integrated with a full-text platform, the Scientific Electronic Library, which indexes more periodicals than RISC (Moskaleva et al., 2018). RISC provides opportunities for both scientometric research and disciplinary survey. First, in contrast to international citation databases, RISC provides access to citation data based on a wide range of Russian sources, which makes it possible to study non-Western Russian social sciences and humanities. Second, RISC has developed a convenient storage system for scientometric information, which allows extracting citation metrics from profiles for a large sample of scholars. Third, RISC has elaborated a number of additional indicators that are not available in international citation databases. These indicators have been implemented to indirectly indicate the quality of the research and, in some cases, the degree of citation gaming: (1) the share of self-citations, (2) the share of publications and citations from the most selective journals, (3) and (4) the impact factors of the publications in which the papers are published and cited, and (5) the share of citations by co-authors.

The main method for collecting empirical information is the online reputation survey of Russian sociologists for evaluating the degree of convergence of expert judgments and metrics. Forming a sample of scientists is especially problematic for a fragmented discipline that is divided into practically isolated research groups or political camps. The sample should take into account the variety of disciplines and, ideally, cover all scientists. We believe that RISC reduces the problem of selecting scientists to participate in the survey as it is difficult for active scholars to bypass the RISC-indexed journals. Recently, Russian universities were required to register their entire faculty on RISC to provide information for state reports. Many universities created a special position that was responsible for the input of information into the database. Thus, we can conclude that RISC contains a relatively representative dataset of Russian scholars. Therefore, RISC covers a population of scientists close to the general population of the scientific field.

We selected authors (a) who have at least three articles in RISC over the past five years (since we strive to survey active scientists); (b) most of whose articles were published in journals classified by RISC as belonging to sociology, or most of whose citations come from such sources; (c) who are registered in the RISC system and who provided an email address in their profiles. Overall, we ended up with 3,689 profiles to whom the survey was sent by email. Subsequently, we received 818 responses (over 20%) which can be considered a good response rate for online surveys. The respondents accurately represented the general population in terms of the organizations with which the scholars are affiliated.

Results

To measure academic reputation, we developed several questions: (1) who among the Russian sociologists [they] would suggest to include in the national jury of experts which evaluates the work of colleagues; (2) who among the Russian sociologists [they] would nominate for an honorary medal for an important contribution to the development of sociology in Russia; (3) who has published research in recent years that [the respondent] found to be particularly interesting (not necessarily in [the respondent's] area of specialization, and (4) who has published research in recent years that [the respondent] found to be particularly interesting in [the respondent's] area of specialization. The sequence of questions may have influenced the results.

One would expect the answers to provide a different set of sociologists. The medal suggests lifelong achievement and the answer to this question will be a list of recognized scholars, while the recent publication of important articles will yield more names of young scientists. We also expected that the distribution of the authors of the influential works should be the least concentrated, since the respondents themselves work in different fields. The distribution of the twenty most frequently mentioned figures in each of the nominations shows that the lists of names obtained from answers of different questions were largely the same. In total, 10 people were on all four lists, another 10 in three out of four lists, six in two lists, and 12 in only one list, and in the vast majority of cases, these 12 share the last lines with someone. In three of the four lists, the largest number of nominations refers to the same three names. There are only two cases when a top 10 scholar in one list fell below the top 20 in at least one of three other lists. We conclude that academic status in sociology is a generalized category, and reputation is less specific than one might expect. So for further calculations, we add the number of times a sociologist was mentioned in any of the four lists of nominations. It provides us with a variable with a larger number of observations.

The data obtained require the use of specialized regression techniques that take into account the nature of such data (negative binomial regression and zero-inflated models). We used negative binomial regression (detailed models can be provided by request). First, we entered the main indicators separately controlled by the research field (Models 1–6). Model 7 presents the main indicators all together. The next model is the one with all the main indicators supplemented with additional more sophisticated indicators (Model 8). For each model, we consider four metrics: AIC, BIC, and two characteristics of the sorting accuracy—the proportion of predicted values based on the scientometric indicators among the top 20 and top 100. The AIC and BIC metrics can be interpreted as the accuracy with which the model approximates the distribution over all values of the dependent variable, and top points out its ability to predict the position at the top of the rating.

All the models offer a significant improvement over the basic model with only controls (having an AIC and BIC of about 13,000). Moreover, for models with a single main variable (Models 1–6), the best results are obtained with the number of articles in the RISC Core (most selective journals) and with the Hirsch index. Models with all the main indicators (Model 7) and with additional indicators (Model 8) produce even better results. The full model gives 63% predictions for the top 100 (with 10 in the top 20); however, one must bear in mind the danger of overfitting the model. In addition, we present how survey and scientometric rankings are matched with each other (Table 1).

Table 1. Match between reputational and citation results (by scholars).

		Reputational ranking			
		Top-20	Top-50	Top-100	Top-200
Citation ranking	Top-20	11	13	13	13
	Top-50	15	21	31	36
	Top-100	17	31	50	59
	Top-200	19	42	69	89

How can the observed mismatches be explained? We distinguished two types of deviant cases: false positive and false negative. False positive cases arise if we do not find the expected effect, i.e., people with high citation rates who do not have high scores in the survey, while false negative cases, in contrast, are sociologists with a low number of citations and a considerable number of nominations. In general, we found 7 cases of people included in the top 20 by citation metrics who are located below the third hundred by survey results. Among false positive scholars, we find a distinct group of those who demonstrate critical values across the entire set of additional indicators: (1) a high level of self-citation (20–40%) and citations by co-authors (40–70%), (2) a low impact factor of publishers and citing journals (0.25–0.35), (3) a very low number of publications and citations in selective journals. Taken separately, these observations can have a completely different meaning, and, as a consequence, the corresponding variables are not significant.

Conclusion

We used scientometric indicators not limited only to traditional metrics, but also special indicators that were developed by RISC (and have no analogues in other citation databases) and are better able to indicate the quality of scientific work. The results of the study allowed us to conclude that scientometric indicators predict the names of the most influential sociologists with significant accuracy. Citation metrics and survey results converge to a large extent, at least with regard to the goal of identifying the disciplinary elite. Contrary to popular expectations, there is no clear evidence that the presence of support groups results in individuals not favored by most peers scoring high in citation metrics or in a survey. We found two types of deviations—false positive and false negative identifications. False positive identifications (high results in scientometrics, low in the survey) are explained by specialization in writing textbooks and explicit gaming of metrics, which can, however, be identified. False negative identifications (low in scientometrics, high in the survey) are less pronounced and are mainly associated with age or an elite narrow specialization (for example, in methodology).

Abstract

We study the effect of using quantitative indicators in grant allocation by using the natural experiment with the increasing publication threshold for principal investigators between two waves of grant competitions. The policy change provides us with the opportunity to study whether reliance on bibliometric indicators brings better results in the grant evaluation process. The following questions are explored in greater detail: whether the policy affected the distribution of funds to researchers with a better publication record, the strategies of increasing publications by individual researchers, and the differences, if any, in policy effects between disciplines. We found that the selection among physicists in the first period was already effective as the grant recipients are prolific authors who publish a lot of highly cited papers. Although social scientists demonstrated a relatively weak ability to publish internationally, the increase in scientometric expectations has improved the publication record regarding the quantity and quality of publications.

Introduction

Researchers recognize that grant funding now plays a more significant role in supporting science compared to institutional funding (Auranen & Nieminen, 2010; Grimpe, 2012; Maisano et al., 2020; Wang et al., 2020). Grant funding is expected to trigger competition among scientists, leading to more visible academic results (Grimpe, 2012; Maisano et al., 2020). The prevalence of grant funding raises the issue of its effectiveness. Are grants an effective mechanism for achieving high academic results? Empirical research has mainly answered this question by analyzing the results of supported projects. The analysis shows that grants do not always increase scientific research effectiveness, and if they do, the effect is relatively small. The results require a shift in focus from analyzing project outcomes to analyzing project selection procedures. Can the process for evaluating applications be improved so that grants are awarded to more capable scientists? What role should the scientometric indicators of researchers play in the selection procedure? We will answer these questions by analyzing data on project leaders' scientific performance who received financial support from the Russian Science Foundation.

The role of objective indicators in selecting applications as opposed to expert assessments is widely discussed in the scientific literature. Research demonstrates that the chances of achieving results are lower for those who did not perform well before receiving the grant (Fedderke & Goldschmidt, 2015). If scientometric indicators make it possible to predict the project's subsequent effectiveness, then evaluation procedure may rely on citation metrics.

Additional empirical evidence is required to confirm this thesis, given the policy implications. However, in general, research focuses more on analyzing the results of grants rather than the achievements of grant recipients. The data on the Russian scientists-winners of the Russian Science Foundation competitions will make it possible to contribute to the discussion about the role of bibliometric indicators in the evaluation of grant proposals.

The Russian case is especially indicative given that scientometric methods are actively applied to assess the research performance. To participate in the grant competition, a scientist is required to meet the publication threshold. Moreover, over the past five years, the thresholds for publication of project managers have increased remarkably. If for the 2014 competition, the project leader in natural sciences obliged to have at least three articles in indexed journals published in three years, in 2017, they required five papers in five years. For social and humanitarian scientists, the changes turned out to be more dramatic. Although the number of publications remained the same, the local journals, not indexed in international databases, disappeared from the list of approved sources.

This change in the policy provides us with the opportunity to study whether reliance on bibliometric indicators brings better results in the grant evaluation process. We focus on recipients of research funding from the Russian Science Foundation, which outlined its policy that established a threshold in the number of indexed publications for a principal investigator. The following topics are explored in greater detail: whether the policy affected the distribution of funds to researchers with a good publication record, the strategies of increasing publications by individual researchers, and the differences, if any, in policy effects between disciplines. We propose that social sciences might experience a less positive effect from increasing publication threshold given that quantitative indicators are considered to have less validity in measuring academic quality. Our analysis bases not only on the analysis of the winners' academic performance but also on comparing the publications of the leaders with a sample of highly cited articles in the relevant fields.

Literature review

Evaluation of the effectiveness of grant funding is dominated by studies that analyze the results of supported research projects, as measured by the quality and quantity of publications. Empirical research differs in data collection strategy - researchers either analyze various foundations' cases, tracking publications that resulted in supported projects. In studying individual foundations' performance, a common approach is to compare the performance of scholars who have received grants with a group of similar authors without a grant.

Empirical studies on individual funds show contradictory results. For example, a study of Italian scientists (Maisano et al., 2020) demonstrates that grant recipients did not have greater productivity than those who did not receive the grant. Analysis of publications by grant applicants in New Zealand showed an increase in publications by 3-15% and citations by 5-26%, depending on the type of financial support (Gush et al., 2018). According to the data on the Turkish foundation's effectiveness, grant funding may not have an exact effect on a significant increase in the number of publications and their subsequent citation (Tonta, 2018). The same result was obtained by evaluating young scientists' performance awarded by Russian grants (Saygitov, 2014).

Thus, studies show that the grant funding does not always bring effective results if we expect that supported projects produce high-impact publications (Fedderke & Goldschmidt, 2015). Even if researchers find an effect, it is often relatively small (Morrillo, 2019; Wang & Shapira, 2015). This may be due to the peculiarities of specific funds, which differ in selection procedures and general policies. For example, a comparative study found that Chinese foundations lead to a high number of publications resulting from grants. In contrast, EU grants are less effective, which can be explained by their emphasis on the project's social impact (Wang et al., 2020). Besides, large grants have significant transaction costs and, therefore, not as effective as one might expect (Clark & Liorens, 2012). On the other hand, it is possible that the selection procedures are not meritocratic - the funding does not go to the best scientists. This assumption has been tested in several studies.

Meritocracy in the procedure means that resources go to those who have already shown high achievements (Maisano et al., 2020). Researchers (Fedderke & Goldschmidt, 2015) collected data on the scientific achievements of those who received additional financial resources and those who did not receive them. The comparison showed that funding led to increased performance; however, the increase in publications is very modest depending on scientists' previous achievements. Grimpe (2012) showed that even the most significant competitions fail to attract the best scientists. An analytical report (Technopolis, 2008) presents a large-scale study of principal investigators of large European grants. In particular, grant recipients are compared to academics in similar fields who have not received grants. In general, it is shown that grant recipients are 2-3 times more likely to be authors of the most highly cited articles (10% of managers are the author of at least one article from the pool of the most highly cited publications (1%); 37% have at least one publication from the pool of 10% most cited articles).

In this regard, it is believed that it is better to strive to concentrate resources in the hands of highly productive scientists because it is then that a high return on investments in science can be expected (Maisano et al., 2020). It may be worth formally starting to rely on quantitative performance indicators when deciding which project should receive funding (Fedderke & Goldschmidt, 2015). We propose to focus on the analysis of the previous scientific performance of scientific leaders and to analyze the increasing requirements for scientometric indicators. We include in the analysis the differences by field of science.

Methods

The data collection process began by producing a list of all principal investigators who had received research funding for projects from the Russian Science Foundation in 2014 and 2017. The Russian Science Foundation was selected for its policy to establish a publication threshold for a principal investigator. These publications are prerequisite for the application process. After producing a list of principal investigators, the next step in data collection was gathering data on publications of these investigators in journals listed under Scopus. Publications were matched with the bibliometric characteristics of journals where articles were published. Scopus was selected due to its coverage. It is important to pay attention to the fact that the calculation of research output of Russian institutions significantly depends on the database used. A study of Russian publication demonstrates that the share of papers from Russia indexed in Scopus is higher in Scopus than it is in WoS. For example, Sterligov expressed the view that WoS sells “top quality,” while Scopus sells “top scope,” explaining why the number of journals indexed in Scopus is almost twice as high as it is in the WoS (Sterligiv, 2017). Although the increase in the share of Russian papers during 2012–2016 occurs in both databases, there is a difference in the main factor. For both Scopus and WoS, the coverage of proceedings was expanded, but in the case of Scopus, the increased number of publications also reflects the inclusion of more Russian language journals (Moed, Markusova & Akoev, 2018). The observational window is five years before the year of application.

Results

Our primary empirical strategy is to compare two waives of grant recipients: the first group of scientists received their grant in 2014 before the scientometric threshold was established, while the second group won a competition in 2017 after the new rules were applied. Further, we briefly report our main results.

In the second wave, 92.7% of scientists who received a grant in social sciences had published a piece in the journals indexed by Scopus, while in the first wave, there were only 54.3% of them. For physicists, this percentage is consistently high - 100% and 96.3% in the first and second periods, respectively.

Table 1 presents the number of publications that grantees published in five years before they receive a grant. On average, before receiving a grant in physics, scientists published 42 articles in the first wave and 35 articles in the second wave. At the same time, the median value does not change - 25 papers for both periods. We also do not see a significant change in the average number of publications among social scientists. On average, social scientists publish five articles.

Table 1. Descriptive statistics for number of publications of grantees.

Field	*Time period*	*N grants*	*mean*	*min*	*max*	*var*	*med*
Physics	First wave	115	42	2	466	4158	25
	Second wave	82	35	2	304	1551	25
Social science	First wave	94	5	1	29	25	3
	Second wave	41	5	1	27	21	4

Table 2 shows that the new research leaders had published papers in more selective set of journals (according to CiteScore metrics). For example, in the first wave, the social sciences investigators had articles published mainly in Q4 (59%). In the second period, the share of Q4 decreased to 29.6% - most of the lost Q4 percent was taken by Q1, Q2 and Q3. Physicists also experienced an "overflow" from lower quartiles to higher ones. Results are significant for both research fields (for physics Pearson chi2 – 69.4263, for social science – 42.9478, p< 0.0001). This can be explained both by an increase in the journals' quartiles and by a better selection of grant recipients in favor of those who publish in selective journals.

Table 2. Publications by quartiles.

	Physics		*Social science*	
Journal quartiles	*First wave (%)*	*Second wave (%)*	*First Wave (%)*	*Second wave (%)*
Q1	2653 (53.7)	1437 (52.4)	30 (12.3)	50 (24.3)
Q2	710 (14.9)	452 (16.5)	13 (5.4)	30 (14.6)
Q3	800 (16.7)	600 (21.9)	57 (23.4)	65 (31.5)
Q4	703 (14.7)	253 (9.2)	144 (59)	61 (29.6)
Total	4776 (100)	2742(100)	244 (100)	206 (100)

We also found that CiteScore and Percentile are higher for physicists than for social scientists. However, at the same time for social science, we see more pronounced positive dynamics for Percentile - in the first period Percentile reached on average 33, in the second - 44 (an increase of 33%). Physicists also grew in Percentile from 59 in the first period to 64 in the second (an increase of 10%).

Given the fact that the number of Russian journals in Scopus almost doubled for analyzed periods, we compared not only the total number of publications, but the share of publications in Russian journals. In the second period, the share of international publications grows for both fields. For the principal investigators in physics in the first period, 73% of publications are non-local, and in the second period is 80%. For recipients of social sciences grants, the growth is even higher - from 41 to 59%.

We further compared the grant recipients with the Russian scientists who authored the most cited papers published in two time periods. We stored 5% of Scopus's most cited articles, where authors / co-authors are scientists with Russian affiliation. To collect the sample of highly-cited publications of Russian authors, we queried in Scopus all publications with Russian affiliation separately for physics and social science, and for both periods. Then, we sorted all publications by the number of citations and restricted the sample to 5 percent of most cited publications. Our aim was to find whether scientists among the authors of these highly-cited articles are from the list of grant recipients.

Table 3 shows that the share of investigators who authored highly cited publications in physics is higher than in social science. However, in social science, we see positive dynamics for two periods. Thus in the first period, 10.6% of leaders had published highly cited papers, in the second already 17.1%. At the same time, we see fewer grants were awarded in the second period in both areas. With a decrease in the number of grants, we conclude that the second wave brings an increase in the selected applications' quality in social sciences.

Table 3. Share of grant recipients who author highly cited papers.

Field	*Time period*	*N grant recipients with highly cited publications*	*N highly cited papers authored by grant recipients*	*Share of grant recipients authored highly cited papers*
Physics	First wave	82	504	71.3
	Second wave	56	270	68.3
Social science	First wave	10	13	10.6
	Second wave	7	14	17.1

To conclude, our results demonstrate the relatively positive effect of reliance on bibliometric indicators in the grant evaluation process. We found that the selection among physicists in the first period was already effective as the grant recipients became prolific authors who publish a lot of highly cited papers. In the second wave, the reduction in the number of grants led to a decrease in the names we looked for in highly cited articles, which is why we found fewer articles for physics. In contrast, the social science investigators are less prolific in publishing internationally. Usually they publish fewer papers in the most selective set of journals that can be explained by the local traditions and limited source coverage in international databases. At the same time, social scientists have improved the publication record regarding the quantity and quality of publications. The improvement in performance in the social sciences and humanities can be attributed to at least two reasons. Scientists could correctly perceive the incentives to publish in international journals and start publishing in prestigious journals, which they had not practiced before. The other explanation is that the competition began to be acquired by scientists who had previously published good articles but rarely participated and/or won in competitions. The information about the organization distribution rather speaks in favor of the second explanation. Social scientists affiliated with the Russian Academy of Sciences or a leading university began to win the competition more often - in 2014, there were 65% of them, in 2017, they were already 82%. The rotation of the competition winners took place in favor of scientists from leading organizations with stronger publications, which should rather be assessed as a positive effect.

Abstract

Methodological mistakes, data errors, and scientific misconduct are considered prevalent problems in science that are often difficult to detect. In this study, we explore the potential of Twitter for discovering these problems with publications. We analyzed tweet texts of three retracted publications about COVID-19 (Coronavirus disease 2019)/SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2) and their retraction notices. We did not find early warning signs in tweet texts regarding one publication, but we did find tweets that casted doubt on the validity of the two other publications shortly after their publication date. An extension of our current work might lead to an early warning system (based on Twitter data) that makes the scientific community aware of problems with certain publications. Other sources, such as blogs or post-publication peer review sites, could be included in such an early warning system.

Introduction

Certain manuscripts are retracted after publication, although they have been reviewed by colleagues in journal peer review (Sotudeh, Barahmand, Yousefi, & Yaghtin, 2020). There are various reasons for retractions of publications. The main reasons are data errors, methodological mistakes, and, or scientific misconduct. These errors can further be "distinguished between 'reputable' errors (those arising despite the investigators' best efforts to avoid them) and 'disreputable' errors (those arising from disregard of acceptable scientific practice)" (Zuckerman, 2020, p. 954). Fang, Steen, and Casadevall (2012) reported that "2,047 biomedical and life-science research articles indexed by PubMed as retracted on May 3, 2012 revealed that only 21.3% of retractions were attributable to error. In contrast, 67.4% of retractions were attributable to misconduct, including fraud or suspected fraud (43.4%), duplicate publication (14.2%), and plagiarism (9.8%)."

In cases of minor problems with a published paper, a correction is usually published. However, if correcting the problems alters conclusions of the study, retraction can be the only possibility for correcting the scientific record. Retraction decisions are usually not done with levity because retractions may damage the scientific reputation of authors and journals. Retractions may cast a poor light on the research capacity of authors and the functionality of journal peer review. Therefore, one should expect that retractions do not occur very often. However, occurrences of scientific misconduct seem to become known to the scientific public often enough so that the topic of scientific misconduct has become "a thriving area of research" (Zuckerman, 2020, p. 945). The Web of Science (WoS; Birkle, Pendlebury, Schnell, & Adams, 2020) has a document type named "retraction" that has indexed documents with publication years since 1974.

Rumors about data errors, methodological mistakes, and scientific misconduct can spread very quickly on social media such as Twitter (a popular micro-blogging platform, see https://www.twitter.com) (Teixeira da Silva Jaime & Dobránszki, 2019). Sugawara et al. (2017) found that discussions on scientific misconduct regarding a study on stimulus-triggered acquisition of pluripotency (STAP) cells in Japan in 2014 occurred on Twitter before they surfaced in newspapers. Do Twitter users mention problems with papers (early) that are later retracted? Are Twitter users who mention retracted publications informed about the paper status? Do they explicitly mention the issues why the publication has been retracted? These are the questions we try to answer in this case study by analyzing the tweets that mention three different retracted publications about COVID-19 (Coronavirus disease 2019)/SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2) and their retraction notices. Since Twitter is a very fast medium, tweets might be used as early indicator for problems with certain publications.

We selected the three publications (Bae et al. (2020a), Wang et al. (2020a), and Mehra, Desai, Ruschitzka, and Patel (2020)) from a post from Retraction Watch about retracted COVID-19/SARS-CoV-2 papers (https://retractionwatch.com/retracted-coronavirus-covid-19-papers/). The three publications have received considerable attention in online media as can be seen from their Altmetric Attention Scores.

Methods

We used the Altmetric.com application programming interface (API) for extracting tweet identifiers for any tweets that mentioned either any of the three retracted publications or their retraction notices on Twitter. The tweet texts and other meta data of the tweets that mentioned any of the publications or retractions on Twitter were downloaded from the Twitter API. We connected to both APIs using R (R Core Team, 2019) with the R packages httr (Wickham, 2017a) and RCurl (Lang & the CRAN team, 2018). The tweets were downloaded between the 6th and the 9th of August 2020 via the Twitter API using R (R Core Team, 2019) and stored in local SQLite database files using the R package RSQLite (Müller, Wickham, James, & Falcon, 2017). Functions from the R package DBI were used for sending database queries (R Special Interest Group on Databases (R-SIG-DB), Wickham, & Müller, 2018).

The R package ggplot2 was used for plotting the time evolution of tweets (Wickham, 2016). The R package tidyverse (Wickham, 2017b) was used for analyses of the Twitter user profiles. The R packages tm (Feinerer, Hornik, & Meyer, 2008), NLP (Hornik, 2014), SnowballC (Bouchet-Valat, 2014), wordcloud (Fellows, 2014), and RColorBrewer (Neuwirth, 2014) were used for producing word clouds. Before searching in tweet texts and displaying them as word clouds, the tweet texts were converted into lower case characters and only alpha-numeric characters were kept. English stop words, punctuation characters, and needless whitespaces were removed.

We downloaded 42,746 tweets for Mehra, Desai, et al. (2020) and 67,038 tweets for its retraction notice, 10,875 tweets for Bae, et al. (2020a) and 3095 tweets for its retraction notice, and 5428 tweets for Wang, et al. (2020a) and 53 tweets for its retraction notice. The retraction notices have received very different numbers of tweets compared to the corresponding papers.

In order to receive information about the people mentioning the three publications or their retraction notices in tweets, we used the classification scheme proposed by Toupin, Millerand, and Larivière (2019) and a modified version of the R code provided by Toupin (2020). The general idea behind most classifications is to capture the interest of a particular account to share scholarly papers using self-descriptions in the profiles (see Haustein, 2019; Toupin & Haustein, 2018; Vainio & Holmberg, 2017).

The results of the classification show that personal accounts are the largest single group for all documents except Wang et al. (2020b). In the case of Wang, et al. (2020b), the user group 'faculty and students' is the largest single group. The user groups 'bots' and 'journals and publishers' are the least frequently occurring groups for all six documents. We expect the most frequent hints to problems with papers especially from the user group 'faculty and students' since this group includes people with the necessary expertise. A critical discussion of papers can be scarcely expected from the user groups 'bots' and 'journals and publishers'.

Results

Twitter activity of Bae, et al. (2020a) and Bae et al. (2020b)

Bae, et al. (2020a) studied the effectiveness of surgical and cotton masks in blocking SARS–CoV-2. The study was published on 6 April 2020 and retracted on 2 June 2020 because they "had not fully recognized the concept of limit of detection (LOD) of the in-house reverse transcriptase polymerase chain reaction used in the study" (Bae, et al., 2020b). In this case, the retraction was made because of a methodological error that was not detected in the peer review process. Figure 1 shows the tweets per day that mentioned either the paper or its retraction. The publication dates of the paper and retraction notice are marked as gray vertical lines. Most tweets mentioning the publication occurred before retraction. However, the second-most frequent tweets per day were recorded on the day of retraction. Therefore, the tweet texts are analyzed using two different time periods: (i) before the publication date of the retraction and (ii) since the publication date of the retraction.

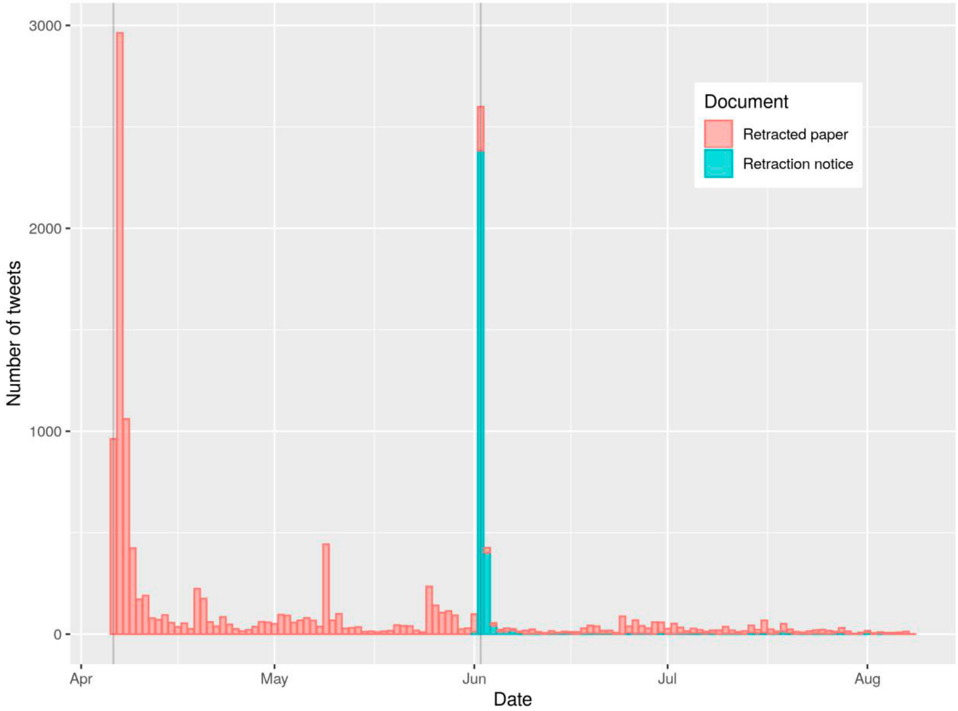

Figure 1: Tweets per day that mentioned either the paper Bae, et al. (2020a) or its retraction Bae, et al. (2020b). The publication dates of the paper and the retraction notice are marked as gray vertical lines.

Figure 2a shows a word cloud from tweet texts based on the tweets mentioning Bae, et al. (2020a) before publication date of the retraction. Figure 2b shows a word cloud from tweet texts based on the tweets mentioning Bae, et al. (2020a) or Bae, et al. (2020b) since publication date of the retraction. In both word clouds, the term 'mask' is the most prominent one. The terms 'surgical' and 'cotton' are the second- and third-most prominent ones in Figure 2a. The two terms are much less prominent in Figure 2b although all three terms ('masks', 'cotton', and 'surgical') appear in the title of both publications.

The publication was retracted because a limit of detection (LOD) has not been recognized. The terms ‘LOD' or 'limit of detection' cannot be spotted on either Figure 2a or Figure 2b. In fact, the term ‘LOD' does not appear in the tweets before retraction and only 19 times since retraction. The term ‘limit of detection' occurred once before retraction (on the evening before where it probably has been announced already) and seven times after retraction. Three tweets mentioned both, ‘LOD' and 'limit of detection'. In the case of Bae, et al. (2020a), we can conclude that the reason for retraction has not been mentioned by Twitter users before a retraction decision has been made and only very rarely (0.5%) after publication of the retraction.

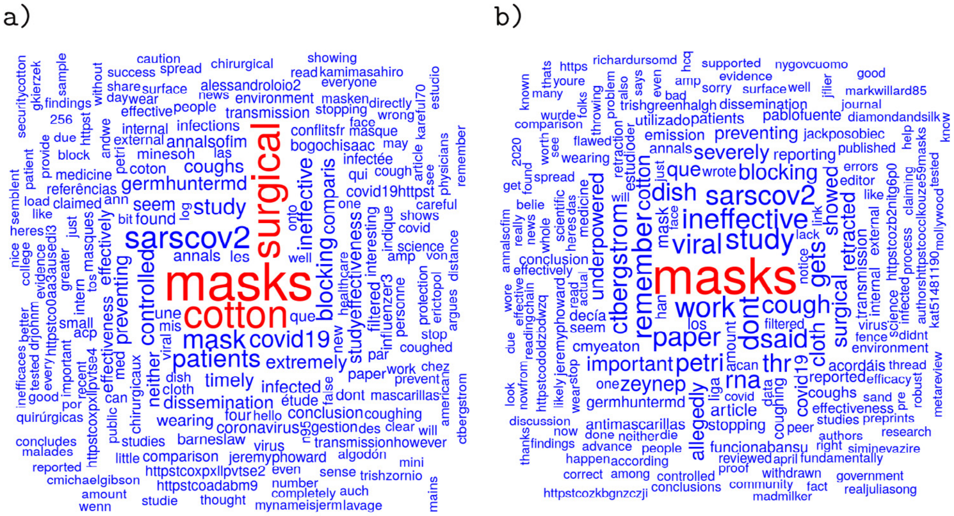

Figure 2: Word cloud from tweet texts based on the tweets mentioning Bae, et al. (2020a) before publication date of the retraction in panel a and based on the tweets mentioning Bae, et al. (2020a) or Bae, et al. (2020b) since publication date of the retraction in panel b

Twitter activity of Wang, et al. (2020a) and Wang, et al. (2020b)

Wang, et al. (2020a) reported that “SARS-CoV-2 infects T lymphocytes through its spike protein-mediated membrane fusion”. The peer review process was very fast: the paper has been submitted on 21 March 2020, and accepted three days later on 24 March 2020. The paper has been published on 7 April 2020, and retracted on 10 July 2020 (Wang, et al., 2020b) because “[a]fter the publication of this article, it came to the authors attention that in order to support the conclusions of the study, the authors should have used primary T cells instead of T-cell lines. In addition, there are concerns that the flow cytometry methodology applied here was flawed. These points resulted in the conclusions being considered invalid.” In this case, the retraction was made because of methodological errors that were not discovered during the peer review process. Figure 3 shows the tweets per day that mentioned either the paper or its retraction. The publication dates of the paper and the retraction notice are marked as gray vertical lines. Most tweets mentioning the publication occurred before retraction. Only very few tweets mentioned the retraction notice (n=53) or the paper after retraction (n=50). The tweet texts are analyzed using two different time periods: (i) before the publication date of the retraction and (ii) since the publication date of the retraction.

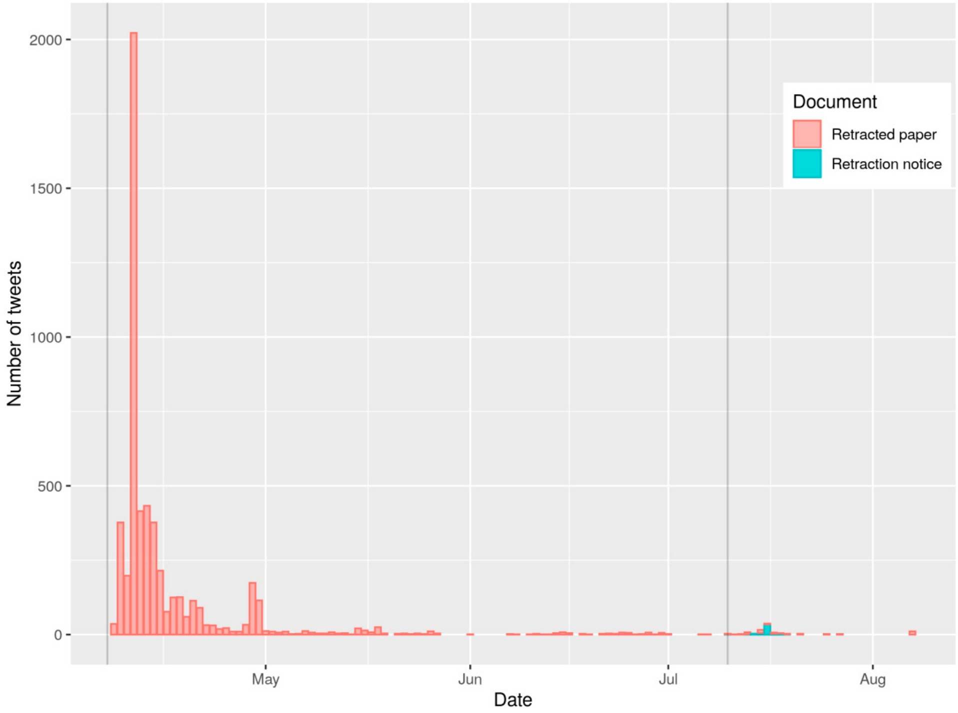

Figure 3: Tweets per day that mentioned either the paper Wang, et al. (2020a) or its retraction Wang, et al. (2020b). The publication dates of the paper and the retraction notice are marked as gray vertical lines.

Figure 4a shows a word cloud from tweet texts based on the tweets mentioning Wang, et al. (2020a) before the publication date of the retraction. Figure 4b shows a word cloud from tweet texts based on the tweets mentioning Wang, et al. (2020a) or Wang, et al. (2020b) since the publication date of the retraction. The most prominent terms in Figure 4a seem to be related to the virus and the disease it is causing whereas the term ‘retracted' is the most prominent one in Figure 4b.

One can easily see the terms ‘tcells’ in Figure 4a and Figure 4b, although not being among the most prominent terms. The study Wang, et al. (2020a) has been retracted because the authors should have used primary T cells instead of T-cell lines and because the flow cytometry methodology applied in the study was flawed. There were 5378 tweets registered before retraction and 103 since then. Only 14 tweets before retraction and four since then included the term ‘primary’ in the tweet text. The first tweet that mentioned problems with the used T cells was posted on 9 April 2020 (i.e., two days after publication and about three months before retraction of the study) and reads: “I would take this with a grain of salt. This was on cell lines, not primary T-cells. No evidence that this infection results in T-cell dysfunction. Furthermore, severe disease is characterized by hyper-immune response. Much is left to be desired here. Not sure what to conclude. https://t.co/15qvCa0fvw” (Sidholm, 2020).

There were 23 tweets that contained the term ‘flow cytometry’ and 101 tweets that contained the term ‘flowcytometry’ (mainly as a hashtag), both before publication of the retraction notice. Most of these 124 tweets (n=117) were retweets as identified by their first two letters ‘RT’ followed by a whitespace. The first tweet that casted doubt on the employed flow cytometry methodology was posted on 9 April 2020 and it reads: “Lots of discussion on Twitter about this paper, however some questions outstanding: Does the flow cytometry actually show cell infection? Where is the positive control comparison using classically infected cells?" (Vincent, 2020). Only a single tweet (retweeted 26 times) was found that mentioned 'flowcytometry' (as a hashtag) and none that mentioned 'flow cytometry' after publication date of the retraction notice.

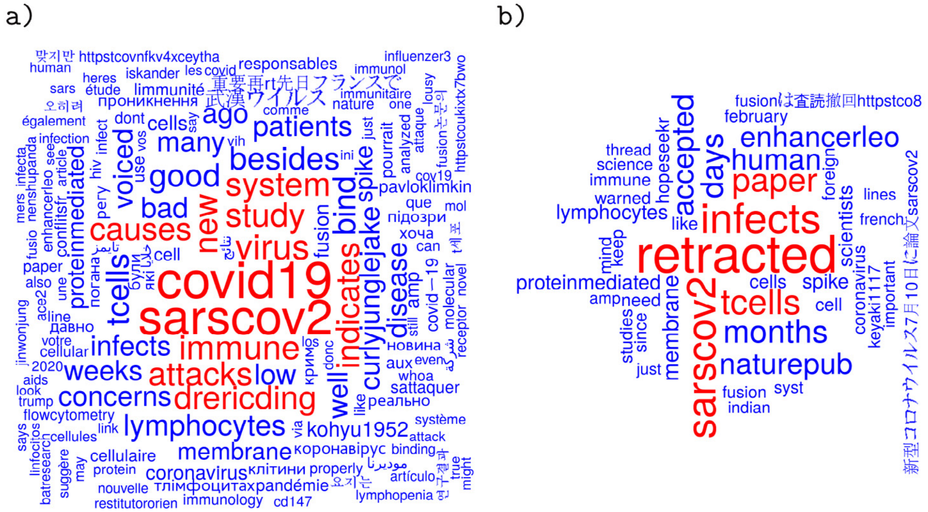

Figure 4: Word cloud from tweet texts based on the tweets mentioning Wang, et al. (2020a) before publication date of the retraction in panel a and based on the tweets mentioning Wang, et al. (2020a) or Wang, et al. (2020b) since publication date of the retraction in panel b

Twitter activity of Mehra, Desai, et al. (2020) and Mehra, Ruschitzka, and Patel (2020)

Probably the most attention among the three publications was drawn to the study by Mehra, Desai, et al. (2020). They reported that they could not confirm a benefit in COVID-19 treatment with hydroxychloroquine. They even reported that hydroxychloroquine increases the risk of complications during medical treatment against COVID-19. The study was published on 22 May 2020, and retracted on 05 June 2020 (Mehra, Ruschitzka, et al., 2020) because "several concerns were raised with respect to the veracity of the data and analyses conducted by Surgisphere Corporation and its founder" and co-author of the study. Surgisphere declined to transfer the full dataset to an independent third-party peer reviewer because that would violate client agreements and confidentiality requirements. Potential benefit or risk of hydroxychloroquine for treatment of COVID-19 is still not clear. In this case, the retraction was made because of doubts regarding the validity of the employed data that was not discovered in the peer review process.

Figure 5 shows the tweets per day that mention either the paper or its retraction. The publication dates of the paper and the retraction notice are marked as gray vertical lines. The retraction notice has been tweeted a day before its official publication date. Because the retraction notice has been tweeted a day before its official publication, the two time periods were organized slightly different: (i) before the day before the publication date of the retraction notice and (ii) since the day before the publication date of the retraction.

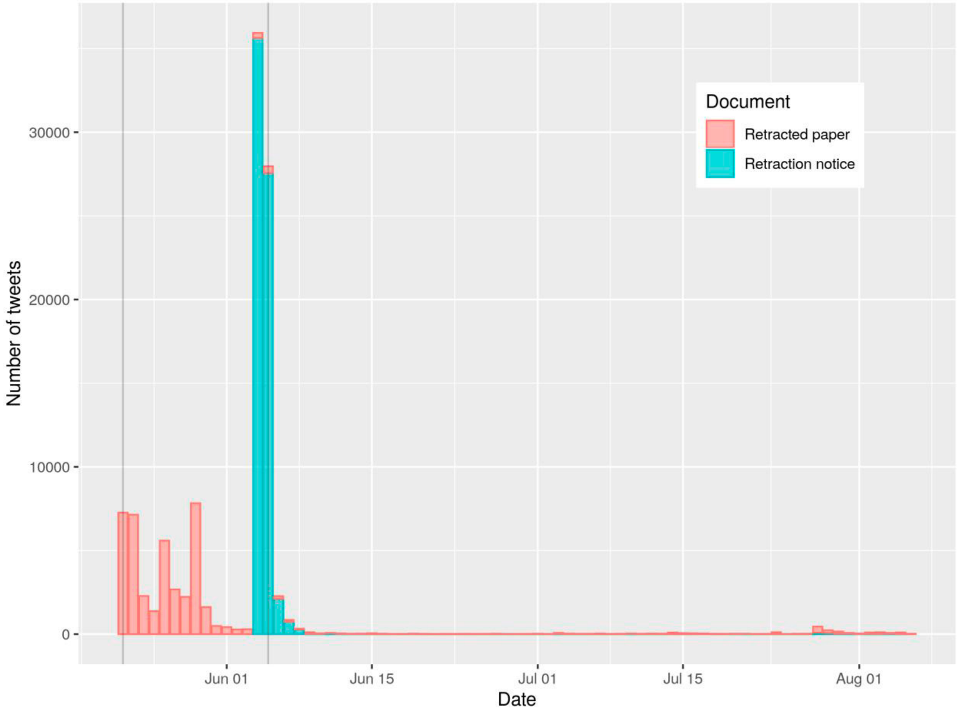

Figure 5: Tweets per day that mention either the paper Mehra, Desai, et al. (2020) or its retraction Mehra, Ruschitzka, et al. (2020). The publication dates of the paper and the retraction notice are marked as gray vertical lines.

Figure 6a shows a word cloud from tweet texts based on the tweets mentioning Mehra, Desai, et al. (2020) before the day before the publication date of the retraction. Figure 6b shows a word cloud from tweet texts based on the tweets mentioning Mehra, Desai, et al. (2020) or Mehra, Ruschitzka, et al. (2020) since the day before the publication date of the retraction. The most prominent terms in Figure 6a are 'lancet' (the journal the study was published in) and 'roaultdidier' (a French physician and microbiologist specializing in infectious diseases who promoted the hydroxychloroquine-based treatment of COVID-19). The most pronounced terms in Figure 6b are 'study', 'thelancet', and 'hydroxychloroquine'. The terms 'retraction' and 'retracted' are also quite prominent.

The publication Mehra, Desai, et al. (2020) was retracted because there was some doubt about the data basis from the company Surgisphere. The term 'surgisphere' appears at the lower border of Figure 6a. The term 'data' can be found in the right part of Figure 6b. The study Mehra, Desai, et al. (2020) was mentioned 39477 times on Twitter before the retraction notice was tweeted for the first time (4 June 2020). Out of these 39477 tweets, 720 contained the term 'surgisphere' and 1819 contained the term 'data'. The first ten tweets mentioning the study and using the term 'data' occurred on the day of publication of the study. None of them mentioned problems regarding the employed data. The first tweet mentioning the term 'surgishphere' was posted on the day of publication of the study (Stamets, 2020) but did not cast doubt on the validity of the data. A later tweet from 24 May 2020 (i.e., two days after publication and eleven days before retraction of the study) mentioning 'surgisphere' as a twitter handle (Arkancideisreal, 2020a) referenced a tweet that casted doubt on the validity of the data (Arkancideisreal, 2020b). Many later tweets mentioning the study and using the term ‘surgisphere’ posted between 29 May 2020 and 2 June 2020 also casted doubt on the employed data, see for example Pinjos (2020) and Schwartz (2020). Some of them linked to an open letter to the authors of the study and Richard Horton (Editor of *The Lancet*), see Watson (2020). Both terms, ‘data’ and ‘surgisphere’, occurred in 61 tweets.

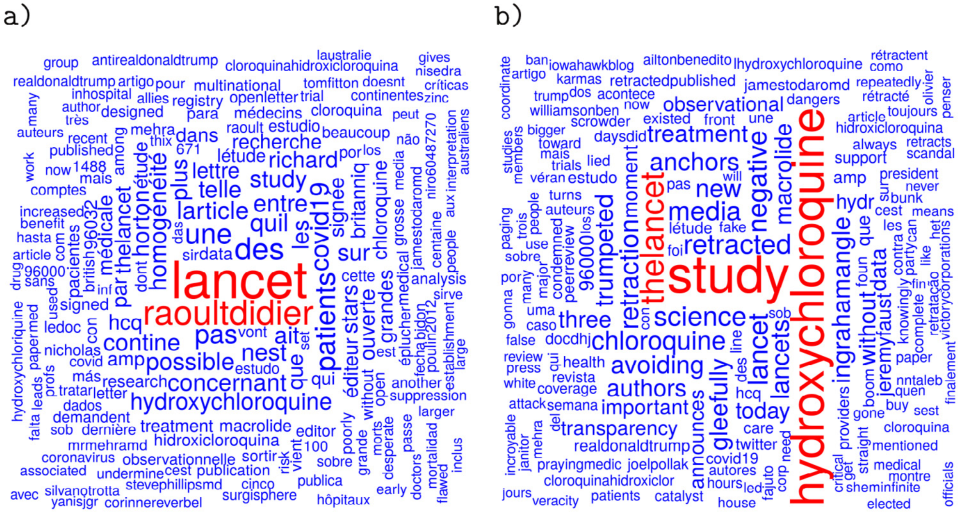

Figure 6: Word cloud from tweet texts based on the tweets mentioning Mehra, Desai, et al. (2020) before the day before the publication date of the retraction in panel a and based on the tweets mentioning Mehra, Desai, et al. (2020) or Mehra, Ruschitzka, et al. (2020) since the day before the publication date of the retraction in panel b

Discussion

Methodological mistakes, data errors, and scientific misconduct are prevalent problems in science that are often difficult to detect. In this case study, we are interested in the question whether tweets can be used to detect problems early with scientific papers. We have analyzed three different papers about COVID-19/SARS-CoV-2 that were retracted at least two weeks after publication.

Mixed conclusions can be drawn from this case study. Our results show that not all problems of publications can be spotted using Twitter data. However, one can find hints to problems regarding publications in tweet texts. In the tweets that mentioned Bae, et al. (2020a), we were not able to find early warnings regarding problems with the publication. Only a tweet on the night before the retraction occurred, was connected to the retraction reason. We were able to find early warning signs in tweet texts that mentioned the other two retracted publications of our study. However, the early warning signs from @John_Will_I_Am regarding the study by Wang, et al. (2020a) are less compelling than the clear warnings from @Arkanicide_is_real regarding the study by Mehra, Desai, et al. (2020).

It is noteworthy, that tweet texts have to be analyzed because many tweets mentioning a publication are not a clear indicator of problems with a publication. Performing more and larger case studies like ours might yield a list of Twitter users who often mention problems with publications early on. Many case studies might lead in a meta-analysis to a curated list of Twitter users who often spotted problems in publications in the past. Such a curated list of Twitter users might be helpful for revealing problems in future publications earlier. Maybe also more problematic publications can be found with such a Twitter-based discovery system than without such a system. Besides monitoring the activity of special Twitter users, a search term list of alarming keywords might be helpful. Such a list will be subject-related and differ from one field to another. Experts of the fields should propose or at least check such a list. Limiting such monitoring to publications that are also discussed on post-publication peer review sites, such as PubPeer, or in blogs might provide a more focused monitoring.

Acknowledgments

IDs of tweets mentioning the studied documents were retrieved from the Altmetric.com API. Tweets with their full text and posting dates were retrieved from the Twitter API. We thank Vanash Patel (Imperial College London) for checking our manuscript for potential misrepresentations of medical sciences. However, any problematic statements are the sole responsibility of the authors.

Abstract

This research-in-progress paper seeks to understand how the pandemic affected international research collaboration different countries and regions. It collected 333,793 preprints submitted to ArXiv between 2019 and 2020 to compare international research collaboration patterns pre-COVID-19 and COVID-19 eras. The paper finds that international research collaboration has been substantially affected by the pandemic, but the impact is manifested in varied extent over different time periods and in different countries. The project observed 1.55% decrease in international research collaboration in 2020 as compared with 2019. More specifically, there was a significant drop of international research collaboration at the early stage of the pandemic (from January 2020 until May 2020), and a sturdy recovery (to pre-COVID time) after May 2020. The change pattern varies by discipline and country. The results also demonstrate the resilience and adaptiveness of the scientific community in maintaining international research collaboration.

Introduction

International Research Collaboration (IRC) is a powerful driving force for innovation and discovery, as witnessed by the most rapid vaccine development in history: many existing COVID-19 vaccines are the result of IRC. IRC has also been found to increase research productivity (Thelwall & Maflahi, 2020), and impact (Wagner & Jonkers, 2017) for researchers. With the pandemic affecting almost every aspect of society, efforts have been invested in investigating its impact on research productivity (Vincent-Lamarre, Sugimoto, & Larivière, 2020), journal submission patterns (Maghfour, Olson & Jacob, 2020), and how scientists collaborated on COVID-19 specific research (Fry, Cai, Zhang & Wagner, 2020; Haghani & Bliemer, 2020). Yet, there's a lack of research examining the impact of the pandemic on IRC patterns. This study aims to fulfill the gap by examining the IRC pattern under the pandemic using submissions to preprint servers.

IRC is a powerful force in improving research productivity (Thelwall & Maflahi, 2020) and impact (Wagner & Jonkers, 2017). Many recent studies have investigated IRC in coronavirus research (Fry, Cai, Zhang & Wagner, 2020; Haghani & Bliemer, 2020) and the impact of the pandemic on research productivity (Vincent-Lamarre, Sugimoto & Larivière, 2020) and journal submission patterns (Maghfour, Olson, & Jacob, 2020). However, the impact of the pandemic on IRC is not clear. This research-in-progress study aims to fill the gap by examining the impact of COVID-19 on IRC using preprint publications.

We collected all preprints submitted to aXriv.org between 2019 and 2020. We used computational methods to extract author affiliations and countries from submitted PDF files. Using 2019 preprint data as the baseline, the study compared the level of IRC during the pandemic at the author-, country-, and discipline-levels to identify the impact of the pandemic on IRC. We aim to answer two research questions:

1. Whether and how IRC changed under the COVID-19 pandemic?
2. Whether and how the change (if any) varies by discipline and country?

Data Collection

Coauthorship is often used to approximate research collaboration. This study considers arXiv.org submissions with more than one author and one country for their affiliations as IRC. Using submissions from preprint servers like arXiv.org is advantageous: it allows us to analyze research output without having to wait for publication delay. Using preprint submissions from arXiv.org, this study leveraged the capabilities of machine learning and cloud computing to extract metadata and geographic information from PDF files. Figure 1 shows the process of data collection.

1. Download the complete set of processed arXiv PDF files for 2019 and 2020 through arXiv bulk data access that is available from Amazon S3[1].
2. Convert PDF files into XML files in NLM JATS format by using an adapted version of CERMINE, a Java library and a web service for extracting metadata and content from PDF files[2].
3. Extract author affiliation information (including country) from NLM JATS XML files.
4. Map country information into *ISO 3166-1 alpha-3* code (i.e., a set of standard three-letter country codes) using a predefined Python dictionary. If a country code cannot be identified, country, address, and affiliation information is used to request geographic coordinates through Google Geocoding API[3]. Country information is extracted from geographic coordinates.
5. Download arXiv metadata through OAI protocol for metadata harvesting.
6. Extract author and discipline information from arXiv metadata.

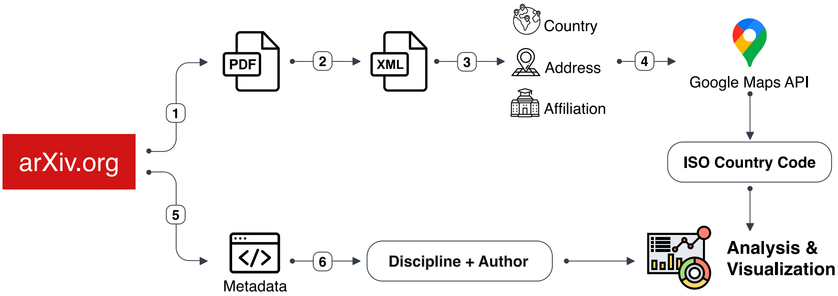

Figure 1. The process of data collection

We collected 155,464 and 178,329 preprints submitted to arXiv in 2019 and 2020, respectively. Country information for author affiliations was not available for some submissions due to missing, typo, etc. Figure 2 shows the number of collected preprints and the percentage of preprints with and without detected country information for each month. Country information was not detected for approximately 20% of harvested preprints. The percentage of preprints missing country information is roughly the same across months. Since most of our analysis is conducted by months, we assume limited impact from the missing on our conclusion. Ultimately, the final analytical sample include 240,648 preprints, 111,257 from 2019 and 128,391 from 2020.

The productivity patterns were also similar between the two years, but different in several months. June was the most productive month in 2020, but October was the one in 2019. The burst might be because scientific activities resumed and rebounded after the first wave of the pandemic in Spring 2020.

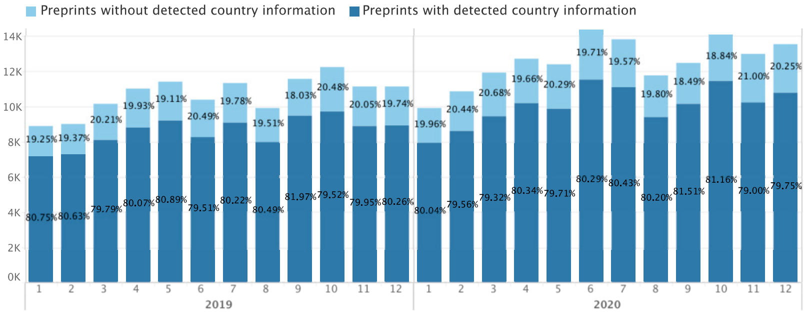

Figure 2. Collected data

Result

Collaboration at the author level

We first analyzed the collaboration at the author level. Figure 3 shows the percentage of papers with multiple authors. 90.34% (99,512) and 89.44% (115,990) of preprints had coauthors in 2019 and 2020, respectively. Compared with coauthorship patterns in 2019, more preprints in 2020 were authored by more than two, three, or four authors, and the pattern was consistent across 12 months. For example, 69.72% of preprints (89,513) were authored by at least three authors in 2020, but 67.95% of preprints (75,598) were authored by at least authors in 2019. We didn't see any evidence showing that multiple-author collaboration was affected by the pandemic.

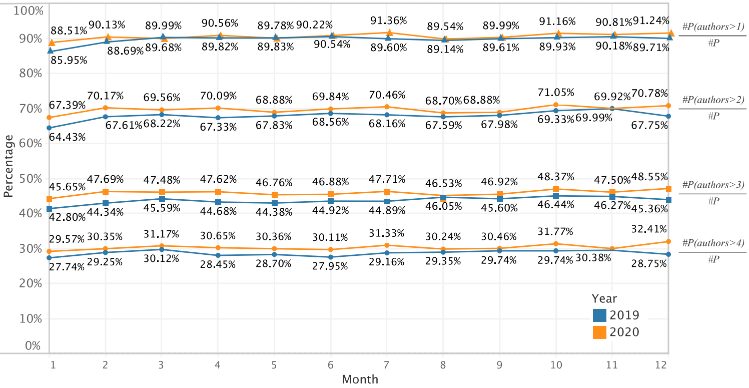

Figure 3. Collaboration at author level. #*P* is the number of papers, and #*P(author>n)* is the number of papers with more than *n* authors.

Collaboration at the country level

The IRC patterns were different between 2019 and 2020. In 2019, 38.81% of collaborative (more than one author) preprints (37,960) was contributed by authors from more than one country. This number declined to 37.26% (43,219) in 2020. Figure 4 shows the percentages of internationally collaborated preprints involving more than one, two, and three countries. Compared with 2019, we observed decreases in internationally collaborated preprints during the first four months of 2020. Since then, the percentage of IRC in 2020 was similar yet slightly lower to that of 2019. One possible explanation for this is that scientists may have adapted to new models of collaboration under the pandemic after the chaos and fluster in the first few months. Universities have been reported to invest more in online meeting tools and other capacities to ensure better communication and collaboration for both students and researchers. By comparing the results presented in Figure 3 and Figure 4, we found changes of IRC intensity in 2019 and 2020 (especially in the first few months of 2020, see Figure 4), though the changes were not noticeable at the author level when both domestic and IRCs are combined (Figure 3). The results suggest that when international collaborations were affected by the pandemic, scientists may have participated more in domestic collaborations to compensate for the impact of the pandemic on their research agenda.

The lower three panels in Figure 4 show the change of IRC with two, three, and more than three countries involved in 2019 and 2020. We observe that the most significant decline happened in the IRC involving more than three countries, especially for the first three months of 2020. This was likely due to the different levels of coordination needed based on the number of countries involved, and the different developing patterns of COVID-19 in different countries during that time.

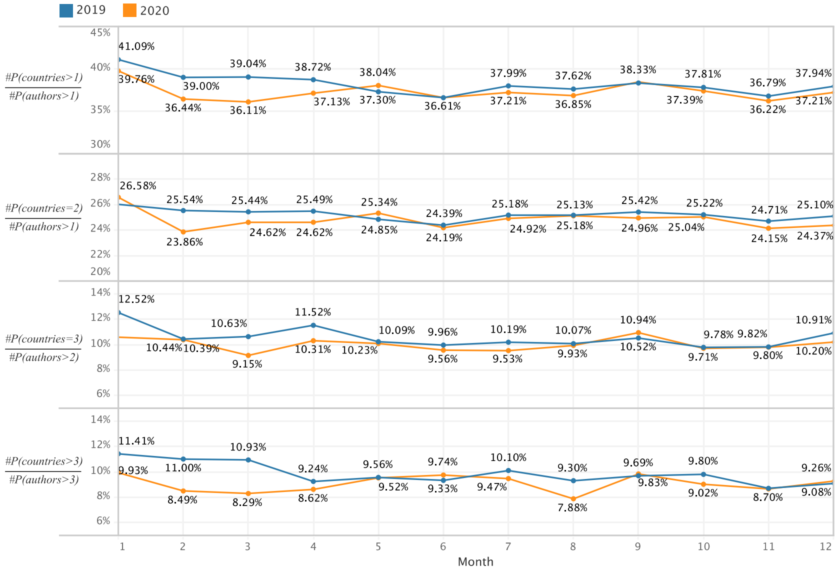

Figure 4. Collaboration at the country level. *#P(countries>n)* is the number of papers with authors from more than *n* countries.

Disciplines

We also compared the changes of IRC under the pandemic across disciplines. arXiv includes preprints from eight disciplines, with the majority of preprints (91.1%) are in physics (33.2%), computer science (29.3%) mathematics (20.6%%), and statistics (8.0%).

Figure 5 shows the percentage of IRC (preprints with authors from at least two countries) over all collaborative preprints in these four disciplines. The patterns in computer science, math, and physics were similar: IRC decreased for the first few months in 2020 and recovered to a similar level in 2019 afterward. The pattern in statistics was slightly different: after the decrease at the beginning of 2020, the IRC rebounded to a higher level than that in 2019.

The time and the extent of being influenced by the pandemic was different across disciplines due to the different nature of the disciplines. In comparison with other disciplines, IRC in computer science was influenced earlier. It takes varying time for scientists in a different discipline to adapt to the pandemic to recover IRC to the level before pandemic. It is also worth noting that some disciplines tended to have even higher level of IRC in the second half of 2020.

For example, scientists in statistics had much more IRC after July 2020 than in 2019. Another observation was that all disciplines except for physics had a dramatic increase in IRC in October 2020, but we need to further investigate this concerted increase.

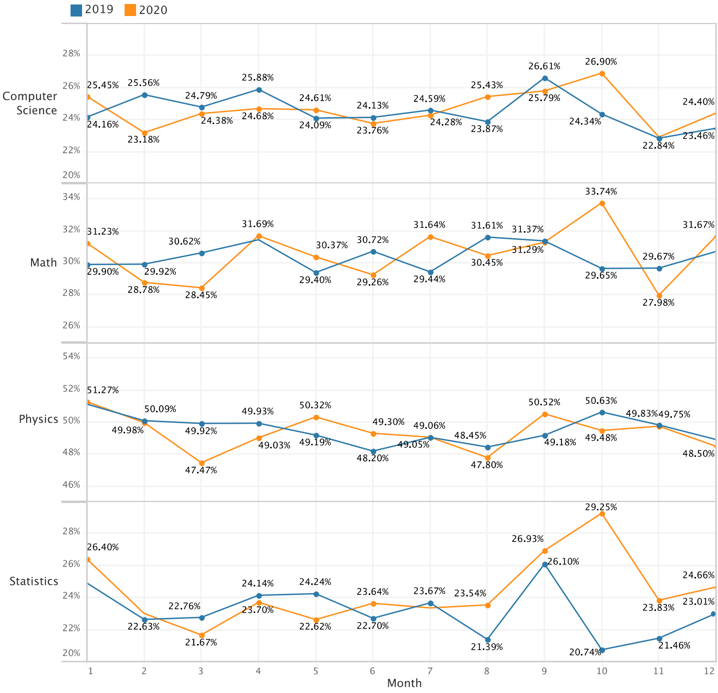

Figure 5. IRC in different disciplines.

Countries

Based on our analysis in previous sections, IRC was mainly hampered by the pandemic in the first four months of 2020. Thus, we examined the percentage change of IRC ($\#P(countries > 1)/\#P(authors > 1)$) in the first four months between 2019 and 2020 (see Figure 6). The IRC of most countries decreased, though with varied country-level differences. The IRC increased in some countries in Eastern Europe, Latin America, the Middle East, and Southeast Asia.

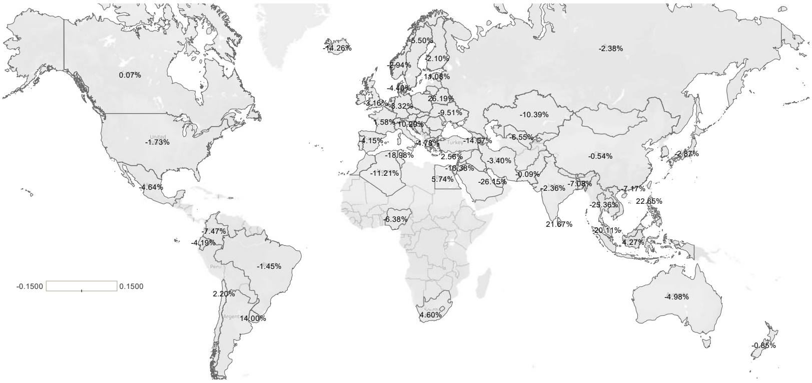

Figure 6. The change of percentage of IRC in the first four months between 2019 and 2020 across countries and regions submitted more than 100 arXiv preprints.

We also analyzed six countries with the most arXiv preprints (see Figure 7). The IRC decreased in the first few months in 2020 and recovered later. Some countries had a higher level of IRC in the second half of 2020 than 2019, such as the United Kingdom and Italy. The exception is France, where IRC was affected by the pandemic throughout the entire year in 2020.

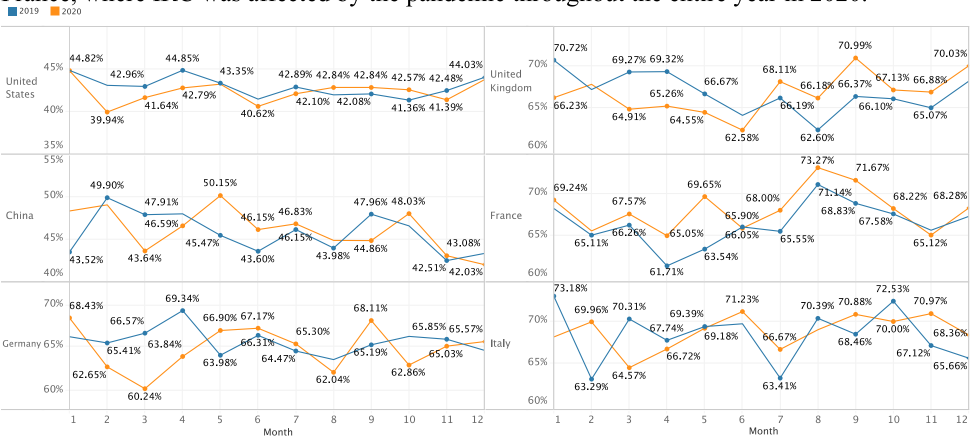

Figure 7. IRC from countries that submitted most preprints to arXiv.

Conclusion and Future Work

In this research-in-progress work, we found changes to IRCs in 2020, which is likely due to the COVID-19 pandemic. IRC rate declined during the first few months of 2020 and bounced back to a level similar to 2019 after May 2020. Yet, the change varied by discipline and country. Quick adoptions to research collaboration norms under the pandemic may have helped IRC resume during COVID-19. Different developing patterns as well as measures and efforts curtailing with COVID-19 by country is likely related to the varying changing patterns of IRC for countries.

Due to the varying impact of the pandemic across time, disciplines, and countries, we will examine factors affecting the impact of the pandemic in future research. For example, we will investigate the factors that alleviate or intensify the impact of the pandemic at the country level and examine the role of geographical and economic proximity in IRC during a public health crisis. This study, along with the future work, will provide a comprehensive and timely description of IRC patterns during the pandemic and provide an in-depth understanding of factors affecting IRC.

Abstract

This paper examines the distribution of Nobel laureates in Physiology/Medicine, Physics, and Chemistry across countries and research organizations. We provide basic information about where future laureates received their education and/or conducted their research, then present heatmaps depicting country and organizational specialization patterns. In addition, we identify the *organizational ultra-elite* in science: universities and research institutes that show continuously above-average numbers of future laureates, typically in one career phase. Furthermore, we identify those universities and research institutes that underwent considerable growth (or decline) in their capabilities for highly innovative research. Also, we compare country-specific profiles with those at the organizational level. Our findings are interpreted in the light of findings from comparative-historical studies.

Introduction

Following the seminal publication by Zuckerman (1977), the Nobel Prizes in Physiology/ Medicine, Physics, and Chemistry have attracted considerable attention from quantitative studies of science, especially with regard to achievement age (Jones & Weinberg, 2011; Redelmeier & Naylor, 2016), the time lag between prize-winning work and awarding of the prize (Becattini, Chatterjee, Fortunato, Pan, & Parolo, 2014; Fortunato, 2014), and the distribution of other science awards and collaboration networks in the years before and after their awarding (Chan, Gleeson, & Torgler, 2014; Chan, Önder, & Torgler, 2015). Several studies examined Nobel laureates from a bibliometric point of view, including spillover effects for the citations of laureates' publications unrelated to the Nobel Prize (Mazloumian, Eom, Helbing, Lozano, & Fortunato, 2011), and differences in citation patterns between landmark papers featuring theory, methods, experiments or inventions (Heinze, Heidler, Heiberger, & Riebling, 2013; Zhou, Xing, Liu, & Xing, 2014). Cross-national comparisons have found that Nobel Prizes "can be used to validate bibliometric indicators" (Rodríguez-Navarro, 2011).

More recently, analyses of the population of Nobel laureates have focused on the rise of North America as a global center of science and technology, its subsequent hegemony (Heinze, Pithan, & Jappe, 2019) and how national institutional contexts have shaped the capabilities of universities and research organizations to achieve scientific breakthroughs (Heinze, Heyden, & Pithan, 2020). These studies found that North America, in particular the United States, replaced Germany as global scientific center by the 1920s, that its hegemony was consolidated in the 1970s, and that although its leadership has come under pressure since the 2000s, a new global powerhouse is not in sight. Furthermore, it was shown that national contexts exerting weak institutional control are associated with organizational capabilities to achieve scientific breakthroughs. More specifically, countries with weak institutional control (United States, United Kingdom) have produced many more Nobel laureates, controlled by population size and by GDP per capita, than those exerting strong control (France, Germany).

However, much less attention has been paid to the distribution of laureates across universities and research institutes (Schlagberger, Bornmann, & Bauer, 2016). There is no comprehensive map of the organizational field in which future laureates were educated, conducted their prize-winning research, and worked when awarded the prestigious prize. Furthermore, rankings that include Nobel laureates, such as the "Academic Ranking of World Universities" (commonly known as Shanghai Ranking), do not consider where future Nobel laureates were educated or conducted their prize-winning research, but focus solely on information at the time when the Nobel Prize was awarded.

Data and Method

This paper examines the distribution of Nobel laureates in Physiology/Medicine, Physics, and Chemistry across national and organizational boundaries. We distinguish three career stages: (1) the university where future Nobel laureates received their highest academic degree (HD), (2) the university or research organization where they performed their prize-winning research (PWR), and (3) the university or research organization where they were employed at the time of the award (NP). Our analysis builds on an existing dataset (Heinze et al., 2020; Heinze, Pithan, et al., 2019) that has been updated and includes the entire time period 1901-2020 (120 years). The primary data source was the Nobel Foundation's website (www.nobelprize.org), enriched by data from secondary sources, such as the American Institute of Physics, American National Biography, Encyclopedia Britannica, Howard Hughes Medical Institute, National Academy of Sciences, Notable Names Database, and Royal Society.

First, we provide basic descriptive information about both the laureate population and the Top-50 universities and research organizations (Tab. 1). *Second*, we present heatmaps based on calculations of the specialization index RESP (see below). This index is calculated using the *Activity Index* (Narin, Carpenter, & Woolf, 1987; Piro et al., 2017), that captures the extent to which certain entities are specialized in certain activities (Formula 1). AI values lower 1.0 indicate a negative specialization (below-average scores), AI values greater 1.0 a positive specialization (above-average). A verbal expression of the AI, applied to Nobel laureates, is given in Formula 2.

Formula 1: General formula of the Activity Index (AI)

$$AI_{ij} := \frac{N_{ij}/\sum_i N_{ij}}{\sum_j N_{ij}/\sum_{ij} N_{ij}}$$

Formula 2: Specific AI applied to career phases of Nobel laureates

$$AI_{ij} := \frac{\text{Nobel laureates of University i in career phase j/Nobel laureates of University i}}{\text{All Nobel laureates in career phase j/All Nobel laureates}}$$

The AI's value range of $[0.0, +\infty]$ lacks an upper limit. Available indexes that are symmetrical both above and below the expected value include for example the *Revealed Symmetric Comparative Advantage (RSCA)* to capture country-specific technical specialization (Laursen, 2000, 2015). Furthermore, the *Relative Specialization Index (RSI*) has been used to map profiles of Scandinavian universities (Piro et al., 2011; 2017; 2014). Interpreting RSCA and RSI is easier than the AI due to their symmetrical value range of $[-1.0, +1.0]$: values lower 0.0 indicate negative specialization; values greater 0.0 indicate positive specialization.

We use a modified version of the RSCA/RSI index that was introduced by Grupp (1994, 1998). Its value range is $[-100.0, +100.0]$ with an expected value of zero (Formula 3). This index, which we call RESP (for "Index of Relative Specialization") is different from RSCA/ RSI in that it is based on the *hyperbolic tangent.* Consequently, its curve is steeper and reaches the upper limits of its value range more quickly than RSCA/RSI. Hence, RESP-based heatmaps are richer in contrast, and present more visibly specialization profiles. For further details, see Heinze, Tunger, Fuchs, Jappe, and Eberhardt (2019).

Formula 3: Relative Specialization (RESP)

$$\mathrm{RESP} \coloneqq 100\,\frac{\mathrm{AI}^2 - 1}{\mathrm{AI}^2 + 1}$$

Note: The subindices i and j of the AI are omitted for the sake of simplicity.

Results

Our dataset contains 1578 career events (HD, PWR, NP) and 341 organizations from 100 years (1901-2000), the latter including universities, public research institutes, and private research laboratories. The four countries with most career events (1229 or 78%) and most organizational entities (232 or 68%) are (in descending order): United States (729 career events & 120 orgs), United Kingdom (243 career events & 40 orgs), Germany (178 career events & 51 orgs), and France (79 career events & 21 orgs). We calculated RESP values based on all countries in the database (n=30), using 20-year periods. Figure 1 displays the results for the four countries.

Apart from the fact that there seems to be no clear career pattern for France, three results are noteworthy. *First*, the United States shows a decreasing specialization in educating future laureates (HD): compared to other countries, the United States increasingly relies on foreign-born and foreign-educated scientists. This result corroborates findings from Stephan and Levin (2001). At the same time, it becomes more specialized in the later career phases (PWR, NP), indicating its growing attractiveness over the 20th century as work environment for future laureates (Heinze et al., 2020). These developments are especially pronounced in the medical sciences. *Second*, Germany has almost the opposite specialization to that of the United States: it shows an increasing specialization in the education of future laureates (HD), whereas its attractiveness as work environment for later career phases has decreased in the second half of the 20th century. *Third*, the United Kingdom shows stability in the two later career phases: its specialization in PWR and NP is visible for the entire 20th century.

The first and second results are in line with comparative-historical evidence that highlights the declining hegemony of German universities in the early 20th century, coupled with an upswing of research universities in the United States (Ben-David, 1960, 1971). Ben-David explains this development both with regard to internal organizational features in North-American universities that were more conducive to the growth of new research fields (compared to those in Germany), and the more pronounced level of decentralized competition in the American university system, particularly between public and private universities (compared to exclusively public higher education in Germany). Also, the first and third results are in line with comparative-historical evidence suggesting that national contexts in United States and the United Kingdom exerted weak institutional control on universities and research organizations, and thus facilitated highly innovative research capabilities in the 20th century (Hollingsworth, 2004, 2006), a finding that is reflected also in data on institutional context in the 21st century (Pruvot & Estermann, 2017).

We turn now to the organizational level. Given the results above, it is certainly not astonishing that the Top-10 universities are from the United States (8) and the United Kingdom (2). Equally important, however, appears the considerable variation among the Top-50 with regard to their representation in the three career phases (Table 1). Therefore, we probed organizational specializations in Nobel laureates' careers. For this purpose, we calculated RESP values for all organizations in the database (n=341), using 20-year periods. Figures 2 and 3 display results for the Top-20. We also checked robustness by calculating RESP values for those organizations with more than two career events and for those with more than ten career events. Overall, specialization patterns were very robust. Therefore, we focus here on results for all organizations in the database. In our view, the following results are noteworthy.

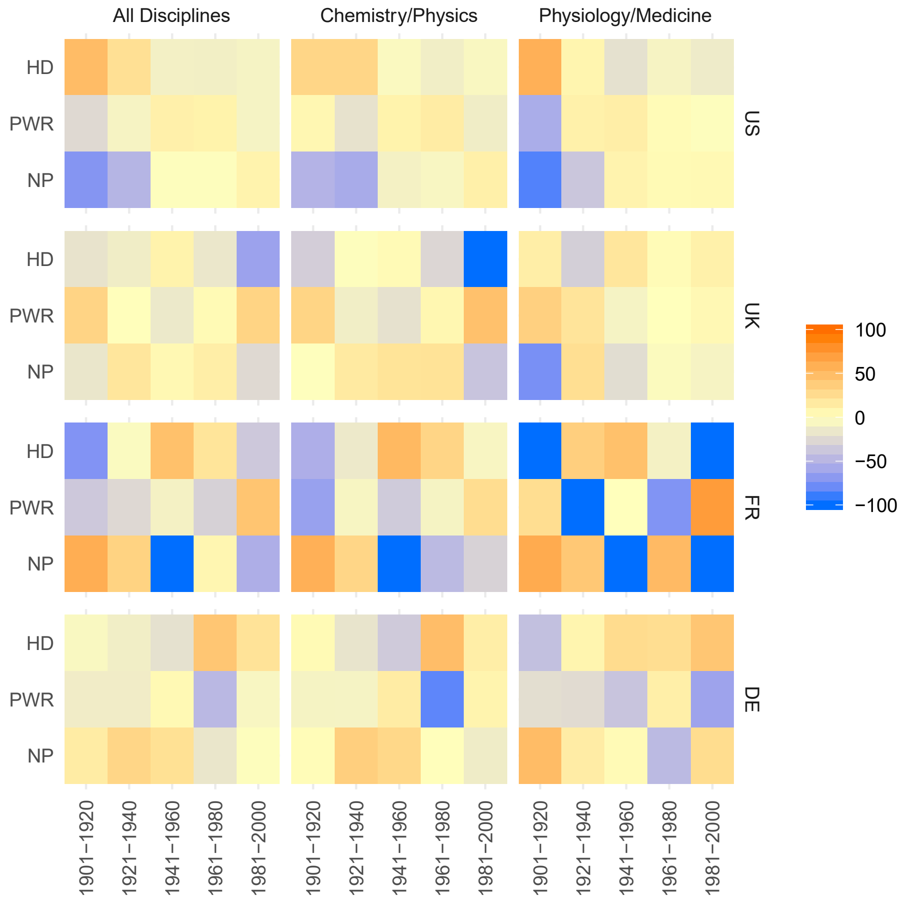

Figure 1. Career specialization profile of countries with Nobel laureates

First, there is some stability in single career phases over time, most notably in the education of future Nobel laureates (HD). Here, in at least four (out of five) consecutive periods, the following universities show a constant positive specialization over the 20th century: Cambridge, Harvard, Columbia, Berkeley, MIT, and Göttingen. Among those with a stable positive specialization in later career phases are in at least four (out of five) consecutive periods: Rockefeller (NP), Bell Labs (PWR), Caltech (NP), and London (NP). Clearly, constant positive specializations in either of PWR and/or NP require considerable resources to building and maintaining capabilities for highly innovative research. Borrowing a term coined by Zuckerman (1977), it is fair to call those universities and research institutes with constant positive specializations in either of the three career phases the *organizational ultra-elite* in global science. To be sure, this ultra-elite constitutes a very thin layer. Note that the Rockefeller Institute (later: Rockefeller University) stands out as the single entity with most 20-year periods in PWR and NP combined, highlighting its particular status among the organizational ultra-elite (for historical details on Rockefeller Institute see Hollingsworth, 2004).

Table 1. Global Top-50 universities and research organizations, 1901-2000

	Country	HD	PWR	NP	Total	Rank

Nagoya University, Nagoya	JP	5	3	0	8	45

Note: HD=highest degree, PWR=prize-winning research, NP=award of Nobel Prize. Column "Total" sums up HD, PWR and NP.

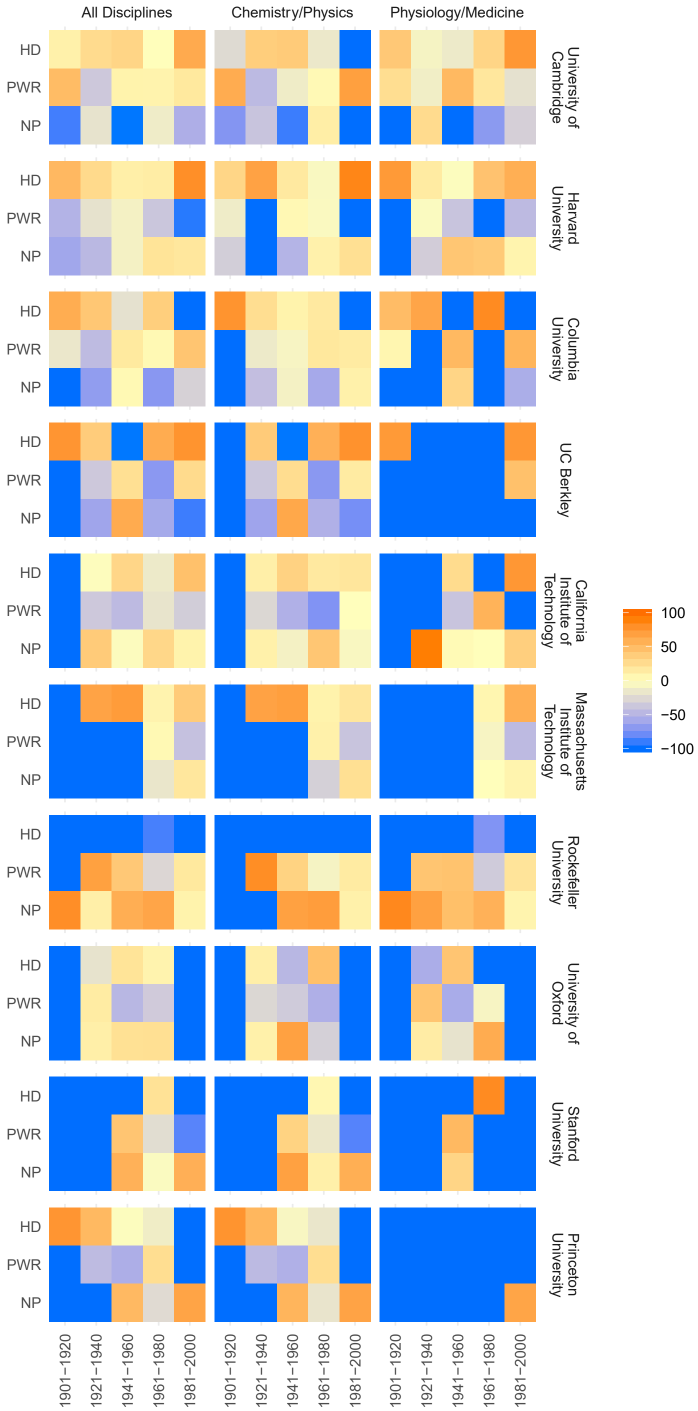

Figure 2. Nobel laureates career pattern of Top-10 universities and research organizations

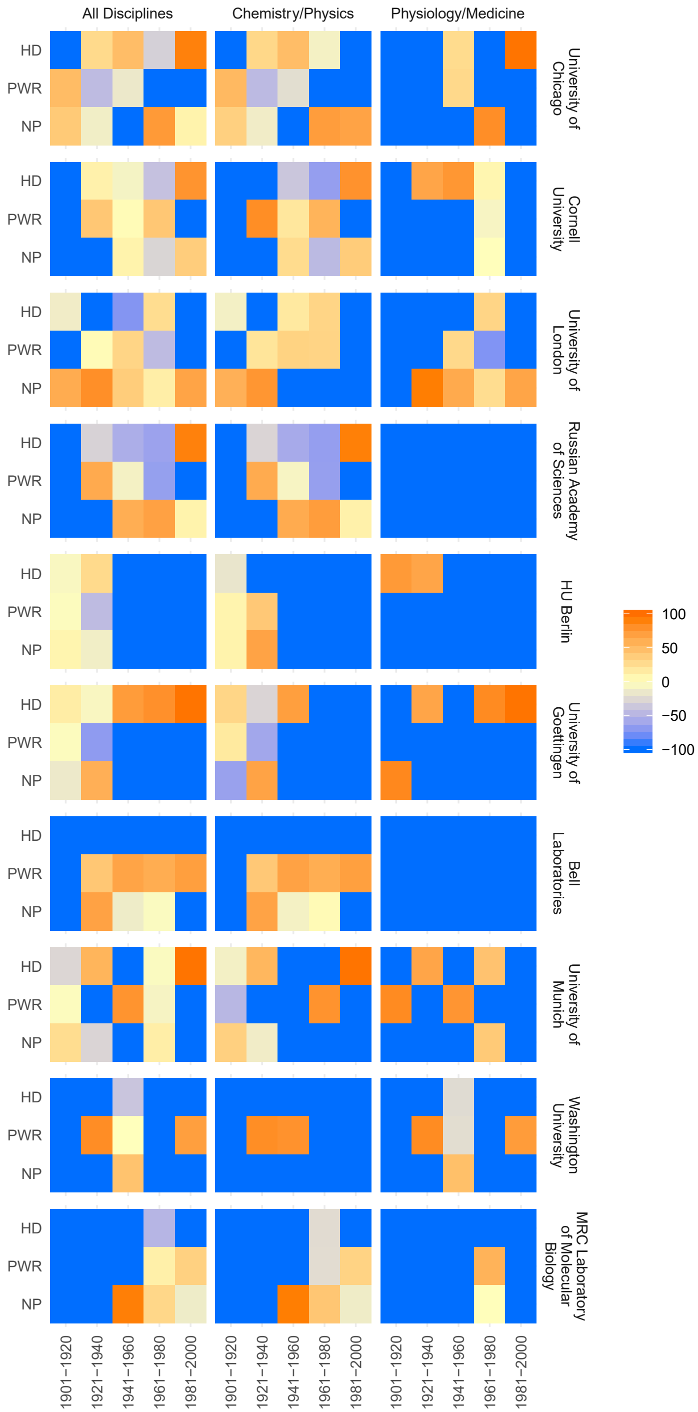

Figure 3. Nobel laureates career pattern of Top-11-20 universities and research organizations

Second, there is no single university or research organization with positive specializations in all three career phases in one (or more) 20-year period(s). More specifically, every university has at least one 20-year period, where no laureate either made his highest academic degree (HD), performed its price-winning research (PWR), or was employed at the time of the award (NP). However, we find examples that come close to that: MIT (1961-2000), Cambridge and Munich (1961-80), Columbia and Oxford (1941-60), HU Berlin and Göttingen (1901-20). Note that above-average scores in the PWR and NP career phases indicate capabilities for highly innovative research at an extremely high level. In addition, consider that some universities underwent a considerable change of their respective capabilities. For example, compare the first (1901-20) and fifth period (1981-2000) for two of the above-mentioned universities: HU Berlin (decrease) and MIT (increase). Also, most often several decades lie between HD and NP, so both HD and PWR observations are concentrated before 1980.

Third, few universities have changed their profile in a given career phase in one particular direction. Among those with growing specialization (over at least four consecutive periods) are Cambridge and Columbia (both PWR); conversely, among those with a decreasing specialization are Princeton (HD) and Göttingen (PWR). This suggests that in Cambridge and Columbia, some intra-organizational process of building-up capabilities to conduct highly innovative research took place, whereas in Princeton and Göttingen we assume that some process of downscaling of such capabilities occurred. How such processes unfolded and why is beyond the scope of this paper, but could be examined from a historical perspective.

In the light of the above-mentioned country-specific patterns, we probed whether they are reflected on the organizational level. Our analysis shows that this is not the case. *First*, there is no single university or research organization that roughly matches all three national specializations over time. Rather, we find some examples where specializations in one career phase (and sometimes two) are similar. Three examples to illustrate this point: 1) Cambridge mirrors the UK pattern in PWR (stable positive); 2) Princeton reflects the US pattern both in HD (decreasing) and NP (increasing), and 3) Göttingen develops a profile similar to that of Germany both in HD (increasing) and in NP (decreasing). *Second*, there are several universities that show patterns quite different from the national level. Two examples: 1) Cambridge is less specialized in the third career phase (NP) than the United Kingdom in general. Although it has educated an above-average number of future Nobel laureates and provided them with attractive working conditions, Cambridge retains them less often than the UK as a whole. 2) Similarly, although Columbia follows the (increasing) specialization of the United States in the first two career phases (HD, PWR), it has a weaker profile in NP compared to the national level.

Discussion

Taken together, our results suggest that analyzing longitudinal specialization patterns with regard to the careers of Nobel laureates yields several important insights complementing those obtained from cross-country comparisons. Interestingly, national career specialization patterns cannot be directly found on the organizational level. If universities and research institutes mirror national patterns, they do so in selected career phases only. However, the overall scientific growth (or decline) of countries can be seen in the profiles of particular universities and research institutes, as examples in Figures 2 and 3 illustrate for the United States and Germany. Perhaps the most important finding is the *organizational ultra-elite*, a group of (mostly private) universities and research institutes that show continuously above-average contributions in the education and employment of future laureates. In the light of commonly used rankings, such as the Shanghai Ranking or the Leiden Ranking that provide information about top-performing universities in the early 21st century, our analysis covers the entire 20th century, and thus gives insights into the building-up and maintenance of capabilities for highly innovative research.

In the future, our dataset can be analyzed further. Besides the RESP values for countries and for particular institutions, the interaction of both can be explored, i.e. how RESP values change in the context of world-wide versus country-wide consideration. Also, for most ultra-elite organizations, information about financial resources and scientific staff are available. The link between RESP values and both financial and human resources could expose more information about ultra-elite research organizations. Finally, we used descriptive statistic for presenting the RESP values here. Of course, RESP values can be statistically analyzed, too.

Notes

All graphs can be found and used under the CC-BY-NC-ND-4.0 international license at https://fachprofile.uni-wuppertal.de/conferences/issi2021.html. The Nobel Laureate dataset will be made publicly available following the completion of the ongoing research project.

Opening the black box of bibliometric mapping algorithms: Which algorithm should I choose?

Matthias Held

matthias.held@tu-berlin.de
Social Studies of Science and Technology, TU Berlin, Hardenbergstr. 16-18, 10623 Berlin, Germany

Abstract

The task of bibliometric mapping involves the usage of a data model together with an algorithm to analyze the data. In the last years, we learned more about the behavior of data models like co-citation or bibliographic coupling and their usefulness for certain tasks. From these studies, however, we learn relatively little about the impact of the choice of the algorithm. Usually, bibliometric mapping algorithms are imported from other disciplines, which means that they have not been developed for this particular purpose. We provide here a framework to analyze if the different assumptions on the data that these algorithms make correspond with the properties of topics they are trying to reconstruct.

Introduction

Ever since the advent of larger and larger networks which can be created from bibliometric data, researchers were confronted with the task to find patterns in these data with the help of algorithms. The reconstruction of scientists' topics is one of these tasks with some decades of history, and predicated upon the idea that these topics can somehow be reconstructed from the traces they leave in the scientists' publications' metadata, if only one chooses a suitable approach and data model.

For the choice of the data model, we have comparative studies which analyze their usefulness to reconstruct the phenomena in question (Shibata et al., 2009; Klavans & Boyack, 2017). What these studies share is that the data model and the algorithm are considered together. The choice of the algorithm, however, is usually not subject to discussion. While Šubelj et al. (2016) systematically do compare a large set of commonly used algorithms and apply them to bibliometric networks, we do not learn why the results differ and which algorithm is suitable for which bibliometric application. The major reasons for the common practice of using algorithms as black box could be: (1) There is tacit knowledge present about the algorithms nobody writes about. (2) We do not know which community detection algorithm to use since we do not know what we are searching for. (3) We are confronted with large networks and therefore simply choose the high-performance algorithms. (4) Most algorithms used come from other disciplines and can be used ready-made as black box. The abovementioned study compares the output of algorithms according to their statistical properties, but these analyses are decoupled from a real bibliometric application. Hence, we still lack studies that assess algorithms under bibliometric laboratory conditions. We need deeper analyses into the properties of the original purposes and assumptions of each algorithm (Gläser et al., 2017: 993-4), and assess their correspondence with the properties of topic structures we are trying to reconstruct.

We present here a framework to analyze properties of algorithms to assess their correspondence with the properties of topics which we derive from our theoretical definition. For applying the framework we chose four algorithms which all have been used in the bibliometric context before and been 'successfully' applied, including studies applying the Louvain algorithm (Glänzel & Thijs, 2017), the Leiden Algorithm (Colavizza et al., 2020), Infomap (Velden et al., 2017) and OSLOM (Šubelj et al., 2016).

First, we provide the derived topic properties along with the criteria to analyse the algorithms which we consider relevant for the task. Then, we provide first results of the analysis for the first algorithm and describe our planned future work.

Properties of topics

For science studies to be able to incorporate the results obtained from bibliometric topic reconstruction studies, both need a (common) theoretically derived definition of topics. Thus, we start with a definition.

We consider topics to emerge from coinciding interpretations and uses of some scientific knowledge by researchers. Havemann et al. (2017:1091) have defined topics as *"a focus on theoretical, methodological or empirical knowledge that is shared by a number of researchers and thereby provides these researchers with a joint frame of reference for the formulation of problems, the selection of methods or objects, the organisation of empirical data, or the interpretation of data"*.

From this definition, several properties of topics can be derived, which in turn shape the demands to approaches aiming to reconstruct topics (Table 1):

1. "Topics are local in the sense that they are primarily topics to the researchers whose decisions are influenced by them and who contribute to them. Methods for topic identification using only local information reconstruct this insider perspective, while methods using also global information construct a compromise between insider and outsider perspectives on topics" (ibid.). Thus, when the purpose of the analysis is the reconstruction of the perspective of the producers of the topics, an approach using mainly local information is to be used.

2. They can have various sizes, from a few researchers working on them, up to many, many more. Hence, methods to reconstruct these should not force a fixed size distribution.

3. One or more researchers can work on several topics, yet share the same method, theory or empirical object. Thus, topics do overlap, and hence reconstruction approaches have to allow the overlap of topics, including pervasive overlap and the detection of hierarchies in the topics.

4. Topics as shared frames of reference are characterized by cohesion, and separation from other topics occurs as secondary result from that. Hence, cohesion should be considered by algorithms. Because topics as shared frames of reference can connect knowledge in many different unique ways (Held et al., 2021), it follows also that the topics can take various structural forms.

Table 1: Topic properties and relevant criteria of bibliometric mapping algorithms.

Properties of topics	Criteria for algorithm analysis
Local	Use of local information
Size variation	Flexible size distribution
Overlapping	Finding overlaps and hierarchies
Cohesive / structurally diverse	Community definition, cohesion-separation trade-off
-	User's degrees of freedom

Usually the users of algorithms are provided some set screws to change the behaviour of the algorithm. The major set screws, which we sum up under the criterium *user's degrees of freedom,* are briefly analysed, since a deeper investigation would comprise a separate study. To our knowledge, these properties of topics and derived criteria for the analysis of algorithms have never been considered and applied before in the context of mapping.

Properties of algorithms

One frequently applied set of approaches in our field consists of optimization algorithms to find communities in bibliometric networks, where the found communities are often directly interpreted as topics[i] (Šubelj et al., 2016; Sjögårde & Ahlgren, 2018). Note that the choice of optimization algorithms is predicated on the idea – next to the assumption that there are topic structures in the networks at all - that these structures (however different they may be) can be detected with one single function that gets optimized and that these structures are best represented by communities (not all relevant larger structures in networks need to be communities, Newman (2012)) .

We take these assumptions as given in this study and, thus, now look at the above-mentioned criteria of several community detection algorithms in order be able to evaluate if these agree with the properties of topics.

Definition of community / separation and cohesion: Each of the tested algorithms is an optimization algorithm, which means that each one optimizes a predefined function, which in turn means that a certain idea of how a community 'looks like' is build (implicitly) into the algorithm and also into the optimization function. For communities to be optimal, they would comprise maximum cohesive, well separated components (in the extreme this means components of cliques) (Havemann et al., 2019). Because these structures are rarely found in networks, each community detection algorithm must find a compromise between separation of the communities and internal cohesion of same. This compromise is tightly linked to the definition of a community. The two problems belong together: *"For a proper community definition, one should take into account both the internal cohesion of the candidate subgraph and its separation from the rest of the network"* (Fortunato & Hric, 2016:6). And each available algorithm represents a different approach to this question. At this point a rather tricky situation seems to appear. Even though so many different algorithms can be found in the community detection literature, some of which have been used for bibliometric purposes, it seems unclear from the literature how to best solve the problem of cohesion and separation (irrespective of our topic reconstruction problem) in line with an agreed-upon definition of community. Different conceptions of how communities should "look like" are built into the algorithms. What all four algorithms have in common is that they detect assortative structures (Newman & Clauset, 2016), i.e. structures that form dense regions, which, at this point, we have to assume to be characteristic for topic structures. However, the question as to how a high cohesion in network communities could be identified has various answers (Havemann et al., 2019), including internal conductance (communities should be hard to split), high density (many links between nodes), high clustering coefficient (number of links in nodes' neighborhoods divided by possible links) (Yang & Leskovec, 2014) or a high value of the second eigenvalue of the community's Laplacian matrix (Tibély, 2012). Again, there is no agreed-upon answer to this question. This also becomes clear when we look at the common efficient algorithms used, like the four analyzed in here, that mainly focus on separation[ii], and the discussion on what cohesion would mean is generally hardly taken up in the literature (ibid.). What separation means, on the other hand, seems more agreed upon.

Most of these considerations usually assume non-overlapping communities. When communities are allowed to overlap (a lot), or are assumed to comprise core-periphery structures, then finding the best trade-off between separation and cohesion becomes a completely different question (Havemann et al., 2019:2).

Use of local information: We consider algorithms which consider the statistics of the entire network and optimize the result using mainly these global statistics as global algorithms. In this paper these would comprise Louvain and Leiden algorithm, as well as Infomap. Those algorithms which consider local statistics by exploring and expanding the local network structures (as introduced by Baumes et al. (2005)) we consider as local algorithms. In this paper OSLOM is an example of this group.

Finding overlaps and hierarchies: Does the algorithm construct overlapping communities, or can it be used to obtain these? Are hierarchies in the network detected or how can the algorithm be used to obtain these?

Flexible size distribution: Does the algorithm force a certain community size distribution? Or tend to create many small or many large clusters?

Users' degrees of freedom: Which decisions does the algorithm request from the user and to which degree does this contribute to the constructedness of the result? More degrees of freedom can be helpful if they support tuning an algorithm to the bibliometric task, while fewer degrees of freedom may force a certain result and prevent experimentation. At the same time many degrees of freedom may make the link between settings screws and the outcomes nontransparent.

Analysis of Algorithms

In Table 2 the first results of the algorithms' properties are provided.

Table 2: Brief overview of four algorithms' properties relevant for topic reconstruction.

	Community Definition / Separation-Cohesion	Local / Global	Overlapping / Hierarchies	Preference of Size	Users' Freedom
OSLOM	Statistically significant community, focus on separation	Local	Pervasive / yes, automatically	unknown	p-value
Louvain	Dense community, focus on separation	Global	No / possible to extract simple hierarchy	unknown	Resolution parameter
Leiden	Dense community, focus on separation	Global	No / possible to extract simple hierarchy	unknown	Resolution parameter
Infomap	Nodes' closeness, focus on separation	Global	Marginal	unknown	Several parameters

Order Statistics Local Optimization Method (OSLOM)

This algorithm has been developed by Lancichinetti et al. (2011), who are authors very active in network science. It is based on the idea to optimize a function that assesses the statistical significance of each cluster. OSLOM starts with a random selection of single nodes as seeds for clusters, and repeatedly adds significant neighbors to node to let the cluster grow. Significance is determined here via a comparison to a distribution that is based on a null model, i.e. a network without community structure. This is done repeatedly, until similar clusters are found again and again, then the algorithm stops. This way, overlapping clusters are found.

Definition of community / separation and cohesion
The test for statistical significance of each community is based on separation. Though OSLOM checks for internal cluster structure in a community (Lancichinetti et al., 2011:5), and decides for splitting or merging of communities, it cannot ensure internal cohesion.

Use of local information
The OSLOM algorithm can mostly be considered a local approach, but also uses global statistics. When OSLOM considers the significance of a cluster, it first considers the surrounding of each cluster to add significant nodes, which is one aspect it can be considered a local approach. However, the assessment of the environment of a cluster is done by comparing it to a global random null model (Lancichinetti et al., 2011: 2), viz. the configuration model, which is also used in many variants of modularity. So, the global statistics play an important role in this step. When each cluster is then labelled "significant" with respect to its surrounding, the inside of the cluster is assessed for significance, using no more the global model, but by comparing it to a null model within this cluster, which makes it a local assessment of cluster statistics. Another local property of OSLOM is its search for possible cluster merging candidates, i.e. clusters which appear to be very similar (which, according to the different iterations for the determination of significance, often overlap a lot), where it is assessed if the overlapping zone is another separate cluster, if everything is merged or if only the overlapping zone remains significant and is kept (Lancichinetti et al., 2011: 5).

Finding overlaps and hierarchies
As OSLOM goes iteratively over each cluster and might add "significant nodes", overlaps between the clusters can occur because a node might be considered significant from the perspective of more than one cluster. Pervasive overlaps can occur.
In principle, OSLOM is able to detect a poly-hierarchy in a network. It searches for the smallest clusters which can be considered significant, and then builds a new network from these clusters, where again each node is assessed for significance. Thus, it is continued until no more significant clusters are found in the next coarser level, and potentially several levels of hierarchy are then found (Lancichinetti et al., 2011: 5).

Flexible size distribution
OSLOM's preference for cluster sizes is still under investigation.

Degrees of freedom as user
One major decision that has to be made is about the significance level P. It has influence on the size of the communities found, lower values lead to larger communities (fewer), higher values to smaller ones (more communities).

Future Work
First, our theoretical analysis of the four algorithms according to our derived criteria will be completed. From this, however, there is still a lot to do in order to make robust suggestions as to the suitability of an algorithm for a certain bibliometric task. It has been shown that no algorithm is suitable to cluster all kinds of networks (Aldecoa & Marín, 2013). Thus, as second step, we intend to use bibliometric benchmark datasets on which we apply the algorithms; and conduct a deeper assessment of the structures these algorithms detect.

Abstract

Due to the advantage of solving complex societal problems and generating meaningful innovations, interdisciplinary research (IDR) has attracted broad attention and extensive support from academia, industry, and government. Most of IDR studies, especially about the quantitative measurement of interdisciplinarity, focus on the perspective of integration. Although impact, as another critical dimension of IDR, has been discussed in recent years, most current studies focus on the impact within the academic research domain, e.g., productivity and citation. Exploring the dynamic evolution of knowledge diffusion, particularly across different disciplinary fields, helps our understanding of IDR and its impact. This paper proposed a novel conceptual framework to investigate the interdisciplinary impact in the broader sense of knowledge diffusion. Beyond the citation count, we care about the citing papers' disciplinary diversity and the cognitive distance between the source paper and citing papers.

Introduction

The complexity and comprehensiveness of significant challenges require solutions developed by fostering effective interdisciplinary collaboration and integrating knowledge from different scientific fields. Under these circumstances, interdisciplinary research (IDR) has attracted wide attention. In order to better explore the IDR, conceptualizing the IDR is the priority task. One of the most broadly-accepted definitions of IDR is set forth in a National Academies' report (National Academy of Sciences et al., 2005). Derived from the above definitions, knowledge integration is the essence of IDR; therefore, in the past few years, most of the studies on IDR, especially about the quantitative measurement of interdisciplinarity, focus on the perspective of integration from ideas (such as concepts and theories), methods (techniques and tools), or data from various fields of knowledge (Porter et al., 2007). Scholars have developed a variety of proxy indicators delivering different insights about the interdisciplinary nature of the object under study, especially from the cognitive perspective (Zhang et al., 2016), the organizational perspective (Zhang et al., 2018), and the policy perspective (Huang et al., 2016).
Impact, as another core dimension of IDR, has also been paid some attention to. In fact, the concept of 'impact' is as complex and multi-faced as 'interdisciplinarity'. The impact can be interpreted from different perspectives. Most of the prior works focus on the impact within the academic research domain, e.g., productivity and citation (Judge et al., 2012; Larivière & Gingras, 2010; Larivière et al., 2015; Steele, 2000; Wang et al., 2015; Yegros-Yegros et al., 2015). In recent work, Zhang et al. (2021) take the broader impact (particularly, PloS usage) into consideration. Although citation impact and 'societal impact' are definitely the important part of the impact of IDR, whether IDR has diffused the knowledge to broader and diverse disciplines are essential dimension deserved to be further investigated.

Method

Forward citation diversity

Forward citation diversity (FCD) is an indicator to measure the diversity among journals citing a given body of research, and "diffusion score" is one of the FCD indicators that is used to trace the influence (Carley & Porter, 2012). Figure 1 presents a concrete example of the relationship between source paper and citing papers. Here, we adopted the full-counting method for the multi-assignment subject system.

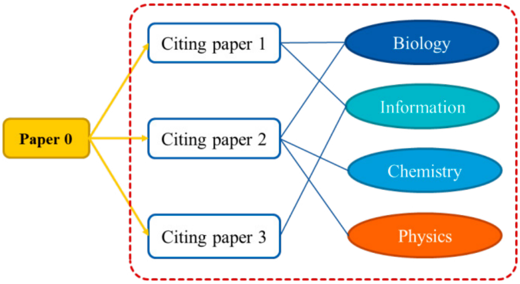

Figure 1. A concrete example of the relation of source paper and citing papers with their corresponding fields

The measurement of FCD is similar to the indicators used for the integration of knowledge generated in different disciplines. It also considers three distinct components: the number of disciplines citing (variety), the distribution of citations among disciplines (balance), and how similar or dissimilar these categories are (disparity) (Stirling, 2007). Its formulate is:

$$FCD{=}1 - \sum_{ij} PF_i * PF_j * SIM_{ij}$$

Where PF_i denotes the proportion of citing publications assigned to the category i in a given paper, SIM_{ij} is Salton's cosine measure of similarity between category i and j. *The* different implementations and comparisons are introduced in our two recent works (Thijs et al., 2021; Huang et al., 2021). FCD scores range from 0 to 1, with higher scores indicative of more significant infiltration into external disciplines. According to the sample similarity/disparity among the four fields provided in Table 1, the FCD value of Paper 0 is 0.478.

Table 1. The sample similarity (disparity) among four fields

	Biology	Information	Chemistry	Physics
Biology	1.0 (0.0)			
Information	0.2 (0.8)	1.0 (0.0)		
Chemistry	0.6 (0.4)	0.1 (0.9)	1.0 (0.0)	
Physics	0.4 (0.6)	0.3 (0.7)	0.8 (0.2)	1.0 (0.0)

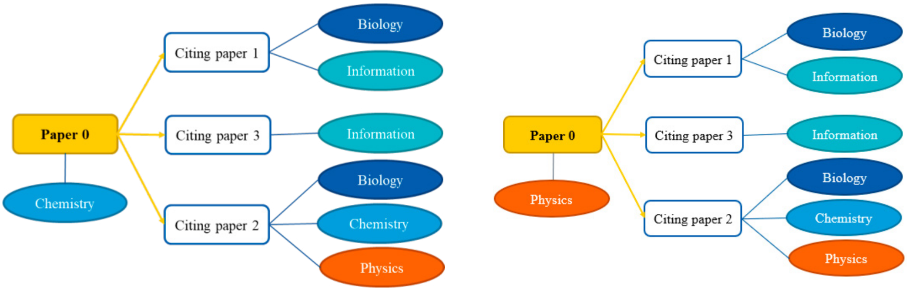
Interdisciplinary impact

The FCD addresses the disciplinary diversity of the citing papers, and it can be treated as an important proxy to trace the knowledge diffusion impact. However, when we consider the source paper's disciplinary category, the situations drive us to figure out supplementary indicators further to cover more different circumstances: a chemistry paper that diffuses the knowledge to other fields is different from a phsics paper that diffuses its knowledge to the same fields. The concrete example of two source papers with different fields and citing papers with their corresponding fields, is shown in Figure 2.

We propose the interdisciplinary impact (IDI) to measure the average disciplinary distance among the source paper and citing papers, and the general formula is as follows:

$$IDI=\frac{1}{n}\sum_{k=0}^{n}\sum_{ij}PC_i * PF_j * DIS_{ij}$$

Where n is the number of citing publications (forward citation), PC_i denotes the proportion of category i in the current publication, PF_j denotes the proportion of category j in the citing publication (forward citation), DIS_{ij} refers to distances between subject field i and j, and $DIS_{ij} = 1 - SIM_{ij}$. With IDI scores range from 0 to 1, higher scores indicate greater knowledge diffusion to distant disciplines.



(a) Source publication is a Chemistry paper

(b) Source publication is a Law paper

Figure 2. Example of two source papers cited in different fields

Forward citation diversity vs. interdisciplinary impact

Either FCD or IDI fails to track interdisciplinary knowledge diffusion of IDR comprehensively; however, combining these two becomes an alternative solution. Figure 3 provides a schematic representation of this twofold perspective, following the conceptualization diagram proposed by Rafols and Meyer (2010). We take individual publications and study knowledge diffusion through their citing papers set, each of the parts in the networks represents a paper (the middle one represents the source paper, and three ones are the citing papers), each shape placed in the oval/round refers to categories of the given paper. Each link indicates the citation between the source paper and citing papers.

		Interdisciplinary impact (IDI)	
		Low	High
Forward diversity index (FCD)	Low			High		
Figure 3. Conceptualization of knowledge diffusion in FCD and IDI

There are four possible combinations:

- High IDI-High FCD: A researcher/study delivers knowledge to distant and diverse fields.
- High IDI-Low FCD: A researcher/study delivers knowledge to distant but limited fields.
- Low IDI-High FCD: A researcher/study delivers knowledge to adjacent but diverse fields.

- Low IDI-Low FCD: A researcher/study delivers knowledge to adjacent and limited fields.

Sample and Results

Based on the indicators proposed in the "Method" section, we compare the results at the level of individual paper level and at the individual researcher level.

Individual paper level

Table 2 presents the results for disciplinary diversity and interdisciplinary impact from the perspective of citing papers for the selected four articles.

Table 2. The knowledge diffusion impact-related indicators of the selected paper

UT	Journal	Num_SC	GE_SC	DIS_SC	FCD	IDI	Type
000275291600016	Chimia	9	0.674	0.830	0.669	0.941	(i)
000315970300193	PLoS One	8	0.422	0.860	0.490	0.794	(ii)
000315307600009	J. R. Soc. Med.	9	0.778	0.813	0.630	0.446	(iii)
000232795300006	Libr. Infor. Sci. Res.	8	0.383	0.704	0.399	0.254	(iv)

Note: Num_SC means the number of subject categories assigned to citing publications; GE_SC indicates the evenness of distribution among citing subject categories; DIS_SC is the average dissimilarity between citing subject categories.

The first paper entitled "How long is the peer review process for journal manuscripts? A case study on Angewandte Chemie International Edition" (000275291600016) published in *Chimia* (Chemistry, Multidisciplinary) is cited in the nine fields: Information Science & Library Science (5), Computer Science, Information Systems (3), Agronomy (1), Computer Science, Interdisciplinary Applications (1), Education & Educational Research (1), Horticulture (1), Medicine, General & Internal (1), Microbiology (1), and Plant Sciences (1). Here, we assume the categories of papers are the same as the classification given to the journal it is published in --it is not perfect but compromised way, and we will discuss it in the "Conclusion and Discussion" section. The first paper delivers information to distant fields, ranging from natural science to life sciences & biomedicine, and social science, and the distribution of citing fields is diverse and relatively balanced.

The second paper entitled "Macro-indicators of citation impacts of six prolific countries: InCites data and the statistical significance of trends" (000315970300193) published in *PLoS One* (Multidisciplinary Science) is cited in the eight fields: Information Science & Library Science (17), Computer Science, Interdisciplinary Applications (12), Computer Science, Information Systems (2), Multidisciplinary Sciences (2), Sociology (1), Surgery (1), Urban Studies (1), and Clinical Neurology (1). The second paper is also cited by the articles from distant fields, but their distributions are so unbalanced that they result in a relatively lower FCD (The citing fields mainly focus on the Information Science & Library Science, and Computer Science, Interdisciplinary Applications).

The third paper entitled "Enhancing the *h* index for the objective assessment of healthcare researcher performance and impact" (000315307600009), published in *Journal of the Royal Society of Medicine* (Medicine, General & Internal), is cited in the nine fields: Medicine, General & Internal (4), Computer Science, Interdisciplinary Applications (1), Information Science & Library Science (1), Education, Scientific Disciplines (1), Emergency Medicine (1), Health Policy & Services (1), Rehabilitation (1), Surgery (1), and Urology & Nephrology (1). Unlike the second one, the third paper is cited by a broad field, but these fields are closer to the field the third paper is assigned to.

The fourth paper entitled "Preference for electronic format of scientific journals - A case study of the Science Library users at the Hebrew University" (000232795300006), published in

Library & Information Science Research (Information Science & Library Science) is cited in the eight fields: Information Science & Library Science (20), Computer Science, Information Systems (5), Biochemistry & Molecular Biology (1), Biology (1), Cell Biology (1), Computer Science, Interdisciplinary Applications (1), Multidisciplinary Sciences (1), and Psychology, Applied (1). On the one hand, the fourth paper is mostly cited by the same field (Information Science & Library Science) or the adjacent field (Computer Science, Information Systems); on the other hand, the distribution of its citing fields are unbalanced.

Individual researcher level

We selected the Derek de Solla Price Memorial Medal winners, who published more than 20 research articles during 2005-2014, as the targeted sample. We first measured the related indicators at the paper level, then aggregated them up to the personal level when relevant by taking the mean score across each researcher's set of papers. The results are shown in Table 3.

Table 3. The knowledge diffusion impact-related indicators of the selected Price award winners

	Aver. Num_SC	Aver. GE_SC	Aver. DIS_SC	FCD	IDI
Bar-Ilan, Judit	9.811	0.645	0.709	0.460	0.421
Bornmann, Lutz	12.638	0.543	0.801	**0.555**	**0.511**
Cronin, Blaise	9.100	0.548	0.715	0.451	0.432
Egghe, Leo	7.193	0.742	0.635	0.405	0.464
Glänzel, Wolfgang	11.203	0.532	0.775	**0.507**	0.477
Leydesdorff, Loet	16.042	0.530	0.797	**0.585**	**0.554**
Moed, Henk F	13.069	0.540	0.788	**0.518**	0.481
Rousseau, Ronald	6.133	0.678	0.649	0.415	0.432
Schubert, Andras	11.821	0.530	0.776	**0.519**	0.467
Thelwall, Mike	11.805	0.590	0.737	0.499	0.478
van Raan, Anthony F J	14.929	0.496	0.813	**0.543**	**0.509**

According to the above table, we can see in the last two columns that Loet Leydesdorff, Lutz Bornmann, and Anthony F J van Raan produce more knowledge diffusion impact on the follow-up studies, so they get a higher score in FCD and IDI. Henk F Moed, Andras Schubert, Wolfgang Glänzel also diffuse their knowledge to a broad range of fields, but these fields are relatively close to the field of the source journal they published, so they perform well in the FCD but relatively lower in IDI.

Conclusion and Discussion

Knowledge diffusion is a dynamic process compared to knowledge integration since citations to a set of published documents can be continuously changing. Therefore, exploring the dynamic evolution of knowledge diffusion, particularly across different disciplinary fields, helps our understanding of IDR and its impact. This paper proposed a novel conceptual framework to investigate the interdisciplinary impact in the broader sense of knowledge diffusion. Compared to the academic impact and social impact mentioned in the previous studies, the combination of FCD and IDI provides a comprehensive scope to understand the broader impact, especially for the IDR that should not only care about the integration of knowledge from two or more disciplines, but also the diffusion of knowledge to solve complex societal problems and generate meaningful innovations. Furthermore, since diffusion can be thought of as integration in reverse, the IDI indicator can also be used to better measure integration--not only considering the disciplinary diversity in the cited references but also the average distance between the cited references and source publication. The IDI is very sensitive to the classification systems of publications. Most of the current classifications are based on journal assignment in which all papers published in a given journal are classified in the same discipline (or set of disciplines) rather than determined by the real content present in the paper. Therefore, a document-based improvement of the subject assignment is necessary. Our other recent study gives solutions for individual-document-based subject assignments by introducing a multiple-generation reference model (Glänzel et al., 2021) .

Acknowledgments

The research underlying this study is done within the framework of the project "Interdisciplinarity & Impact" (2019-2023) funded by the Flemish Government.

Abstract

With this contribution we address the problem of identifying so called key publications, i.e. publications, one should read, in order to generate an overview of a topic. To this end we introduce the reference citation plot as a useful approach for identifying such publications by plotting a paper's number of references and number of citations, respectively. The first one was chosen in order to estimate the broadness of a publication's knowledge base. This concept is perpetuated by introducing the Reference and the Citation Topic Width, which measure the disciplinary broadness of the references and of the citing papers. We demonstrate the usage of these metrics within the field of technology foresight.

Introduction and problem

Where should one start reading, if one delves into a scientific topic? What are the publications one should definitely read? This is one of many problems, scientists and researchers have to deal with in their every-day work. Within technology foresight, this problem is even aggravated, since in many cases futurist have to deal with very different topics stemming from various scientific fields, although they are no experts in this particular field (Schulze et al. 2020). An obvious approach to address this problem would be, to start with a suitable review paper. However, it has been shown by Harzing (2013) and Colebunders & Rousseau (2013), that a significant number of publications in the Web of Science might have been misclassified regarding their document type. This observation is consistent with our experience in carrying out literature research on a regular basis. Thus, we wanted to establish a plausible and yet feasible paper-based approach, which should be easy to implement, in order to identify *key publications*. Those are publications, which are particularly suitable to gain an overview of a topic and to identify current research highlights. Thus, the notion of a key publication is broader than that of a review paper as it tries to take into account the different aspects of a typical foresight process.

Our approach

Description of the system used

We used an in-house database based on the Web of Science data, which is part of a support system for technology foresight, which has been developed at the Fraunhofer INT (John, 2018). The system consists of three components. First, a graph database implementing an RDF graph model forms the core of the system. This approach is particularly well-suited for storing highly interconnected bibliographic data by utilizing a generic data model. One advantage of this approach is, that it allows to reduce complex analyses to simple queries using SPARQL, the corresponding query language for RDF graph databases. A high-performance search engine is used to perform searches on the approximately 65 Million publications (as of January 2021) stored in the database. The technology analysts at the Fraunhofer INT interact with the systems via an intuitive graphical user interface, which consists of two different parts, namely a search interface for a typical literature research, and an analytic view, including different dashboards. The latter provides a comprehensive data-driven view on a topic and the corresponding publications.

Description of the metrics considered

In order to identify those publications, which provide a suitable overview over a specific topic, we make the following assumption: an author must have acquired a rather broad knowledge base to be able to present such an overview. In contrast, papers which deal with certain specific and detailed aspects of a topic, do not necessarily refer to the aggregated body of knowledge on this topic. As a consequence, we wanted to construct a proxy for measuring the broadness of a paper's knowledge base. Therefore, we considered the number of references N_{ref} of a paper as first proxy to measure the broadness of its knowledge base. Since citing and being cited only depends on the point of view, it seemed logical to use the number of citations T_c as a second metric. Thus, we implemented a simple scatter plot in our system, which depicts N_{ref} on the x-axis and T_c on the y-axis. We called this plot *reference-citation plot,* and it is shown in Figure 2.

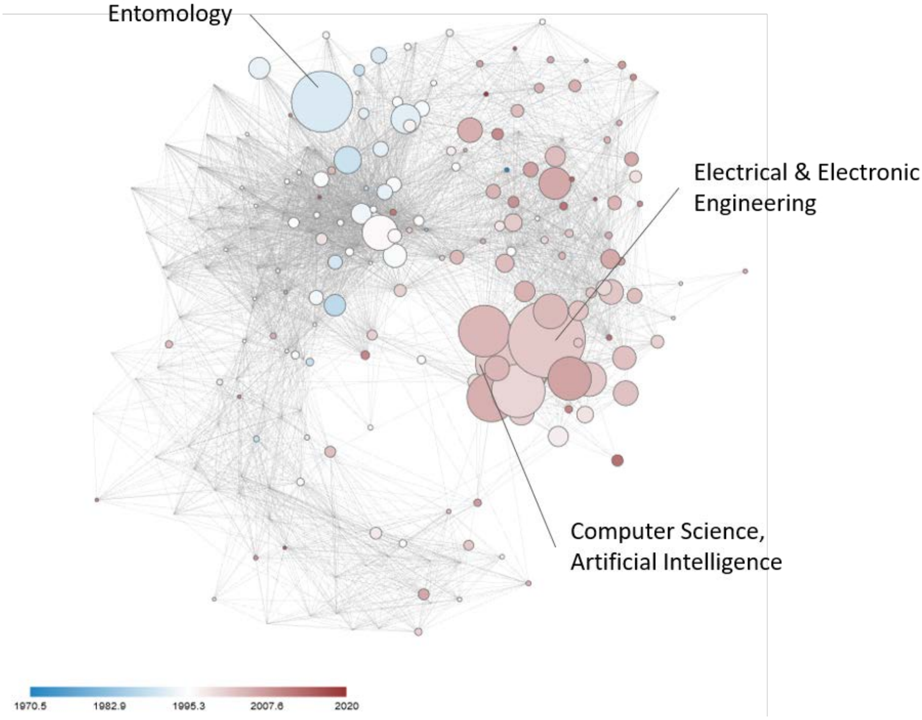

Figure 1: Overlay Map for generating an overview of the topic "bee colony". Each bubble represents a subject category and its color is determined by the mean age of publications in the respective category.

In a second step we measured the number of disciplines, indicated by the subject categories of the Web of Science, the references originated from. We call this the *Reference Topic Width RTW*. It is based on the observation, that some papers access knowledge from only a few different disciplines, while others have a broad knowledge base meaning they are referring to publications from many disciplines. Finally, we once again refer to the mirror-inverted relationship between citing and being cited and introduce the *Citing Topic Width CTW* which represents the number of disciplines the citing papers of a publication are assigned to.

A didactic example

As an example, we chose the topic “bee colony”. The reason for this will become clear at the end of this contribution. Using the simple search query “bee colon*”, which corresponds to a typical topic search in the Web of Science web-interface, resulting in 8.253 publications as of January 2021.

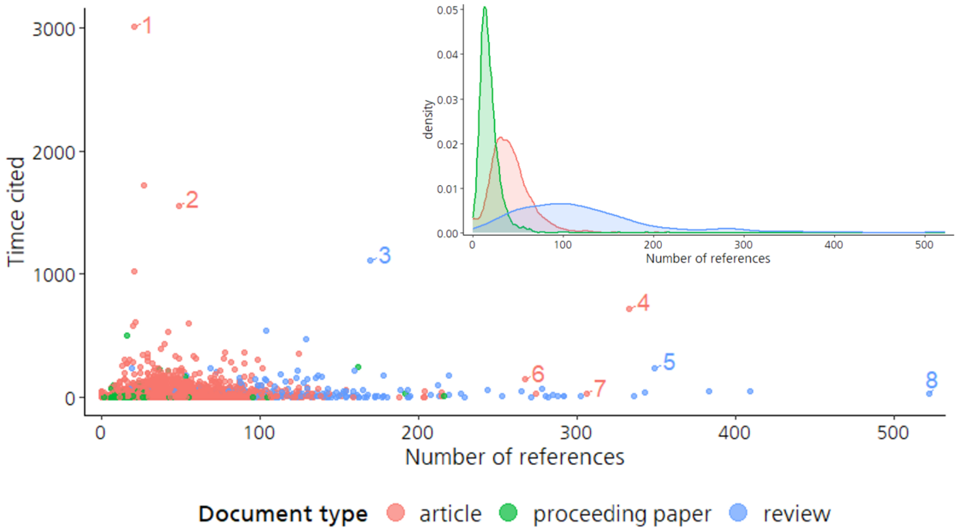

Figure 2: Reference Citation Plot for the topic “bee colony”. Details for the eight marked papers are given in Table 1. The inlay displays a density plot for the distribution function of the number of references for three different document types.

Generating an overview

First, we present an overview over the topic by using the overlay maps developed by Rafols et al. (2010). This kind of representation of the disciplinary structure of a topic was extended by adding further options for coloring the bubbles, which represent the subject categories. The possibility to scale the color by the mean age of the publications (see Figure 1) proved to be particularly useful. This coloring scheme reveals, that the topic “bee colony” is obviously partitioned between two different broader research areas. The first and older one, as indicated by the blue colors, can be found in the upper left and comprises subject categories stemming from the life sciences, like Entomology, Zoology, Ecology etc. The second, broader area covers disciplines from Computer Science and Engineering. These disciplines contain more recent publications as indicated by the red colors of the bubbles. This example demonstrates, that coloring the bubbles offers the opportunity to gain further and deeper insight into the disciplinary structure of a topic which is particularly valuable in the context of technology foresight. Since the user is enabled to interact with the map in the browser-based system, it still further enhances the opportunities of such an analysis.

The Reference Citation Plot

The reference citation plot for the topic “bee colony” is shown in Figure 2. The underlying idea of this representation is to generate a quick overview. Possible survey articles can be found in the lower right part of the plot, regardless of whether they are tagged correctly as a review paper or not. As can be seen, there is a considerable number of articles with more than 100 references which are not tagged as review papers. Indeed, the titles of the paper 4, 6 and 7 (see Table 1) confirm, that these papers have the character of a review, although they are labelled as articles. In order to check, whether our assumption regarding the amount of references of review papers is correct, we analyzed the frequency distribution of this number using a density plot (see Figure 2, inlay). The observed shift of the maximum of the distribution confirms our assumption. As expected proceeding papers tend to have fewer references (maximum at approximately 14 references), than articles (maximum at ~35) and review papers (maximum at ~100).

Table 1. Title and key indicators of the eight publications marked in Figure 2 and 4. The color of the title indicates the document type, i.e. red for articles and blue for review papers.

Title	*Number*	*TC*	*Nref*	*RTW*	*CTW*
A powerful and efficient algorithm for numerical function optimization: artificial bee colony (ABC) algorithm	1	3008	21	7	115
A comparative study of Artificial Bee Colony algorithm	2	1556	49	16	96
Bee declines driven by combined stress from parasites, pesticides, and lack of flowers	3	1107	170	29	78
A comprehensive survey: artificial bee colony (ABC) algorithm and applications	4	718	333	48	83
A Comprehensive Survey on Particle Swarm Optimization Algorithm and Its Applications	5	239	349	74	95
A survey of swarm intelligence for dynamic optimization: Algorithms and applications	6	144	267	33	34
Multi-population techniques in nature inspired optimization algorithms: A comprehensive survey	7	27	306	58	22
Catalog of the Indo-Malayan/Australasian stingless bees (Hymenoptera: Apidae: Meliponini)	8	25	522	23	12

A closer look at the titles also reveals the reason for the thematic split observed in the overlay map in Figure 1. While, as expected, the biological part deals with bees (e.g. paper 3 and 8 in Table 1), the computational and engineering part is about a global optimization algorithm named artificial bee colony (ABC) algorithm.

Additionally, the reference citation plot allows the quick identification of highly cited papers, which are located in the upper left part of the plot. Such papers are possible breakthrough papers, which might indicate important developments within a topic. Paper 1 in Figure 2 is an example for this hypothesis, as it described the aforementioned optimization algorithm for the first time.

Utilizing the disciplinary broadness of references and citations

In Figure 3 we present a scatter plot of the RTW and the CTW. Again, we marked the papers listed in Table 1 for a rough orientation. The first intriguing observation is, that in some cases review articles tend to have a broader knowledge base in terms of disciplines than regular articles (e.g. paper 4, 5 and 8 in Table 1). Other, rather thematically specific publications, like paper 3 or 8, build upon a knowledge base, which comprises only a few disciplines, resulting in a low value of the RTW. From the point of view of technology foresight this distinction is

quite useful, since it allows researchers to select the necessary literature for a deep dive into a topic.
The examples given in Table 1 regarding the CTW demonstrate, that this metric is useful too, since it measures the disciplinary broadness of a publication's impact. This becomes particularly clear with respect to paper 1. Although it has a rather narrow knowledge base as measured by RTW, it has influenced applications in many different areas as can be concluded from the high value of the CTW. We were able to confirm this, by taking a closer look at the overlay map, where we identified a number of applications of the ABC algorithm stemming from different disciplines and fields of application. We want to point out, that this is an important insight for technology foresight.

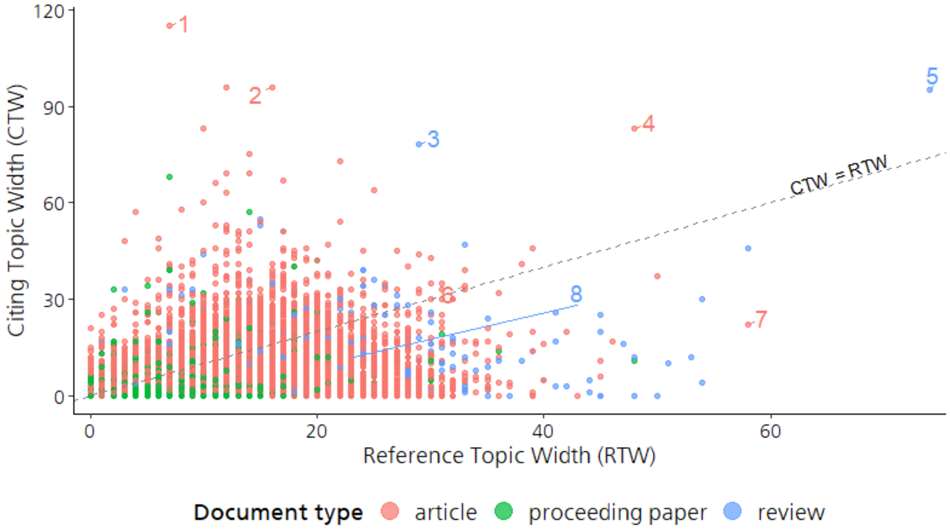

Figure 3: Scatter plot displaying RTW and CTW. Additionally, the line where RTW equals CTW is shown. Publications below this line have a larger RTW than CTW.

Furthermore, in some cases we observed, that the disciplinary perception of a paper differs significantly from the disciplinary structure of its knowledge base, which is also apparent from Figure 3. In order to analyse this aspect, we first took a closer look at the difference between CTW and RTW. If this difference is greater than 0, the paper's disciplinary perception is broader than its knowledge base. A density plot of the distribution of this difference is presented in Figure 3. Although in most cases, the difference is smaller than 0, indicating a disciplinary narrowing, there are some publications for which we observed a disciplinary broadening. Such a shift is of possible interest for technology foresight and needs to be investigated further.

Conclusion & Outlook

As demonstrated, the idea to measure the broadness of a paper's knowledge base is intriguing and helpful for identifying key publications. Although we can only present a simple anecdotic example here, the approach has proven quite useful in everyday literature research at the Fraunhofer INT. Of course, a more systematic investigation is necessary in order to overcome its anecdotical character. It is noteworthy, that this approach is transferable to other databases.

The difference of the CTW and RTW values indicate, that the disciplinary structure of a paper's knowledge base and its citing papers have changed. Such a shift might be an important indicator, which might be particularly useful in the context of technology foresight.

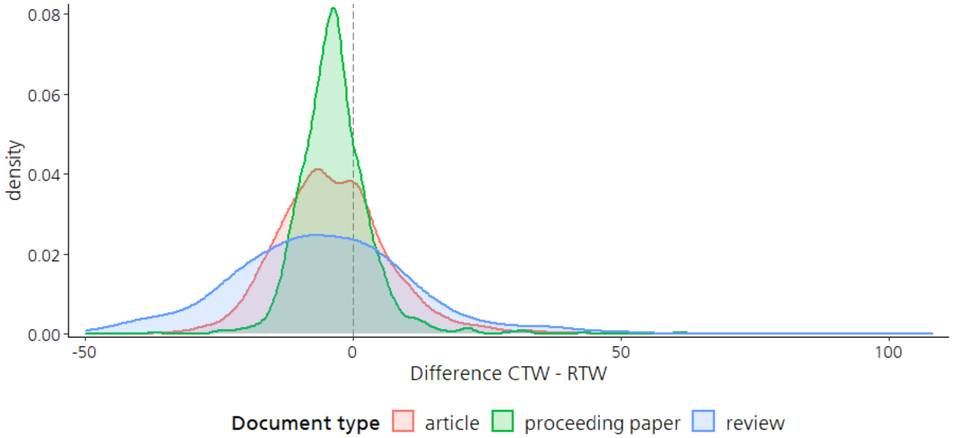

Figure 4: Density plot of the difference between CTW and RTW.

There are several directions of future research. First of all, not only the number of different disciplines should be considered, since it only covers the variety of the knowledge base (Rafols & Meyer, 2010). It could prove useful, to assess its diversity too. Additionally, different categorization systems such as those implemented in the Dimensions system (Herzog, Hook, & Konkiel, 2020) should be explored.

Abstract

Scientific literature reviews are an important entry point for researchers to get a first overview of a scientific topic and to find more publications that are worth reading. Also, evidence exists that reviews are more often cited than original research articles. This makes it important that reviews are correctly classified in literature databases. In our research, we used the Web of Science (WoS) by Clarivate Analytics and analysed a total of 1.8 million reviews. Clarivate had a review classification policy in force from 1992-2010. In the present paper, we wish to highlight the effects this policy has had on the distribution of reviews in the WoS in general and also in the Subject Categories. We find distinct distributions in groups of Subject Categories, discuss their meaning and potential pitfalls for researchers wanting to use reviews in the WoS.

Introduction

Dedicated scientific literature reviews (henceforth referred to in this paper as "reviews") constitute a central element of scholarly communication. Reviews strive to collect scientific knowledge in the form of research papers and present them in a systematic and orderly way. As such, a review also represents a selection of research papers that in the opinion of the authors represents the most important and current research on different topics. Normally, reviews do not describe new research themselves but rather the research contained in other research articles. In this way, reviews are an important entry point for researchers to get a first overview of a scientific topic and to find more publications that are worth reading. The University of Texas Libraries describes them as "virtual gold mines if you want to find out what the key articles are for a given topic" and "review articles are good places to get a basic idea about a topic" (see references for the website address. Reviews are also written for scientists in their own respective communities so that they can look back at recent developments of their field. At our institute where we conduct many studies in the field of technological foresight, reviews are an important aspect for our technology analysts to get a first understanding of current research on different topics (Torraco 2016).

According to Colebunders und Rousseau (2013) and Colebunders et al. (2014) the number of reviews in the fields of Tropical Medicine, Infectious Disease and Oncology increased and they were more likely to be cited than were normal research articles. Since, as these authors note, "impact factors and citations are increasingly used to evaluate scientists and […] reviews receive more citations than do normal research articles" an interesting question to answer is how high the number of "mislabeled reviews" in the WoS is, since reviews might be cited which actually are no reviews and actual reviews cannot be found because they are not classified as reviews.

In her excellent paper on the same topic, Harzing (2013) describes the situation she found in 2011. She analysed the document categories with regard to the Social Sciences (also mentioning the Sciences) and used a data set based on a journal sample. The present research-in-progress paper wishes to build upon this work and expand the data set used and the scope.

The WoS describes a very straightforward definition of what a review is. On one of the official websites by Clarivate Analytics (the company behind the WoS) the following definition is listed (Garfield 1994):

> *"In the JCR system any article containing more than 100 references is coded as a review. Articles in "review" sections of research or clinical journals are also coded as reviews, as are articles whose titles contain the word "review" or "overview.""*

It is important to note a couple of things about this definition, though. The text on the Clarivate site (https://clarivate.com/webofsciencegroup/essays/impact-factor/) was originally published by Eugene Garfield in a comment in the "Current Contents", a source of information on different journals. The present authors were unable to get a copy of the original paper, but there are at least two digital versions of them, one of those the text on the Clarivate homepage. Interestingly enough the text on the homepage is edited, at least because of the insertion of the name "Clarivate Analytics" a company that was only founded in 2016. Whether or not more changes to the original text have been made could not be ascertained. It is also important that Garfield notes that reviews are often more cited than "normal" research articles but the policy he describes might lead to artificial inflation of the number of reviews inside of a journal. The other important thing is that the text is published under a section called "essays", and as such does not constitute the official policy of the WoS. However, the described procedure was used for a period of time, as also Harzing (2013) describes in her paper. It is this policy of the WoS and its effect on document classification that we study in detail in the present paper.

Reaching out to Clarivate Analytics, we got the information via personal email correspondence that indeed such a policy was in force from 1992-2010 and that the classification of a review was based upon a) the publisher if he lists an article under a section that implies that it is a review, b) the words "Review of the literature" in the title of the article, the abstract or the introduction, c) the words "Review, Systematic Review or Mini-review" appear in the title of the article and must appear elsewhere in the article, d) the article in question has more than 100 references and finally e) reviews which were presented at conferences were processed as Proceedings Papers.

Among others, the central questions we wanted to answer was what effects this policy had on the reviews in the WoS in general and whether it affected the different scientific disciplines (based on the so-called Subject Categories (SCs) of the WoS) in different ways. We used these categories since they were readily available in the data.

Methods

Our institute uses both the online version of the WoS and an offline database of the same data. The latter allows us to employ more detailed analyses than with the online tools alone. We are aware that other institutions might have such an offline access to the data and thus other options to find reviews or review-like papers. It is our opinion, though, that for most researchers, the online version is the one typically used. Our data subscription includes the Science Citation Index Expanded and the Social Sciences Citation Index for the years 1970 till today as well as the Conference Proceedings Citation Index – Science and the Conference Proceedings Citation Index – Social Science & Humanities for the years 1990 till today. In total, our offline database includes about 62 million publications (in June 2020).

For the present study, we used a data set from July/August 2020 containing all publications that have the document type "Review". In total, this data set contains ca. 1,8 million reviews. We also split this data set by SCs since those are an approximation of scientific disciplines. We did this in order to see whether there were any differences between reviews in, e.g. the life sciences or engineering. To analyse the data sets, we used RStudio and different scripts in R. The analytical approach is straightforward. The data set contains information about the WoS-ID of the publication, its publication year, the total number of references, and finally the SCs to which the paper is assigned. It should be noted that a paper can be assigned to multiple SCs.

Results

As a first approach to the data set, we took a look at all publications with the document type "Review" (1.8 million publications) and sorted them by the number of references each had. In a next step, we deleted the reviews with 0 references (nref = 0) and those with more than 500 (nref > 500). The reason for removing the reviews with zero references (about 30.000 publications) was that from our point of view those did not represent typical scientific reviews, i.e. an overview of the literature of a specific scientific field or topic. Why such publications exist at all seems to be due to at least two reasons. The obvious one is incorrect indexing. For example, a review named "Matrix Metalloproteinases – a review" (WoS-Accession Number: A1993KP25900004) was indexed correctly as a review. However, no cited references were indexed. But looking into the actual PDF of the paper (or, if available, the original article itself) one can see that the publication includes a long list of references (H. Birkedal-Hansen et al. 1993). There are other, current, examples like "An overview of wild edible fruits of Western Ghats, India" by Sreekumar et al. (2020). This paper is also indexed as being "Early Access" so maybe the error in the number of references will be corrected in the future. It seems to us that this is a simple error in indexing and we take note of it. This means that for our analysis, we lost some relevant reviews when we deleted reviews with a nref of 0. This is an error that can be found on the online version of the WoS as well as in our offline data. We did not have the resources to check all excluded reviews manually. We assume this kind of error is responsible for most of the reviews with zero references. However, there can also be found publications that indeed have zero references like Thomas et al. (2011) "The Dawn Spacecraft" which is a description of the titular spacecraft and its mission. In total, we think that with only 2% of all reviews, deleting these papers from our data set is an acceptable trade-off to improve the validity of our data set. As for the reviews with more than 500 references, we found 7673. We excluded those because they represent the very long endtail of an already very long tail in the data set. Including these does not improve the validity of the data set. In total we deleted about 40.000 publications or 2% of all reviews in the Web of Science)

With the remaining 98% of all reviews in the WoS we plotted Figure 1. It can be seen quite plainly that the number of reviews rises with the number of the references until it reaches a peak at about 50 references (with 17.000 reviews having this number of references). After that the number of reviews gradually declines. Thus far, this seems to correspond with the nature of reviews, meaning that a certain amount of referenced literature is needed to actually make a review and after reaching a certain amount of references the number of reviews simply drops off, probably for a variety of reasons (e.g. the amount of work one needs to put into a review grows with each reference). The number of these references probably also depends on the discipline for which the review is written (more on that later).

The more interesting to note in Figure 1 is an unexpected second peak at about 100 references (with ca. 13 000 reviews). This peak is, of course, due to the policy, the WoS used until 2010 to classify any publication as a review which had 100 or more references. But this peak also shows that the number of reviews has thus been artificially inflated, due to company policy. As Harzing (2013) noted that this led to a huge number of normal articles to be classified as reviews. Since the policy was abandoned, Clarivate Analytics was probably also of the opinion that their policy did not match the reality of the scientific publication practices. But since the peak is still there in the data set, what does this mean for researchers, bibliometricians, policy makers and other users of the WoS?

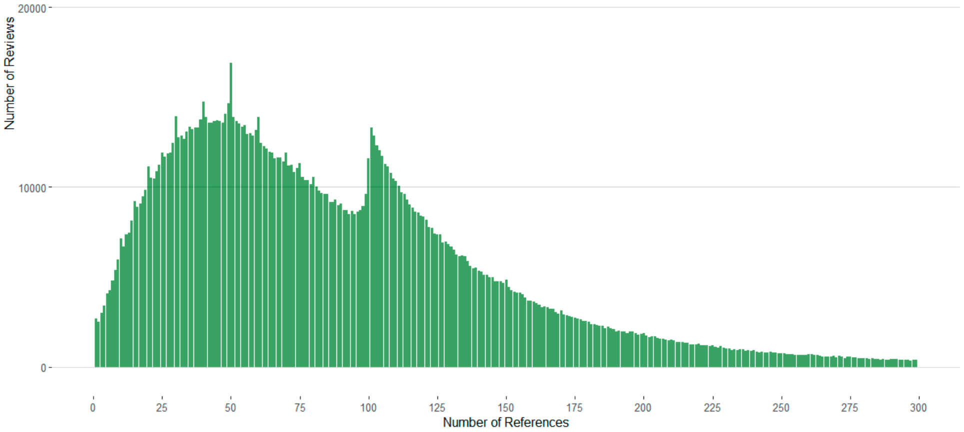

Figure 1: The distribution of reviews in the Web of Science (1970-2019).

Similar to Figure 1 we created graphs for each of the Web of Science’s so-called SCs. SCs are classifications which are used to label every journal in the WoS using at least one SC (some have more). It is important to note that the SCs are journal- and not article-based. This means that it is not always clear which publication from a journal with two or more SCs is part of one, the other, or both SCs. There is a whole body of literature on the question whether the SCs are a good classification of scientific disciplines for journals. See for example Leydesdorff und Rafols 2009, who argue that even though there exist “inaccuracies in the attribution of journals to the ISI SCs” those “presumably […] average out” for the main structure of the disciplines.

Looking at a total of 236 SCs we found that it was possible to categorize the SCs into three broad groups and that two of those did not correspond to the distribution found in Figure 1. Namely, one of the broad groups included most Social Sciences and the Humanities and looked like the examples in Figure 2.

This group has two peaks, one at about nref > 25 and one at about 100. We called this group the “Camel” group because it included two humps.

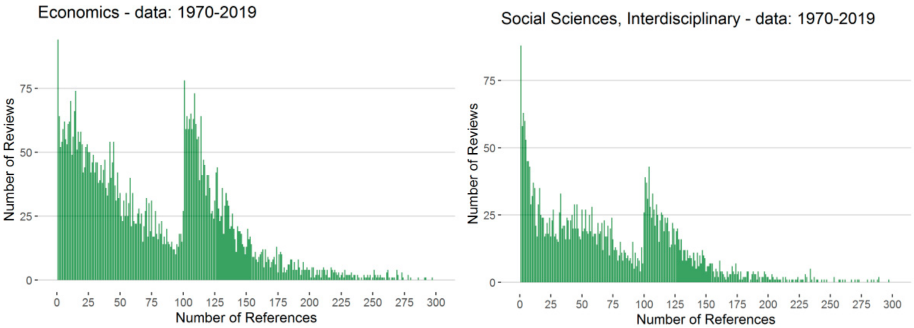

Figure 2: Examples for the „Camel“-group.

The next group we have encountered in our data seems to have a typical distribution that looks like this (see Figure 3):

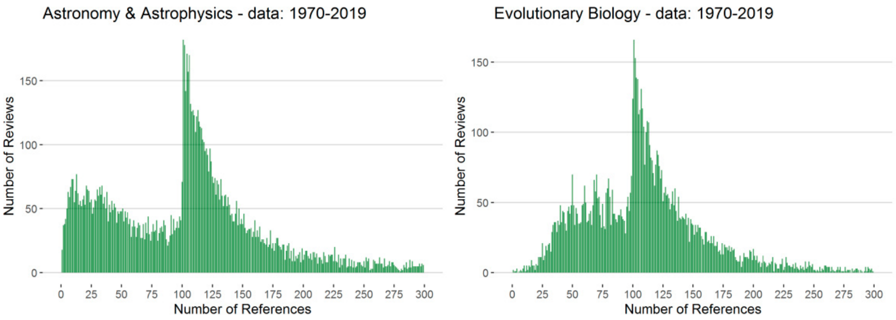

Figure 3: Examples for the „Sharkfin“-group

This kind of distribution has different kinds of peaks left of nref = 100 but at about this point there is a very strong solitary peak, which is why we called this group the „sharkfins“. As to the SCs in which this distribution surfaces, there seems to be no common characteristic but it can rather be found in the natural sciences, engineering, arts and humanities.

The final group we found in our data set had rather typical distributions when looking at bibliographic data (see Figure 4):

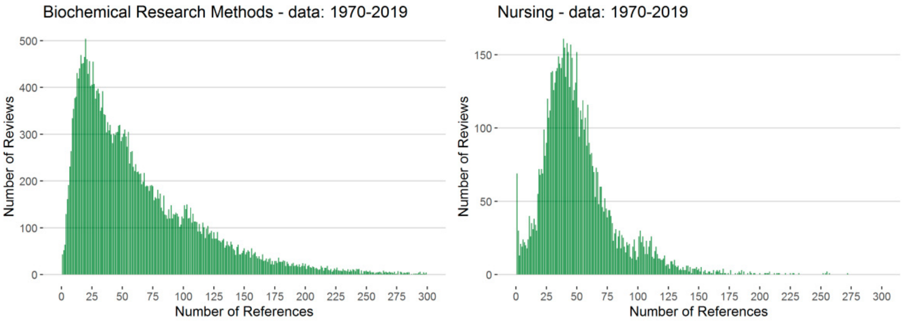

Figure 4: Examples for the left-skewed group of SC-distributions

These distributions seem to follow a Poisson distribution and appear to be typical for medical and life science SCs in general.

To sum up, our results suggest that there are three groups of distributions of reviews:

1. The “Camel”-group that seems to be typical for the Social Sciences and Arts & Humanities.
2. The left-skewed group that is typical for life science SCs.
3. Finally, the “Sharkfins” that can be found in a great variety of SCs.

Discussion and conclusion

In the present research-in-progress paper, we were able to show that Clarivate’s policy from 1992-2010 had a profound effect on the distributions of reviews in the WoS, similar to Harzing (2013) but on a broader scale. Also, according to the distributions, there are groups of SCs that are more strongly affected (the “Camels” and “Sharkfins”) than others (the life science SCs). With this information researchers using the WoS already have an idea which SCs have a higher number of mislabeled reviews than others. In our further research on this topic we will split the data set into three time periods (pre-policy, policy and post-policy) to see how the distribution of reviews in the WoS behaved before and after the policy and whether those had a lower amount of mislabeled reviews. Based on this, we want to calculate an indicator based on the average number of references for reviews of specific SCs in order to recommend possible future policies that keep the amount of mislabeled reviews at a minimum while not being to complicated to implement.

Acknowledgments

We would like to thank the two anonymous reviewers for their helpful and constructive comments which we integrated into the final version of our paper.

Abstract

Global publication trends in research integrity and research ethics (RIRE) have increased exponentially. Over 25,700 publications on RIRE from Web of Science across the period 1990-2018 form the basis of this study. Countries, institutions, and their collaborations on RIRE are analyzed. Results show that developed countries in North America and Western Europe contribute to most of the global publications on RIRE. However, despite China's significant growth on RIRE study in recent years, the increase is not comparable to its rapid growth in overall publications for science and technology. International collaboration on RIRE increased from ~2% of the total publications in 1990 to 23% in 2018. Developed countries dominate international collaborations on RIRE, with USA– Canada, USA-UK and UK-Australia as top collaborating pairs. The proportion of multi-authored, multi-institutional and multi-country papers has grown over the years, indicating the trend towards increased collaborations in RIRE studies.

Introduction

Globally, research has been on an upward trajectory. The number of scientific publications has increased exponentially (Larsen and von Ins 2010; Powell et al. 2017; Zhang et al. 2015), fueled by societal and commercial interests. These are evidenced by increases of R&D funding, numbers of researchers, commercialization potential, and participation of emerging countries (Bhattacharya et al. 2015; Javed and Liu 2018; Moiwo and Tao 2013; Shashnov and Kotsemir 2018). Alongside the expanding research landscape, the role of ethics and integrity continues to serve as a basis for good research practices. The necessity and shared responsibility of all stakeholders to uphold standards and principles is expected to continue to grow as more countries commit to funding research and more researchers contribute to the knowledge base (Titus et al. 2008).

Whereas research ethics defines the standard framework of acceptable conduct in research (Resnik 2020), research integrity represents the adherence of conduct to ethical principles which renders trust and confidence of the given methods and results. Both are complementary in supporting responsible scientific conduct (Bird 2006; Braun et al. 2020). The absence of either facet can have potentially dire consequences which could erode public trust in research. Clinical research without ethical protocols can marginalize vulnerable study participants (Schüklenk 2000). Flippant or perfunctory conduct, skewed or exaggerated data, or outright fraudulent results has the potential to misdirect future paths of research (L. M. Bouter et al. 2016; Coxon et al. 2019). Poor research may also mislead or misinform policymakers, thereby undermining government support for research in terms of its reliability and future funding (Michalek et al. 2010). In the competitive research landscape, researchers and institutions also face increasing pressure and demands (Haven et al. 2019), potentially leading to corner-cutting or compromising of standards.

The ongoing discourse led to flourishing of research ethics and research integrity (RIRE)-related fields (Aubert Bonn and Pinxten 2019). In the last 10 to 15 years, the number of retractions has increased (Steen et al. 2013), signalling a greater awareness and identification of appropriate publication conduct (Fanelli 2013). Moreover, institutions are adopting policies and regulations to promote good practices (Geller et al. 2010; Lins and Carvalho 2014). In this work, we explore and identify the global trends of the broad scope of responsible research, in terms of RIRE, through bibliometric analysis, between 1990-2018. We aim to characterize the shifts, trends, and participants in order to provide a broad-view understanding about the research activities and developments over the years.

Data Set and Methods

Web of Science (WoS) was used as database source for the study. The period of study was restricted between 1990-2018. In view of the broad range of dissemination methods in the field, where key papers can take the form of editorials or notes (Aubert Bonn and Pinxten 2019), all publication types were included. Publications containing keywords related to RIRE, such as "scientific ethics" or "scientific integrity" or "publication ethics" or "publication integrity" or "scientific misconduct" or "scientific dishonesty" or "publication misconduct" or "publication dishonesty" or "academic cheating" or "scientific cheating" or "research cheating" or "publication cheating" or “bioethics” or “plagiarism” or "research misconduct" or "research dishonesty" or "academic misconduct" or "academic dishonesty" or "Research Integrity" or "Research Ethics" or "Academic Integrity" or "Academic Ethics" were used for the search. The terms were refined and selected to ensure inclusion of relevant RIRE topics. Over 25,700 publications were identified and used for subsequent bibliometric analysis and citation mapping. For bibliometric analysis, frequency counts were determined based on the field element. To calculate ratios of publications of a country in terms of global shares, publications associated with the target country in each category (RIRE or All Subject Areas) were obtained. The % Share of Global Research Integry/Ethics papers is computed as the ratio of papers associated with an authoring country over the total number of papers in the subject globally. The % Share of Global Research in All Subjects was taken as the publication count per country over the counts on All Subject Areas globally. Data for the latter was obtained from the InCites database. The Share Difference is computed as the difference of % Share of Global Research on RIRE papers and % Share of All Papers on All Subject Areas.

VOSViewer (VOSviewer 2020), developed by CWTS in Leiden University (The Netherlands), was employed to conduct scientific mapping and extract keywords in the publications to elucidate the topics in RIRE. In order to understand the country-specific topics on RIRE, publications on research integrity/ethics were also analyzed by country.

Results and Discussion

Global yearly publications on RIRE between 1990-2018 show a steady increase (Figure 1(a)). Publication volume rose from 101 publications in 1990 to 2315 in 2018, with a compound annual growth rate (CAGR) of 12.8%. The United States dominates in publishing topics related to RIRE with 8594 cumulative publications, followed by England, Canada, Australia, Spain, Brazil, Germany, Italy, France, and China. The majority of top 10 countries researching on RIRE are generally higher-income western nations, with a track-record of reputable institutions and research. China is the only Asian country amongst the top 10 (10th), while India is in the 13th position (Figure 1(b)).

Figure 2 gives the country-level differences between global publication shares on RIRE to shares in All Research Areas for leading countries between 1990-2018.

USA, Canada, UK, and Australia are found to have positive variance, while China, Germany, France, Italy and India have negative variance, indicating that the latter group of countries has relatively less research activity on RIRE compared to overall research activity. Yet, the reasons may differ amongst countries. The lag in RIRE-related research within the emerging countries is thought to be attributable to a host of factors, such as publication priorities in technical disciplines, or ongoing development and enforcement of research ethics and integrity policies within the institutions (Ana et al. 2013; Fanelli et al. 2015; Okonta and Rossouw 2014). For example, China exhibited exceptional publication growth, accounting for 8.3% of all global research publications between 1990-2018 in all subject areas (the second country by scholarly output after the United States). By contrast, publications on RIRE only accounted for 2.0% of the global output on RIRE.

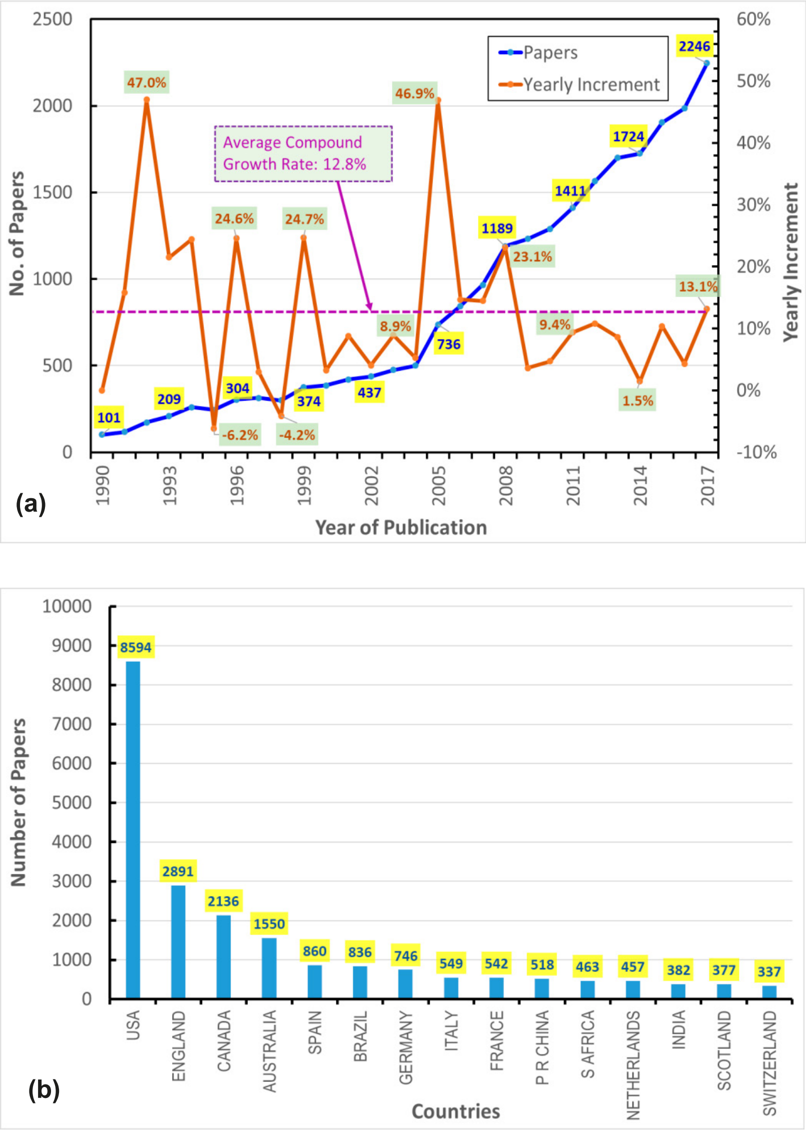

Figure 1 – (a) Yearly publication trends of publications in RIRE-related topics. The primary y-axis represents the number of papers per year, while the secondary y-axis shows the yearly increment. (b) Publication count on RIRE topics from 1990-2018 by country.

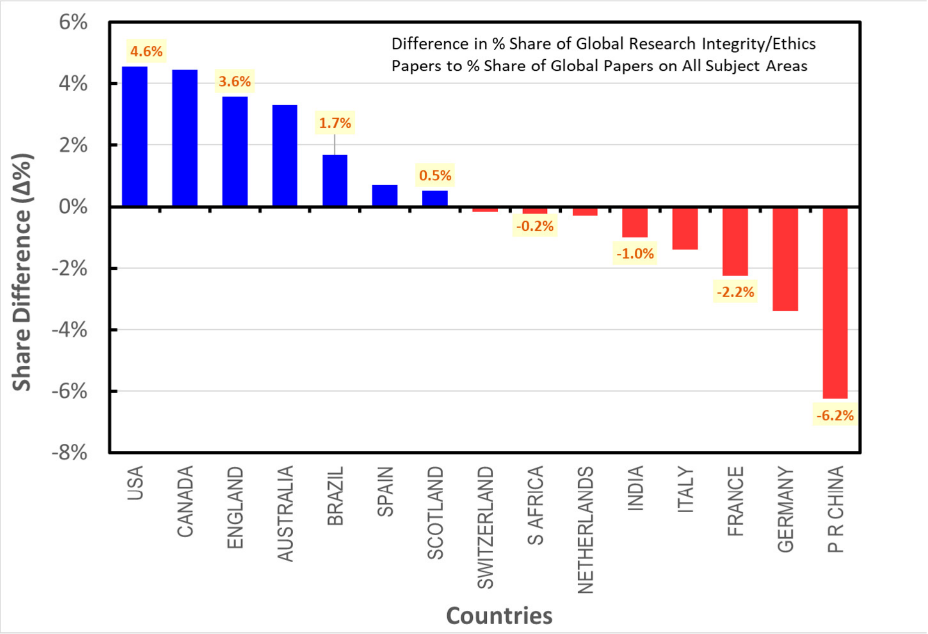

Figure 2. Share difference in global publications on RIRE against All Research Areas for top countries between 1990-2018.

A comparative analysis is further conducted on the two leading publishers globally, USA and China, along with a comparison between emerging countries (China and India). Figure 3(a) shows the global shares of RIRE publications compared with global shares from all research areas for both USA and China. Compared to the world output, USA exhibited declines in both categories. Meanwhile, publication shares of China rose from less than 1% in 1990 to 17.9% in 2018, ranking second in research publication output in WoS. However, although China has grown its research capacity dramatically in the past three decades, its participation in RIRE-related work is comparatively lower (3.5%) and not commensurate with its overall growth (Ataie-Ashtiani 2017, 2018; Qiu 2010; Yang 2013).

The current ratio of Chinese publications on RIRE relative to the country's total number of publications in 2018, marked at 0.016%, is equal to that of the USA in 1990. The Chinese government has taken firm steps to respond to the problems of RIRE deficiency (Zeng & Resnik, 2010; Qiu, 2015; Yi, Standaert, & Nemery et al., 2017; Cyranoski, 2018), such as developing ethics policies and establishing oversight committees. An extensive punishment system was announced that could have significant consequences for offenders — far beyond their academic careers (Cyranoski, 2018). Offending researchers could face restrictions on jobs, loans, and business opportunities. With these measures, improvement on RIRE is anticipated. However, most importantly, research and education in RIRE should be enhanced (Zeng, & Resnik, 2010), so that a healthy research community with high standard research ethics can be established.

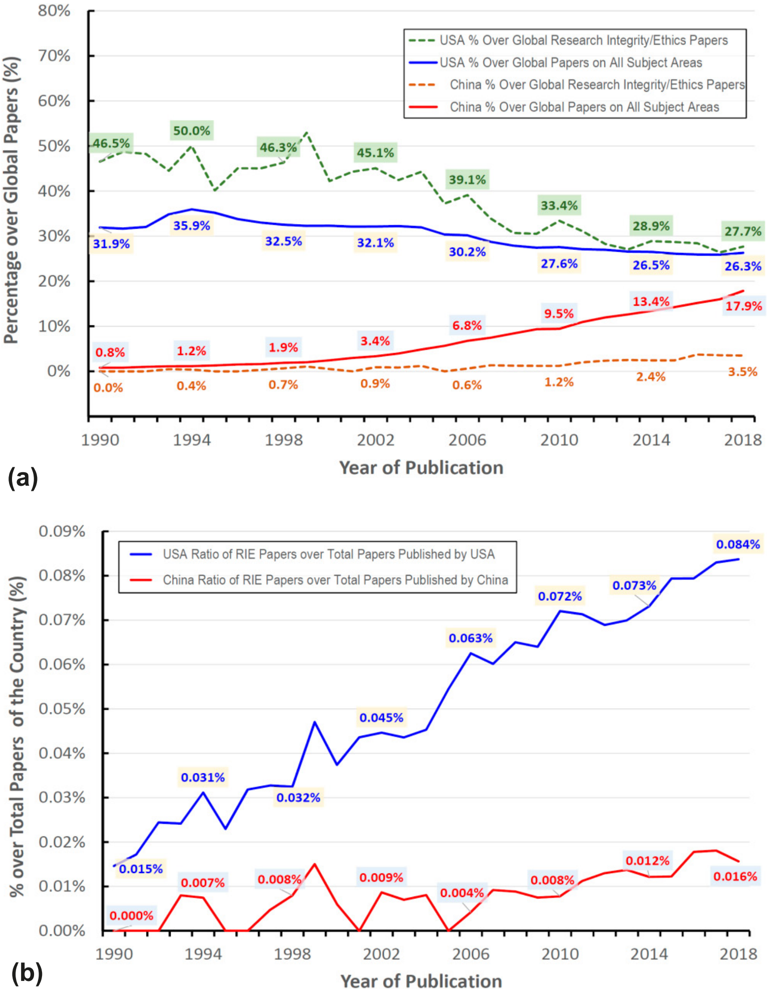

Figure 3 – (a) Proportion of US and Chinese publications globally on RIRE (dashed) compared with proportions in all research areas of global publication (solid). (b) Proportion of US and Chinese publications against total publications in all research areas.

Figures 4(a) and (b) show a comparison of global shares in RIRE publications relative to all research areas held by China and India. While India and China have comparable publications shares on RIRE, China has a far greater growth rate on publications in all research areas (Bhattacharya, Shilpa, & Kaul, 2015).

Based on the global keyword co-occurrence mapping, some of the key RIRE topics gravitate around research ethics, bioethics, and integrity (Figure 5). Research ethics addresses the protocols and policies for adherence in conducting scientific investigation. Many pertain to clinical research methodology matters, with terms such as 'institutional review board', 'informed consent', 'privacy', and 'ethics committees'. Bioethics represents a specialized case addressing ethics in biomedical and medical research, such as social values in medical ethics (e.g. decision-making, dignity, euthanasia, death, quality of life) or the intersection of research with biotechnology (e.g. cloning, stem cells). The dominance of medical-related ethics is further observed based on journal frequency, where *BMJ Open*, *J Med Ethics*, *AM J Bioethics*, and *Bioethics* are some of the most common journals amongst the publications. Another cluster relates to matters of research integrity, prominently on ‘plagiarism’ and ‘scientific misconduct’. Plagiarism, taking credit for the intellectual work of another, is seen in both education and research spheres. Works on the former include studies related to student academic integrity, such as cheating. Scientific misconduct refers to authorship matters with keywords such as publication transparency, publication ethics, and conflict of interest. This forms a comparatively smaller subset, but has been a topic of growing interest in the last 20 years (Aubert Bonn and Pinxten 2019).

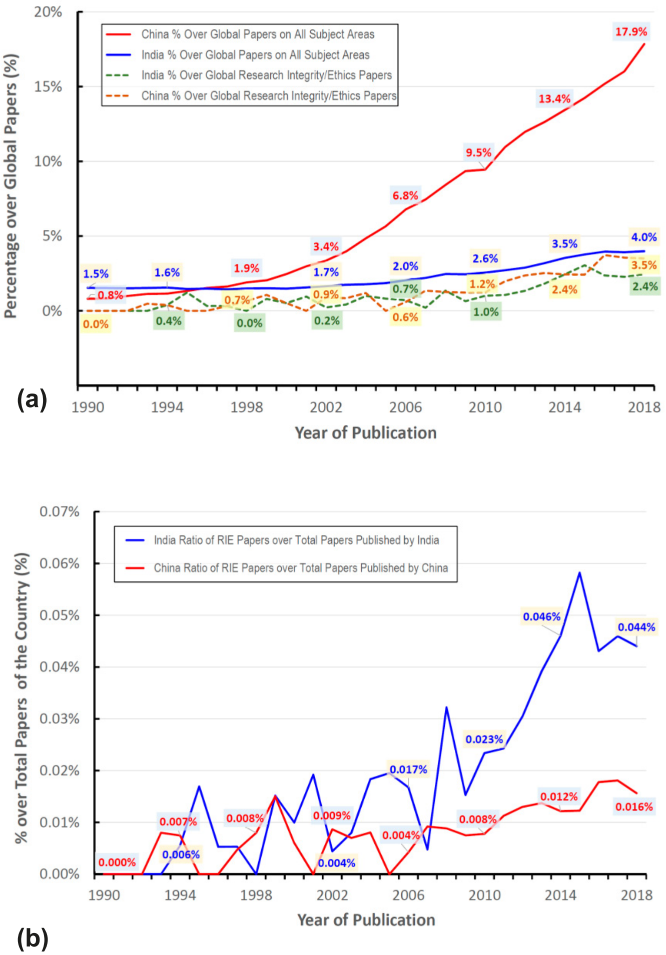

Figure 4 – (a) Proportion of publications from China and India globally on RIRE (dashed) compared with proportions in all research areas of global publication (solid). (b) Proportion of publications from China and India against total publications in all research areas.

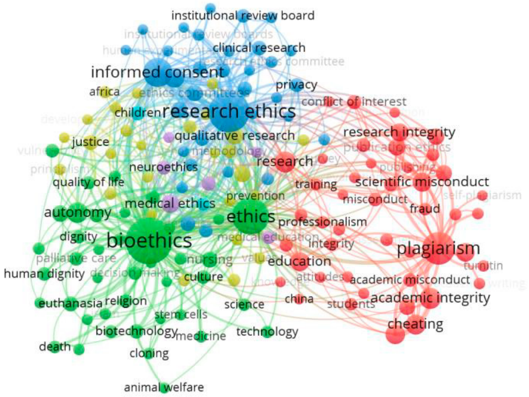

Figure 5 – Author keyword co-occurrence network mapping, showing the three main themes in RIRE research between 1990-2018: research ethics, bioethics, and integrity.

Country collaboration patterns based on co-authorship networks show that countries leading in publications are engaged in international collaboration and form a central part of a cluster (Figure 6). USA exhibits the greatest centrality compared to the other top 10 nations. The node proximity of the collaboration map suggests that western European countries work more closely, likely facilitated by geographic proximity. Meanwhile, another cluster is identified to consist mostly of Spanish-speaking countries (e.g. Spain, Mexico, Colombia, Argentina, Chile), linked to Brazil. China and India most closely collaborate with Southeast Asian, African, and Middle Eastern nations. Topical inspection of network maps by each country reveals variations in the RIRE focus. Publications in wealthier nations such as USA, England, and Canada focus publications more on academics (Dwan et al. 2008; McCabe et al. 2001, 2006), social sciences (Minkler 2004), medical, and biosciences (Begley and Ioannidis 2015; Dickersin and Rennie 2003; Hopewell et al. 2009; Wolf et al. 2012). Those of middle-income countries such as Brazil and South Africa center around social science and healthcare matters (Cabral et al. 2006; de Castilho and Kalil 2005; Diniz et al. 1999), such as ethics related to healthcare policies or protocols (Benatar and Singer 2000, 2010; Shapiro and Benatar 2005). Meanwhile, publications from China are associated with higher education (Gray and Jordan 2012) and research misconduct matters (Lin 2013; Macfarlane et al. 2014).

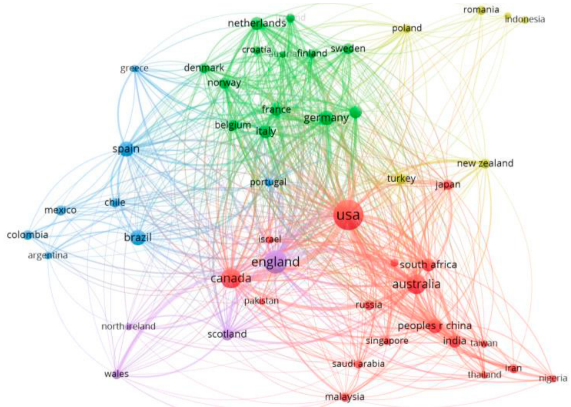

Figure 6. Country co-authorship network map between 1990-2018.

Figure 7(a) shows yearly trends of publication output which are international collaborations by absolute count (primary axis), and by proportion of all publications (secondary axis). International collaboration grew from around 2% of total publications in 1990 to 23% of total publications in 2018. Most collaborations arise from Western nations, with the top 10 consisting of pair combinations between the USA, Canada, England, Australia, England, Scotland, Wales, France, Netherlands, and Germany (Figure S1). In terms of authorship, single-authored papers dropped from 70.4% in 1990-2004 to 36.3% in 2015-2018, while papers with 4 authors increased 3-fold, and papers with 8 and 10 authors increased by one order of magnitude. Single-institutional papers dropped from 82.1% in 1990-2004 to 45.1% in 2015-2018, while papers with 4 institutions increased 5-fold, and papers with 8 institutions have increased by one order of magnitude. Single-country papers dropped form 95.4% in 1990-2004 to 81.1% in 2015-2018, while papers with 2 countries have almost increased 4-fold. In all cases, RIRE publications are becoming more collaborative institutionally, nationally, and internationally (Figure 7(b)-(d)).
We note that there are some limitations to the study. The skew towards the natural sciences and engineering within the database may result in the analysis to reflect these fields more dominantly, while underrepresenting others such as the social sciences and humanities. This is likely to have contributed to the stronger representation of medical ethics-related works, which is part of the database curation.

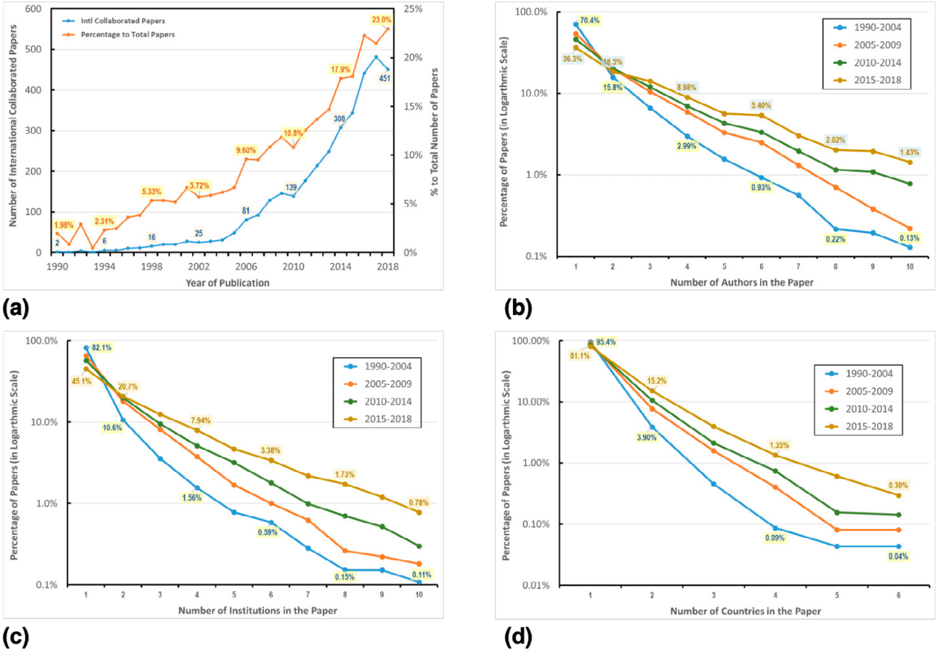

Figure 7. (a) International collaborations in RIRE publications between 1990-2018 and trends at the (b) author- (c) institutional- and (d) country-level.

Conclusions

In this study, bibliometric analysis was used to capture and characterize the macroscopic trends within the broader RIRE research community. The results indicate that while RIRE productivity has continued to grow between 1990-2018, there are variations between countries on factors such as topics of publication and rate of growth. A number of key areas are found within RIRE research, including research integrity, bioethics, scientific misconduct, and plagiarism, which exhibit some geographic dependence, with countries of greater centrality exhibiting a broader scope of topic coverage. Top contributors of RIRE research and collaboration partners are generally dominated by wealthier nations such as the United States, England, Canada, Australia, Germany, and France, with typical collaboration pairings amongst fellow top publishers such as US-Canada and US-England. Although emerging countries have a growing presence in global research participation on all subjects, and in some cases outpacing more developed and counterparts, RIRE-related publications do not follow the subject share proportion growth rates in the same manner. For example, China exhibited meteoric growth in research and innovation, becoming the second leading country in science and technology, with publications from China accounting for a 17.9% share of global papers on all subjects. However, its RIRE growth has not been accompanied in equal measure, holding a smaller global subject share of 3.5%.

Based on current trends, we expect there will be a sustained interest and discourse in RIRE topics as research integrity and research ethics are universal concerns (L. Bouter 2020) for several reasons. First, the credibility and research reputation of a university is intimately tied to its ability produce quality research with good accountability (Hudson 2008). There is added visibility from publicly available databases which monitor research activities, such as Retraction Watch. Currently, institutions (Aubert Bonn et al. 2017) and countries have substantially different norms and standards governing scientific work (Leshner, & Turekian, 2009) and international collaboration. We found that international collaboration on RIRE increased from around 2% of the total publications in 1990 to 23% of total publications in 2018. The relative decrease in single author papers, single institution papers, and single country papers, and the increase of two or multiple author/institution/country papers over time, indicates that joint papers in RIRE are involving more countries, institution, and authors. As more institutions adopt initiatives such as formal structured training (DuBois et al. 2008; Ferguson et al. 2007; Satalkar and Shaw 2019; Sponholz 2000), there may be more opportunities for further collaboration and communication towards harmonizing standards to promote more uniform global research practices (Frankel, Leshner, & Yang, 2016). Secondly, the scope of topics is expected to change depending on factors such as relevance to the publishing country or funding agency, and forthcoming applications or technologies. As an example, bioethics is largely affected by the developments within the sector, such as stem cells and cloning. With the integration of artificial intelligence, machine learning, and big data permeating sectors including the medical practice (e.g. patient data records and collection, genomic data and physiologic data), we expect that the future discourse would evolve accordingly, dictated by the prevailing innovations and commercialization.

A Unique Approach to Characterizing Types of Prolific Authors

Richard Klavans[1] and Kevin W. Boyack[2]

Abstract

How do research communities differ in terms of their mix of different types of authors? We introduce a unique approach to characterizing prolific authors in terms of their roles in research communities as reflected by their publication profiles. This approach builds upon Kuhnian concepts of incommensurability (members of one research community do not fully understanding the conceptual framework of another research community) and the more recent literature on types of experts (hedgehogs and foxes). To illustrate these concepts, we use bibliometric data to characterize highly prolific authors as hedgehogs (they know a lot about a single research community), foxes (they know a lot about multiple research communities) and non-conformist (what they know doesn't fit with the way research communities have been defined). Data on the prolific authors who publish in *Scientometrics* and one of the reviews of the first draft of this article are used to illustrate the potential for this approach.

Introduction

The ability to use very large document collections to characterize tens of thousands of Kuhnian research communities has opened up new avenues of inquiry. For instance, we can now explore the sociological understanding of how these communities differ from each other and the corresponding insights that can arise from this understanding.

A prime example of this paradigmatic framework is the recent work at NIH where a text-based method (word2vec) was used to cluster NIH proposals into document clusters (Hoppe et al., 2019). Each document cluster, since it uses a different vector of words, is considered to be a different conceptual framework. Once these frameworks were identified, it was then discovered that African-American/black researchers tended to propose research on topics with lower award rates. This analysis provided unique insights into addressing racial bias in the funding of US medical research. Racial bias was associated with underlying biases in conceptual frameworks and can be addressed by a better understanding of these implicit psychological biases (Livingston, 2021) and redirecting funding to these research communities.

Another example of this paradigmatic framework is the recent work at the Center for Security and Emerging Technology (CSET), a think tank that was started in 2019 by Jason Matheny (former Director of IARPA and currently serving in the Biden Administration). One of their recent publications (Rahkovsky, Toney, Boyack, Klavans, & Murdick, 2021) identified 127,000 Kuhnian research communities using 1.4 billion citation links among 105 million documents from Dimensions, Microsoft Academic Graph, Web of Science and the Chinese National Knowledge Infrastructure. This analysis resulted in specific forecasts about the research communities in Artificial Intelligence that are expected to have exceptional growth in the next three years. These nominated research communities represent an emerging threat or opportunity. These forecasts are correspondingly tested using techniques that are commonly used to evaluate the accuracy of weather forecasts.

The purpose of this study is to introduce a unique author-level measure that can be used in studies such as the two mentioned above. We rely on bibliometric information about the research communities that an author publishes in order to classify authors as hedgehogs, foxes and non-conformists. The following two sections describes the related literature and the theoretical framework for the proposed measures. We then proceed with a description of a

Kuhnian model (100,000 research communities derived from a direct citation analysis of the Scopus database) and the classification of prolific researchers who have published in journal *Scientometrics* in recent years. One of the reviews of our first draft is also used to illustrate how this indicator might be useful to understanding how research communities are evolving. The final section describes the limitations and implications of this study.

Empirical Precedent

There is empirical precedent for studying types of individuals that populate a research community. For instance, Robert and Fusfeld (1980) identified critical roles (i.e., "people functions") in a team of researchers in a research lab. Studies that describe author contributions to an article (Sauermann & Haeussler, 2017) described the different hats worn by (or roles of) an individual scientist such as obtaining funding, planning, running experiments and writing. Journal editors are often thought of as having the role of gatekeepers (Crane, 1967). The roles of scientists in interfacing with society have also been explored (Spruijt et al., 2014).

There is also an extensive bibliometric literature on how one might characterize different authors using different bibliometric indicators. They can be characterized by how prolific they are and whether their activities are focused or dispersed (Abramo, D'Angelo, & Di Costa, 2017, 2019). They can be characterized by how quickly they have reached a certain level of productivity (Abramo, D'Angelo, & Di Costa, 2018; Costas, Van Leeuwen, & Bordons, 2010) and the degree to which they are involved in team science (Wuchty, Jones, & Uzzi, 2007). One recent review listed over 100 bibliometric-based indicators that have been used to characterize individual authors (Wildgaard, Schneider, & Larsen, 2014).

There are, however, no studies that use the bibliometric data on prolific authors to characterize the role they might play as an author, a leader or perhaps even as a reviewer in a specific research community, and the corresponding number of research communities where the author would be considered an expert in. The following section describes the theoretical basis for creating such an indicator.

Theory

This study builds on Kuhn's (1970) concept of a research community and Tetlow's (2006) characterization of experts as hedgehogs and foxes.

Kuhn's theory, as originally proposed, was based on the possibility that the norms of good science are social and can be detected by examining the communication patterns between researchers. Although he viewed research communities as groups of authors rather than groups of documents, he was well aware of Garfield's new (at that time) citation database and noted that direct citations could be used to detect research communities due to the fact that they could be considered as evidence of communication links between researchers. Much of the early work on science mapping – clustering documents using citation links – was based on this theoretical root because it was viewed as a proxy for communication.

We are returning to this theoretical root because it appears that most current document clustering exercises (including some of ours) have been aimed at identifying scientific 'topics' without explicitly defining what a topic is and without reference to any underlying theory (Held, Laudel, & Gläser, 2021). Further, we seem to have lost sight of the researchers themselves, that they view themselves as belonging to communities, that each researcher may have a different perception of a given community and its organizing principle, and that the inside and outside views of a community may be different.

We do not advocate the clustering of authors to identify Kuhnian research communities. If one clusters authors, the organizing basis of the community (i.e., the focal point, theory, method, topic, etc.) must be determined from other features, most commonly from documents and their metadata. Even then it may be difficult to identify the focal point of a cluster of authors given that some authors are prolific and can be identified as members of multiple communities. Clustering of documents is more straight-forward in that the focal point of a cluster of documents can be identified more readily and with less ambiguity. Citation links provide a ready source of information with which to cluster, and this brings us back full circle to Kuhn. The difference may be, however, that the current generation of researchers start with methods and gives lip service to theory while the early pioneers of our field put theory first and then proceeded to methods.[1]

We correspondingly use clusters of documents based on direct citation to identify Kuhnian research communities, while explicitly remembering that it is the relationship between citations and communication patterns that is the basis for claiming that document clusters derived from citation patterns may represent Kuhnian research communities. Direct citations are evidence of communications between members of a research community but not because the citing author is communicating with the cited author. The communication link is between the author and the reviewers of the article. Reviewers are usually selected because they have some knowledge about the thing that the author is talking about. It is not uncommon for reviewers to point out gaps in the reference lists. And it is not uncommon for authors to realize that a highly critical review is, in many cases, a signal that the author did not effectively communicate the unique perspective of the research community that the document is aimed at. It is this dialogue between an author and his peer reviewers that is central to the process of community evolution. But all we can directly observe are the negotiated set of cited references from this dialogue. Overall, it is the relationship between citations and communication patterns that is the basis for claiming that document clusters, derived from citation patterns, are a reasonable way to represent Kuhnian research communities.

We are also building on Tetlow's [2006] study of types of experts in order to better characterize the types of reviewers that exist in a research community. Tetlow, in an extensive study of the accuracy of expert forecasts within the political domain, noted that some experts 'knew a lot about one thing' (hedgehogs) while others 'knew a lot about many things' (foxes). This concept is applied to prolific authors. An author that focuses their effort in a single research community could be considered a hedgehog when they are asked to review a paper. An author that has an extensive publication record in two or more research communities could be considered a fox (than know a lot about many things). And perhaps most importantly, those highly prolific authors who don't focus their publications in any research community represent a third type of reviewer (not anticipated by Tetlow). These experts aren't conforming to the social norms of research and are therefore considered non-conforming.

In summary, Tetlow's concept of hedgehogs and foxes is used to characterize the types of reviewers that exist in a research community. The link between these two theoretical perspectives is used to better understand the composition of research communities (percentage of hedgehogs, foxes and non-conformists) and how differences in this composition is related to broader issues about the structure and evolution of research.

Data and Methods

This study is based on Scopus data and is enabled by 1) our existing detailed model of research communities and 2) Scopus author profiles and the assignment of author-ids to individual papers (Baas, Schotten, Plume, Côté, & Karimi, 2020).

[1] We acknowledge Jochen Gläser for discussions in which this became much more clear. After reviewing many of the studies of document clustering, he has concluded that advocates of different document clustering algorithms have lost sight of what their theoretical assumptions are. We agree with his assessment, not because there isn't any theory that is applicable to the document clustering problem, but rather because those that do this work describe their theoretical framework in a perfunctory manner. As such, the theory section of this paper is intended to redirect our thinking toward theory in light of decades of neglect.

Our model consists of 46,100,988 papers indexed by Scopus (1996-2019) that have references or are cited and thus can be linked into a cluster of papers via citation patterns. The model also contains over 44.5 million additional documents cited at least twice by the indexed papers. These so-called non-source documents are those for which we do not have references and include documents not indexed by Scopus along with some documents from before 1996 that do appear in Scopus. Clustering of documents was done using our established process (Klavans & Boyack, 2017) with the Leiden algorithm (Traag, Waltman, & Van Eck, 2019). The input consisted of over 1.13 billion direct citation links between the 90+ million documents, resulting in a model containing 104,638 clusters (representing research communities), each of which contained at least 75 documents.

As subject for our case study we selected the 14 research communities where *Scientometrics* is the dominant journal. From the perspective of *Scientometrics*, these 14 research communities represent the areas of research where the journal has the highest relative influence. Characteristics of these research communities, including the number of papers, number of unique authors, and least-squares growth rate are given in Table 1. The publication output of these communities varies widely. From 2015 to 2019, over 500 papers per year were published on issues around research evaluation (RC #365) while less than 12 papers per year were published on analyzing funding acknowledgements. (RC #39409).

Table 1. Characteristics of 14 research communities where *Scientometrics* is the lead journal. Time period 2015-2019. *%Grow* is the growth rate.

RC	*Phrases (description)*	*#Doc*	*#Auth*	*%Grow*

81246	Reference publication year spectroscopy	62	109	23.7%
39409	Funding acknowledgements / funding ratios / funding data	57	120	25.6%

We note that three of the research communities in Table 1 may not be well known to most researchers in the scientometrics community. RC #15058 is typified by papers with titles such as "Top 100 cited articles in <a branch of medicine>" that are scattered throughout the medical literature. RC #13588 contains papers that do a cursory analysis of the output of a single journal while RC #9942 is focused on bibliometrics as applied to economics journals and researchers. In each of these research communities the paper counts per journal are very low (typically single digits) and they appear in our list simply because *Scientometrics* has the largest number of papers even though that number is small.

The number and frequency of papers published by different authors varies widely. Ioannidis et al. (2014) showed that authors who published continuously over a 16 year period, while a very small percentage (<1%) of the author population, account for over 40% of papers, garner far more citations per paper than less prolific authors and are therefore disproportionally influential. On the lower end, Price & Gürsey (1975) pointed out that a large fraction of authors only publish one paper; in their sample 56% of authors only published one paper in a seven year period. We found that 19.7% (3246/16483) of the authors accounted for in Table 1 only published one paper during the 2015-2019 time period while 37.3% (6156/16483) published at least 12 articles over the same period. The following analysis focuses specifically on these prolific authors.

There are no set criteria for determining what constitutes a prolific author and what level of publication in a research community represents 'knowing about' that research community. We have arbitrarily set a threshold of 12 publications over the four-year period from 2015-2018 (or three papers per year on average) to identify prolific authors. In addition, we specify that an author must publish at least four publications in a research community over that four-year period as evidence that she 'knows about that research community'. We believe that these publication rates are sufficient to classify an individual as a hedgehog, a fox, or neither. Given that our case example focuses on *Scientometrics*, we limit our analysis to those authors who have at least 50% of their publications during the time period in the 14 research communities listed in Table 1.

Prolific authors in scientometrics were classified into one of four types as follows:

- *Hedgehog* – at least four papers in only one research community
- *Fox2* – at least four papers in exactly two research communities
- *Fox3+* – at least four papers in three or more research communities
- *Nonconformist* – prolific, but with papers spread out among research communities such that the threshold of four papers in any single community is not met.

We consider hedgehogs and foxes to be the core authors in a community.

Results

Of the 16,483 unique authors that published in our set of 14 research communities we find 93 who meet the criteria mentioned above. Table 2 shows the distribution of author types as a function of the number of articles. Authors with at least three papers but less than four papers per year were most likely to be *hedgehogs*. Authors with at least four papers per year are very unlikely to be *nonconformists* – only one out of 45 authors in our set with at least 16 papers did not have at least four papers in any single research community. Authors with at least five papers per year are more likely to be *foxes* than *hedgehogs*. However, we do see some *hedgehogs* with large numbers of papers. Examples of each author type will be given later.

Table 2. Author type distribution as a function of production.

#Articles (2015-2018)	*#Nonconform*	*#Hedgehog*	*#Fox2*	*#Fox3+*
12-15 (3+ per year)	5	38	5	0
16-19 (4+ per year)	1	9	8	1
20-27 (5,6+ per year)	0	2	6	2
28-39 (7,8,9+ per year)	0	1	2	3
40+ (10+ per year)	0	1	1	8

The distribution of author types by research community is shown in Table 3. In general, larger communities have larger numbers of these prolific authors, with a mix of *foxes* and *hedgehogs*, as might be expected. However, there are some communities that differ from this norm. For example. RC #4581 on peer review has only three *hedgehogs* and no *foxes*, a very small set of core authors for a community with nearly 200 papers per year. RC #13588 on journal studies has no core authors. RC #81246 on research publication year spectroscopy has three *foxes*, and thus has a relatively large and productive set of core authors whose influence might help this community to continue to grow at a high rate.

Table 3. Author type distribution by research community.

RC	*Short label*	*#Doc*	*#Hedgehog*	*#Fox2*	*#Fox3+*

37671	Title length	66		1	
81246	RPYS	62			3
39409	Funding data	57	1		

It is also interesting to look at specific authors and their personal research portfolios. The three most productive authors from each author group are listed in Table 4 along with the research communities in which they have at least four papers. Total papers, numbers of papers in the 14 *Scientometrics* research communities (#Doc14) and the largest number of papers by the author in any community are also listed.

Ronald Rousseau is a prototypical example of a *hedgehog*. He is very productive with 47 papers over the four-year period, 30 of which are in the seven of the 14 Scientometrics communities. His primary area of focus is RC #365 with 21 papers, followed by RC #6344 with three papers. His remaining 23 papers are dispersed among 19 other research communities. Our primary example of a *Fox2* is Felix Moya-Anegón. Of his 28 papers, 24 are in the Scientometrics communities with 16 in RC #365 and 6 in RC #6344. Our third example of a *Fox2*, Stefanie Haustein, is notable in that her second community, RC #3406, is outside of our set of 14 communities. This community is focused on open access, which is certainly highly relevant to the scientometrics community even though *Scientometrics* is not the leading publication venue in the topic.

Lutz Bornmann and Mike Thelwall are two examples of a *Fox3+*. Each has 121 papers over the four-year period and each has at least four papers in six different research communities. Both authors are highly active in one community that is outside our set, RC #36708 (innovation policy) for Bornmann and RC #232 (sentiment analysis) for Thelwall. Those familiar with the works of these authors will recognize their output in these topics. Thelwall's output is more dispersed than Bornmann's in that the former has 36 publications outside our set of communities while the latter has 15.

Table 4. Top three most productive authors from each author type. Research communities outside the list from Table 1 are shown in italic font.

Name	*Type*	*RC#*	*#Doc*	*#Doc14*	*#Large*
Rousseau, R.	Hedgehog	365	47	30	21
Cobo, M.J.	Hedgehog	6344	34	18	11
Sivertsen, G.	Hedgehog	15746	21	19	16
Moya-Anegón, F.	Fox2	365, 6344	28	24	16
Kousha, K.	Fox2	9183, 15746	28	21	9
Haustein, S.	Fox2	9183, *3406*	27	20	16
Bornmann, L.	Fox3+	365, 9183, 81246, 6344, 5104, *36708*	121	106	56
Thelwall, M.	Fox3+	9183, 365, 15746, *232*, 5104, 12107	121	85	35
Leydesdorff, L.	Fox3+	6344, 365, 81246, *630*, 5104, *41710*	74	49	19
Rafols, I.	Nonconf		17	11	3
Soheili, F.	Nonconf		15	8	3
Torres-Salinas, D.	Nonconf		14	8	3

Our primary example of a *nonconformist* is Ismael Rafols. Eleven of his 17 publications were in six of our 14 research communities, with three each in RC #365 and RC #15746. His six remaining publications were in six different research communities dealing with topic modeling, technology foresight, patent analysis and translational science. While there were only six *nonconformists* in our sample, these people may be extremely important because they may represent a fundamentally different 'logic' for deciding which research communities to participate in. 87 of our 93 core authors are focusing their work within one or more research communities. On average, *hedgehogs* have 52% of their papers in their dominant community, *foxes* have 40% of their papers in their dominant community, while *nonconformists* have less than 25% of their papers in a dominant community. *Hedgehogs* and *foxes* thus seem to choose topics in a way that is consistent with the communication patterns assumed by Kuhn to be at the foundation of a research community. *Nonconformists* seem to have broader interests that may indicate a different 'logic' about topic choice.

Discussion

We have significantly revised this paper to illustrate how the proposed indicators relate to the two comments we received by reviewers. The first review we received stated that "the results of the selected example were somewhat debatable" and "thought provoking". This review is non-communicative (no specific comments, suggestions or criticism) and not actionable (the review does not require any revisions on our part).

The second review, however, has had a significant impact on our revisions and is an excellent example of the types of issues we wanted to communicate in this paper. The second reviewer starts with a summary of what we intended- but not what we said in our initial abstract and introduction. This reviewer realized that we were interested in a 'research community' approach. Our abstract and introduction did not stress this fundamental point.

A detailed review followed that mentioned weakness that "could be easily revised in a new version". It started with specifics about articles on individual-level bibliometric indicators and establishing of thresholds. This was followed by a more general observation that the examples we provided are 'illustrative' and ended with the following statement:

> "*The theoretical propositions of the introduction do not come back in the discussion. This is unfortunate because this is one of the strongest points of the manuscript. I would recommend extending the discussion on how more individual-level and*

> *community-based approaches could have more relevance in the light of Kuhn's theory, as well as other related theories.*"

This statement prompted a major revision of the paper. Perhaps more importantly, the comments from the second review may help illustrate some of the issues we are trying to address. Based on the comments we assume that the second reviewer is well versed in Kuhnian theory, individual-level indicators and science mapping, and thus seems to have skills that are found in two research communities: RC#365 (evaluation and bibliometric indicators) and RC#6344 (science mapping, topics, communities). We thus posit that the second reviewer is a fox with a publication record in these two communities and was well qualified to review this work.

We agree with the comments of both reviewers: the results of this study are illustrative rather than conclusive. Our thresholds were based on our experience and our perceptions of norms in science and were not based on theory or data. Thus, we do not argue that the thresholds are correct. Instead, we are simply using an initial set of thresholds to illustrate that there are different authorship profiles within research communities and that, once defined, the mix between these different types of authors (hedgehogs, foxes and non-conformists in this paper) can be determined. It is unclear to us if theory would suggest any particular threshold. Nevertheless, additional research can certainly be undertaken to determine the sensitivity of such results to different thresholds and to quantify the perception of researchers as to what level of publication is considered prolific.

The mix between hedgehogs and foxes in these two research communities (Table 3) may provide insights into how these research communities might evolve. The ratio is 18:22 for RC:365 and 3:12 for RC:6344. Or stated differently, RC:6344 has a far greater percentage of prolific authors that have expertise outside of RC:6344. A research community with a higher proportion of foxes may have more porous boundaries and thus might undergo more structural change in the future.

The use of altmetrics (RC #9183) could help to improve the classification of prolific authors into different types deals with communication outside the traditional realm of citations. RC #5104 deals with collaboration and co-authorship, and it would be interesting to understand if *hedgehogs*, *foxes* and *nonconformists* have different collaboration patterns, and if so, if those different patterns lead to different types of impact (e.g., academic vs. economic). The relationship between author type and transformative research or interdisciplinarity (RC #6864) would also be interesting to funders and other institutions.

Limitations and Future Directions

The analysis presented here is preliminary and is subject to several limitations. First, as mentioned above, we have relied only upon our own opinions as to the reasonableness of the classification. Others may have different opinions, and those could be equally valid to ours. Thus, as mentioned, we plan to seek other opinions. Second, the results are reliant upon the classification system that was used. A less granular set of research communities would obviously increase the number of *hedgehogs* and reduce the number of *foxes* if the same thresholds were used. However, given that we are seeking to identify differences, we favor the use of a large number of highly differentiated research communities. Changes to thresholds would also make a difference in how authors are classified. Fractions of papers by research community could be used rather than number of papers and this would likely reduce the need to split the *fox* type into two types.

Third, this analysis was performed for the single, relatively small research field associated with the journal *Scientometrics*. This area has a relatively low number of authors per paper; certainly the large teams that often author papers in biomedicine and physics are not present in this field.

Fields with larger teams may have different characteristics. In any case, the results here cannot yet be generalized to other fields. This is something we plan to investigate in the future. In addition, author order was not accounted for in this study, and may make a difference in the roles played by authors in communities. Despite these limitations, we find the results to be interesting enough to continue investigation.

In the future we plan to expand this work to identify author types in multiple ways. For instance, we plan to explore the relationship between full and fractional publication counts and how that relates to who is a prolific author. We also hope to explore whether particular research communities exhibit individualistic or collective behavior and the age of researchers in a community to identify so-called human resource profiles at the community level. If successful, these efforts will give us a new way to understand differences in research communities from a person-oriented perspective.

Abstract

To fully take advantage of rigorous literature-based study (e.g., bibliometrics or systematic literature reviews), databases that enable the inclusion of all relevant documents are needed. As many currently available bibliographic databases inherit characteristics of the core-periphery model of scientific production or are unbalanced in their thematic structure, the need for a model for custom bibliographic databases creation procedure arises. At the same time, the adoption of machine learning is apparent throughout science, technology and business, as we learn how to maximise its usefulness. We investigate what model for custom bibliographic database could be adopted, especially taking into consideration the inclusion of analogue publications. Such documents need to be converted into digital form, hence we propose machine learning algorithms and then we explore their accuracy in analogue documents inclusion into the custom bibliographic database for the case of Polish management sciences methodology. We explore the application of neural networks for image preprocessing and optical character recognition, and subsequent application of conditional random fields to obtain a bibliographic database. Our results are highly suggestive and reveal the applicability of the proposed model consisting of database search and snowballing.

Introduction

Web of Science, Scopus, Google Scholar, and beyond

Bibliographic data sources are crucial both for systematic literature reviews (SLRs) and bibliometrics. Their growing importance led to multiple papers on databases selection for both bibliometrics (e.g. entire issue of Quantitative Science Studies, see: Waltman & Larivière, 2020) and SLRs (e.g., Bramer, Rethlefsen, Kleijnen, & Franco, 2017). While bibliometrics usually goes after raw coverage, SLRs do involve other factors, like precision, recall, and number needed to read (NNR); these were the criteria used for database combinations evaluation (e.g., Bramer et al., 2017).

We adapt the definition of a bibliographic database as in the Sile et al. (2018, p. 311): "structured set of bibliographic metadata (e.g. title, publication type, year, and author) in line with requirements for data when calculating the most basic indicator of research output", bearing in mind, that custom databases provide an opportunity to study different types of research output.

Quantitative Science Studies (QSS) dedicated the special issue on data sources (Waltman & Larivière, 2020). It featured Web of Science (WoS, Birkle, Pendlebury, Schnell, & Adams, 2020), Scopus (Baas, Schotten, Plume, Côté, & Karimi, 2020), Dimensions (Herzog, Hook, & Konkiel, 2020), Microsoft Academic Graph (Herzog et al., 2020), CrossRef (Hendricks, Tkaczyk, Lin, & Feeney, 2020), and OpenCitations (Peroni & Shotton, 2020). The issue does not include national databases (which usually contain non-English documents), despite their numerous existence. Sile et al. (2018) listed 21 national European (and Israeli) databases and provided a comprehensiveness study on 13 of them. They have argued, while databases' comprehensiveness may lead to different insights from bibliometrics-supported research evaluation, the main issue remains within the setup of the database (Sile et al., 2018, p. 320). For this reason, conscious data source selection and its further preparation are of such importance. Alternative data sources should be established, as databases not always provide out-of-the-box coverage required; avoiding the inclusion of documents of certain type or language may lead to overlooking current important issues, that of time being are only published in these excluded types or languages. Of course, those important scientific achievements are likely to be published as articles in English, nevertheless, some important details may be missing or waiting till their translation and publication in international journals.

How much may we believe the databases?

The issue of data sources for bibliometrics and systematic literature reviews are far beyond the usual concerns expressed in studies utilising these methods. While usually the limitations of the study that stems from the database imperfections are mentioned, they rarely depict the complexity and choices that are made with the database selection and preparation, raising a question if researchers do not *believe* in the databases integrity inadequately to the reality. Below we present some of the problems, related to data sources in the SLRs and bibliometrics. Franceschini, Maisano, and Mastrogiacomo (2016a) listed errors of the Scopus database, that were later on commented by Elsevier (Meester, Colledge, & Dyas, 2016) to fall into two categories: 1) conservative linking, 2) conservative deduplication. Conservative, that is – precision is more valued than recall. Franceschini, Maisano, and Mastrogiacomo (2016b) further presented their detailed systematic error classification for both Scopus and Web of Science, based on two categories of errors: 1) pre-existing errors in data, and 2) database mapping errors.

Multiple examples from different fields provide a strong basis to argue, that databases are not neutral, and results may vary – for that reason each of the databases might give us a different result (Bar-Ilan, 2017). Therefore, however custom databases might include bias, this bias nevertheless has already been part of existing databases.

Reasons to introduce a model for custom bibliographic database creation procedure

There are examples of using a custom created database to perform context-embedded research: Tunger and Eulerich (2018) used "Jourqual" journal ranking as the basis for the journal selection, from which articles on corporate governance in German-speaking countries were searched. There are several reasons clarifying the need for custom databases, mostly related to the documents' coverage of existing solutions. Web of Science was discussed to be inclined towards English-language journals by 20-25% (Archambault, Vignola-Gagné, Côté, Larivière, & Gingrasb, 2006). De Moya-Anegón et al. (2007) observed that 15% of journals published in Scopus were in a language other than English, compared to 26% of Ulrich's Core collection in 2005. Cowhitt and Cutts (2020), studied thirteen different databases' journals lists and found that databases included in their overlap study "overwhelmingly" cover USA and UK publications' production. These findings are in line with the core-periphery model of scientific production.

Frandsen and Nicolaisen (2008) showed for the case of economics and psychology, there might be not only differences between disciplines but also intradisciplinary ones. This stresses the need for a model for custom database creation procedure not only to include a national perspective but also conduct in-depth disciplines mapping.

Database selection usually restrains the type of documents analysed, and the questions on other types of publications appear. Butler and Visser (2006) explored that a number of "non-source" items, including books and books' chapters, could be found in the WoS (then ISI) database, but they were cautious in their conclusions. Abrizah and Thelwall (2014) researched arts, humanities and social sciences books of five Malaysian university presses and concluded that in total 45% of books were ever cited, with a natural inclination towards older publications. It would mean that 55% of publications cannot be discovered through cited references of the retrieved search results. Hence, the mentioned sources might not be appropriate for their context and language bias, inter- and intra-discipline differences, and selection of the included documents' type. Creating custom databases might overcome some of these issues. It is crucial especially for social sciences and humanities since a significant share of documents is published in national journals, or as other publication types than articles (Sivertsen & Larsen, 2012).

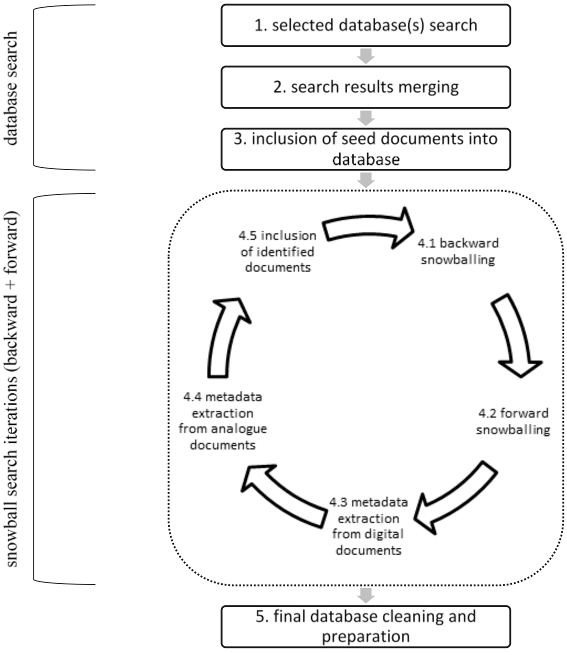
A summary on the development of scientometrics, regarding databases as well, has been recently given by van Raan (2019). When additional sources appeared, the popularity of the research utilising them grew, but also made many studies predicated on the use of such databases. Now, with the ability to automate tasks traditionally done by humans (for the impression of what machines are capable of now, see Wang et al., 2020), the opportunity to create high-quality, custom databases more easily appears. The adoption of machine learning is apparent throughout science, technology and business, as we learn how to maximise its usefulness (Jordan & Mitchell, 2015). We propose a model for custom database creation procedure in social sciences that employ machine learning (ML) algorithms, as this approach outperforms non-ML solutions for citation parsing (Tkaczyk, Collins, Sheridan, & Beel, 2018). Machine learning is a field devoted to "algorithms and techniques for automating solutions to complex problems" (Rebala, Ravi, & Churiwala, 2019), and these algorithms take data to learn a model (rules) of operation.

Providing a model for country-level bibliometrics database creation procedure addresses the call for methodological guidance on the SLRs, and bibliometrics in management (Breslin & Bailey, 2020), but as discussed, the entire social sciences should benefit. We follow the call to reveal methodological issues and research methods relevant to language and country-level context under the cultural influence (Lee, 2020, p. 283), to shed light on "different ways of knowing" (Botha, 2011), to encourage (qualitative) methodology diversity (Bansal & Corley, 2011; Cassell, 2016). Establishing a model that allows for robust country-level analysis could contribute to the plurality of methods available. Creating such a database is not necessarily associated with any nation or country; rather, it should be considered to be custom, tailored to the needs of the research. The research question, that will be further investigated in the next sections, is: **What model for custom bibliographic database creation for non-English documents could be adopted?**

Model for custom bibliographic database creation procedure

As a starting point for custom database creation, we propose a usual search done with existing sources. Echchakoui (2020) argued that database merging is needed, as a combined dataset leads to different results than each of the sources would suggest when taken separately. This is in line with the findings of Bramer et al. (2017). Hence, the use of multiple databases seems reasonable, as the first way of ensuring proper coverage, along with the use of more specialised databases.

The second step, which was proven to be useful in literature search for SLRs, and certainly in the case of bibliometrics as well, is snowballing. Backward snowballing means searching within bibliographic sections of already obtained documents (called "seed documents") and forward snowballing refers to searching for documents citing the ones already obtained (Mourão et al., 2020). We propose a model of procedure that combines the usual search and merging researchers do while conducting systematic literature review or bibliometrics with some postulates of Mourão et al. (2020) mixed search strategy ("DB search + BS*FS"). Our unique contribution is by discussing the need to use less popular (e.g., country-level) databases to provide documents embedded within context (at least, in social sciences) and to showcase pipeline to: 1) scan, 2) post-process, 3) extract and segment citations as needed for further backward snowballing, utilising machine learning. The model for the custom bibliographic database creation procedure is depicted in Figure 1.



database search
snowball search iterations (backward + forward)
1. selected database(s) search
2. search results merging
3. inclusion of seed documents into database
4.1 backward snowballing
4.2 forward snowballing
4.3 metadata extraction from digital documents
4.4 metadata extraction from analogue documents
4.5 inclusion of identified documents
5. final database cleaning and preparation

Figure 1. Model of the custom bibliographic database creation procedure
Source: Own study based on Echchakoui (2020), Bramer et al. (2017), and Mourão et al. (2020).

We aim to explore the applicability of the above model to create a custom bibliographic database for social sciences research of non-English documents. The model itself should be applicable not only within the case studied. For the reasons outlined in the introduction, due to context-dependency, we believe the most significant impact it may achieve in social sciences. In this paper, we provide qualitative research of exploratory type for the case of the Polish management methodology scholars, as this is a perfect example of a research object for which bibliometric/systematic literature review would be extremely difficult without the use of the custom created bibliographic database. The details of the methodology used are presented in the subsequent section.

Methodology

This study is qualitative research of exploratory type – it tries to answer the question if a database could be created for the case given, with the theoretical background presented in the prior section. We argue that further efforts will allow for establishing a robust model to both preserve rigour of SLRs and bibliometrics while bringing diversity that custom bibliographic databases might offer.

For the case studied in this paper, we applied only backward snowballing, for the literature studied in majority comprises publications absent from citation indexing databases. Also, the forward snowballing is relatively well-described, e.g., by Felizardo, Mendes, Kalinowski, Souza, and Vijaykumar (2016).

Despite the theoretical contribution, our unique approach is exemplified by the use of machine learning for step 4.4 of the proposed model. While the execution of other steps is well-discussed in articles, the extraction of relevant metadata from printed documents remains to be challenging and unapproached. Several recommendations for computer vision appliances for books processing and scanning (Prashanth, Sai Vivek, Ruthvik Reddy, & Aruna, 2019;

Suddaby, Ganzin, & Minkus, 2017), even these in braille (Kawabe, Seto, Nambo, & Shimomura, 2020), are available. The first section ("3.1. Database search") will present the databases search we utilised, while the second will discuss the mentioned snowball search with the use of the machine learning approach ("3.2. Snowball search").

Database search

Three databases were queried several times, with the last run being made on 10.12.2020: Web of Science, Scopus, BazEkon[1].

The queries were following:

1. Scopus: authkey("research method*" or methodology) or title("research method*" or methodology) and subjarea(busi) and affilcountry(poland) and doctype(ar)
2. Web of Science: ((ak=("research method*" or methodology) or ti=("research method*" or methodology)) and su=(business & economics) and cu=(poland)) and document types: (article)
3. BazEkon: sl_kl = metodologia badań or sl_kl = metody badawcze or sl_kl = methodology of science or sl_kl = research methodology or sl_kl = research methods

BazEkon is focused on the fields of science equivalent to the Scopus "BUSI" and WoS "Business & Economics". The further abstract screening was performed as part of the inclusion strategy.

Snowball search

The necessity to perform a large number of scans (not all documents feature a bibliography section, as they provide footnotes; also, our project includes future content analysis), the use of standard scanners would be too time-consuming. Cutting publications to use fast scanning was not possible either. Hence, we decided to take an approach known from different hardware settings (e.g., BookLiberator, n.d.) and software approaches (e.g., Quan, Zhou, & Chen, 2017) to take photos and process them further. Image processing to obtain extracted pages and perform optical character recognition is a well-described task and there is little innovation to bring. Nevertheless, when the number of pages needed to scan for analysis counts in tens of thousands (this project involves ca. 80 000 scanned pages) the process itself (pipeline) has to become robust and for this simple reason deserves description. Another restriction was cost-effectiveness; the research project itself did not involve financing high enough to obtain any of advanced scanning machines. Instead, simple hardware tool was developed, with total costs below $35. The hardware requires a camera or smartphone to take photos of both pages at once. We used a relatively small dataset of 200 segmented photos of books for Tensorflow (Abadi et al., 2015) U-Net convolutional neural network (Ronneberger, Fischer, & Brox, 2015) to extract pages. Further, we have performed perspective transformation and cleaning using OpenCV (Bradski, 2000) python library. Next in our pipeline was Tesseract OCR (tesseract-ocr, 2020) to perform optical character recognition (OCR). For the reasons of modularity, future extension, and updates, we decided to use AnyStyle (inukshuk, 2020) as our last step, that is, metadata cited references parsing. One of the full-featured alternatives to use with born-digital documents is GROBID (kermitt2, 2020), which is also actively maintained. Unfortunately, CERMINE (CeON, 2018; Tkaczyk, Szostek, Fedoryszak, Dendek, & Bolikowski, 2015) the last update on the GitHub repo was done in 2018, which puts in question further use of this tool. Both of them did not perform well on scanned documents. We decided to use all the BazEkon seed documents to retrain the AnyStyle parser; the default model displayed fair performance with English-language, but for the context studied needed training on custom data. We evaluate the impact

[1] https://bazekon.uek.krakow.pl

of training data volume and variety by random splitting dataset and hence performing accuracy simulation (50 samples for each level of volume, and variety were collected, with 1530 training and 382 test references manually segmented). Employing this approach should inform us on the desired size of the training dataset for the tool used.

Machine learning is not the only option, but the most flexible one to perform pages extraction and OCR; various digitalisation programs and documentation management tools, like ABBYY FineReader or Readiris, allow for photos processing, but few customizations can be done, comparing to those available when programming in R or python.

For data merging, we used a citation key for exact matching, similar to the one provided by the Web of Science plain text export.

Results

Databases search

After inclusion was performed, basic descriptive statistics of databases involved were calculated (see Table 1). Scopus usually is a better solution for social sciences, and it brought more results, especially for articles involving European affiliation than Web of Science. However, WoS proved to be better for the discovery of the Polish methodology articles – first, it provided a greater share of Poland-affiliated to European-affiliated documents than Scopus did, finally bringing almost twice more records; secondly, the number needed to read was significantly lower, and the number of results included almost three times more than in Scopus. After deduplication, it was discovered, that all articles included in the Scopus database, were also found in Web of Science.

Table 1. Database search results and inclusion.

Variable	*Scopus*	*WoS*	*BazEkon*
Worldwide articles (W)	8017	6755	-
Europe-affiliated articles (E)	3694	2432	-
Poland-affiliated (P)	68	112	905
E/W	46.08%	36.00%	-
P/W	0.85%	1.66%	-
P/E	1.84%	4.61%	-
Included articles	6	22	81
Number Needed to Read (NNR)	11.33	5.09	11.17

The only leverage in terms of non-source items, that could be calculated precisely, was the one concerning Journal Citation Report (JCR) items abbreviations (Clarivate, n.d.) as the abbreviations list (Web of Knowledge, n.d.) has shown deficiencies in retrieving abbreviations of items, including those in Emerging Sources Citation. For a merged WoS-Scopus database, we extracted 1081 references (765 unique), of which 409 (194 unique) pointed JCR sources, and 672 (571 unique) pointed non-JCR sources. Therefore, for unique items, the non-JCR share was 74.64%.

Snowball search – analogue document metadata extraction

AnyStyle, utilising Conditional Random Fields (CRF) machine learning approach provides researchers with state-of-the-art citations segmentation output. One drawback of the machine learning approach employed with AnyStyle needs to supply manually segmented references which will serve as the training dataset. It is not clear how many manually segmented samples should be provided (the volume of a dataset), and from how many distinct documents (variety of dataset). Hence, some basic analysis of the accuracy improvement while increasing variety will be performed using both simulation and slicing dataset. For one of the random splits, we present overall performance in Table 2. As tested, the valid keys counted for 358 out of 382 test dataset, resulting in 93.72% accuracy of the merged author, year and title field.

Table 2. Cited references parsing performance.

note	0.990	0.972	0.981	0.500
DOI	0.997	0.995	0.996	1.000

It is seen (Figure 2) that a dataset exceeding 250 sequences is mostly important to improve the whole sequence segmentation although, n terms of individual tokens (words) the change is less impressive. Thus, for single field analysis (e.g., this of cited authors) the segmented dataset might start as low as 250 segmentations, but if more fields are used at once (e.g., as composite IDs for document citation-based network creation) the required dataset size should not be smaller than 1500 segmented references (to which testing dataset should be added, with at least 20% of training volume). To the issue of volume and variety of dataset, the problem of the structure of citations is added.

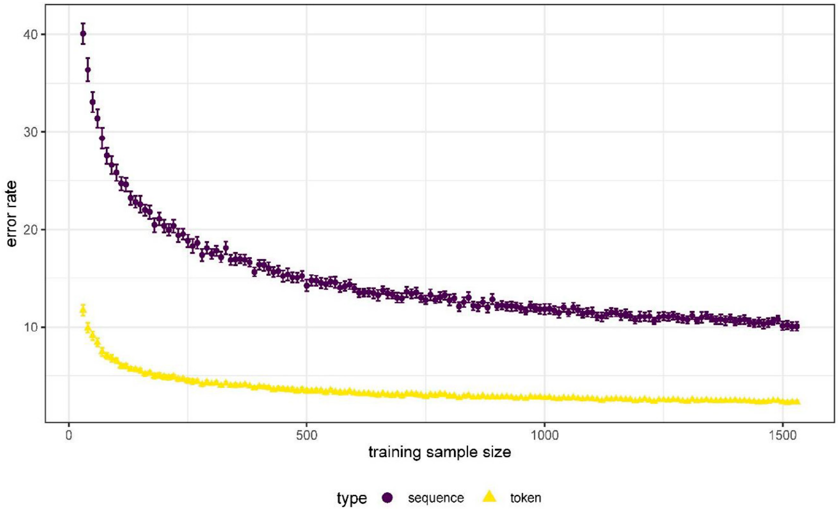

Figure 2. Training sample size (volume) vs error rate.
Source: own study.

Dataset variety significantly influences the error rate (see Figure 3). Researchers should aim for increasing variety of dataset, and only then increase its volume.

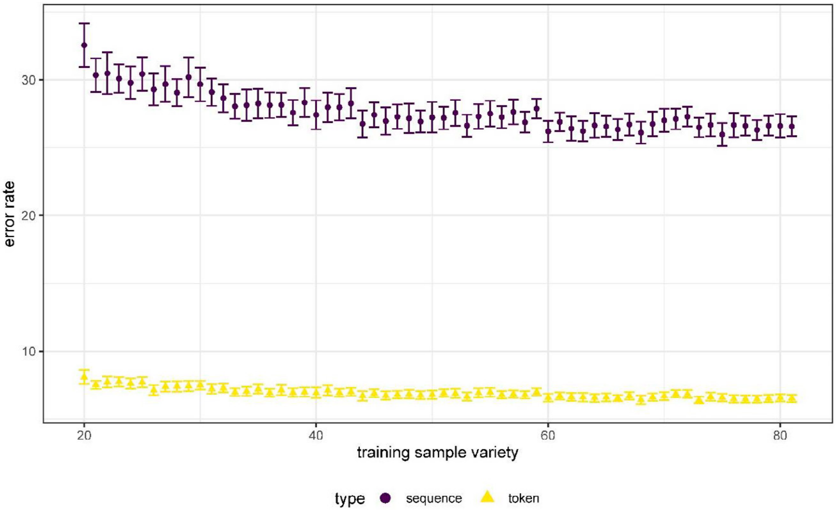

Figure 3. Training sample variety vs error rate.
Source: own study.

Scanning itself takes about 1-4 seconds per page, depending on the condition of the book and the type of paper being used. Cited references creation is therefore quite fast, for bibliography usually spans across few pages only. Tesseract OCR performed fairly (however, was resource-consuming in terms of time and computing, for results see Figure 4), but the text overlay (at the current state of the project) did not allow for automatic references extraction with satisfying accuracy. Instead, manual treatment (taking on average about three minutes per document) was needed. Subsequent cited references parsing performed well.

Conclusions

The main conclusion, as depicted by performing the most controversial step of custom bibliographic database creation, “4.4 metadata extraction from analogue documents”, is that the proposed model was successfully applied, and should be further developed. Hence, the model for custom bibliographic database creation utilising database search for seed documents and subsequent backward and forward snowballing, including analogue documents as well, answers our research question. Both pages extraction and cited references parsing presented fair performance, hence allowing to include analogue documents and gain independence from the selected coverage of existing bibliographic databases. The proposed model of custom bibliographic database creation proved to be useful in the case studied. Hopefully, it could contribute to the more diversified systematic literature reviews and bibliometrics in all fields of social sciences, when conducted for non-English context – however, we only attempted to employ the model for a single case, as this was exploratory research, but we encourage other researchers to test our model in different settings or contribute with their own.

The last conclusion is related to the cited references’ parser training dataset creation. 1500 references from at least 100 unique sources should give expected results for a more complex study, while for single field extraction even 250 might work. Better than segmenting a few articles’ full references, it is to sample a couple of references out of each document, to achieve higher variety and overall accuracy.

Limitations and recommendations for future research

We deliberately have not included a part for forward snowballing, as it is described by other researchers, and the procedure similar to one presented by Felizardo, Mendes, Kalinowski, Souza, and Vijaykumar (2016) could be used. Optimally, after each step of backward snowballing, forward snowballing should be carried out – but in our case, the majority of included literature is absent from citation indexing databases, hence the utility of providing forward snowballing was low.

Certain topics require strict inclusion criteria for the reason of the relative popularity of keywords as compared against the actual content of the paper. Possibly full-text analysis utilising e.g., machine learning classification trained on agreed dataset could serve as more objectified filtering than doing it manually. It should form a basis for future research recommendations.

Other limitations stem from the training datasets; enlarging cited references data volume and variety should increase the accuracy of the model, and the same applies to the U-Net convolutional neural network. While the current performance was fair, using better models allows for more precise research output, and before undertaking the next steps in the conducted research project, we should try to train such models.

Also, models for books’ sections extraction and citations attribution should be constructed, to allow for a study of research items of less variance in length (in terms of pages). Precise references extraction models should be proposed as part of the pipeline mentioned, to further reduce human input in the database creation. Preferably these should result in software that takes images as input and provides bibliographic records as output.

Some limitations of the proposed model itself stem from technological barriers and data accuracy. However using machine learning contributes to a significant reduction of time and effort needed for custom database creation, the process of scanning analogue documents is still time-consuming and can damage original documents. Also, quality control of the data is needed, as in the case of extant databases; extensive post-processing eliminating known issues (e.g., names disambiguation) might introduce serious challenge for researchers, especially given different alphabets and naming conventions.

Abstract

The paper presents the preliminary results of a research project on the international mobility of young Russian researchers. This study is focused on the impact of education or work experience abroad on their future scientific careers, particularly their publication activity. The case study of the one large Russian university was examined: a unique for Russia database combining both biographical data (information from CV published openly) and publication activity indicators (data from Scopus) of employees of this university was collected. A positive relationship between the international mobility and scientific productivity of scientists was revealed. Those involved in international mobility not only publish more scientific articles on average but their papers are published in journals of higher level and are cited more often. We also found some differences in the choice of topics and collaboration behavior between mobile and non-mobile scientists.

Introduction

Academic mobility is one of the key issues in the S&T policy for the last four decades in developed countries. For nations, mobile researchers are seen as a good source for enhancing their national innovation system. For research organizations, scientists with experience working abroad can be a valuable source for international collaboration. According to the results of previous studies, the experience of studying or working abroad increases involvement in the process of exchange of knowledge and technologies both with other countries and within their own country (De Filippo et al., 2009; Edler et al., 2011; Scellato et al., 2012, 2017). Moreover, the experience of mobility can significantly impact the cognitive career of researcher, bringing new perspectives or new theoretical or empirical approaches; as well as community career, by gaining new links with peers in the scientific community (Gläser & Laudel, 2015), or even impact on the change of research practice (Gläser et al., 2014). However, the effects of mobility can vary on different career stages of researchers and mobility duration (Cañibano et al., 2020) or even scientific discipline (Laudel & Bielick, 2019).

There is a well-known assumption that mobile researchers show higher publication activity. However, the empirical evidence is contradictory so far. Most studies have shown that scientists with international experience have higher research performance (Gureyev et al., 2020; Netz, Hampel & Aman, 2020). Still, there is evidence that mobile researchers failed to demonstrate higher research productivity than their local counterparts (Horta et al., 2019; Shin et al. 2014). There is a possible explanation that this difference comes from national research systems where mobile researchers come back. Within the last 15 years, many studies devoted to returnee's career tracks and their publication activity (those specialists who left the country and then returned). A study based on the example of scientists from Argentina showed that international work experience does not affect the total number of publications, but it does affect the share of publications in high-impact journals (Jonkers & Cruz-Castro, 2013). Similar results were in a study of Chinese researchers (Jonkers & Tijssen, 2008). In addition, an analysis of the career growth of 370 professors in Japan showed that work experience abroad was statistically associated with faster subsequent career advancement, even though there was no effect on publication activity (Lawson & Shibayama, 2015). A study devoted to Chinese mobile researchers showed, returnees are encountering significant barriers in publishing their work in international journals after their change in affiliation from an overseas to a Chinese university (Gao & Liu, 2020). Moreover, they are struggling to change their research focus when they returned to China because the previous one fails to fit the domestic research agenda (Ibid.).

To the best of our knowledge, Russian scientists are not studied thoroughly in this way. The 'brain drain' was the dominant framework during the 1990s, when scientists were leaving the country en masse. For a long time, the mobility of scientists was analyzed only from that perspective. However, in the last decade, the agenda has begun to change. In this study, the case of one large Russian university was examined. The study is focused on the impact of education or work experience abroad on the scientific career of young researchers, particularly on their publication activity.

Following the goal of our study, we compiled the unique for Russia database with the combination of biographical data got from their CVs and bibliometric information derived from the Scopus database. The goal was to overcome the significant incompleteness of the data extracted from bibliography descriptions of publications alone. This approach is not the most common in studies of mobility and research performance, since the data sets required are not easily available. Implementation of such an approach in Russia is even more limited due to specificities of public availability of bibliographical data of Russian scientists. Most Russian universities and research organizations post very brief information about their employees. It is also unusual practice for Russian scientists to publish their CVs in open access.

One of our aims was to look beyond the performance indicators to understand what exactly changes in the research profile of a scientist after he or she moves to another country and then returns. The novelty of our study is as follows: when exploring the relationship between mobility and productivity of researchers we try to reveal the mechanisms of this relation. When it is discovered that mobile researchers publish more or get more citations than non-mobile, sometimes the authors make suggestions that mobility could affect this in several ways – mobile researchers could be more motivated to publish, they probably have a bigger circle of potential coauthors, they gain access to new knowledge and develop new skills in new places, they transfer knowledge themselves, they also can get access to resources and infrastructure. While the plausibility of these factors is confirmed in qualitative studies there is a lack of quantitative research on these factors (Netz, Hampel & Aman, 2020). Today we still do not know what factors are the main drivers of productivity and impact.

In this exploratory study, we analyze several aspects of relationship between mobility and the publication profiles of researchers. The first one is the overall researcher performance. The first hypothesis (H1) is that mobile researchers will have higher number of publications better citation indicators and publish in journals of higher quality. The second one is a collaboration. The second hypothesis (H2) is that mobile researchers tend to have more professional ties which affect productivity. It was tested in some studies with the data on co-authorship but usually was discussed in the context of international collaboration (for example Jonkers & Cruz-Castro, 2013; Jöns, 2007; Netz, Hampel & Aman, 2020). We were interested in whether mobile researchers collaborate more than non-mobile, considering not only international collaboration. The third factor we study here is research topics. The third hypothesis (H3) is that mobile scientists have more diverse research portfolios in terms of research topics. Mobility can cause a shift in the topics researchers are working on, which can affect performance. A researcher can start a new topic in a new place, probably more "fruitful", can drop old ones. To our knowledge, this subject has not been investigated in quantitative studies scientific mobility. In general, mobile researchers not only publish more – they make research and publish differently, and bibliometric analysis can be used to trace some of this difference.

Methodology

For our study, we chose the case of the National Research University Higher School of Economics (HSE University), a large university situated in Moscow with branches in three other cities (Saint-Petersburg, Nizhniy Novgorod, and Perm). Despite the title, HSE University has a very diverse range of departments and research units, from physical to philosophical[1]. HSE University has its own internal programs to support international mobility, is actively working to integrate researchers and teachers into the international academic community, and is recruiting specialists from leading foreign universities and research organizations.

HSE University is among Russian leaders in terms of completeness and availability of data on employees located in the public domain[2]. Each HSE University employee has a personal page on university web-portal with data on education, professional experience, publications etc. including the info on his/her professional/academic/studying mobility. Many HSE employees post their CVs on personal pages. We've collected a database of young mobile and non-mobile researchers affiliated with HSE University where bibliometric data (information about Scopus-indexed publications) were combined with the biographical information of researchers (experience of international mobility) gathered from their personal pages at HSE University web-portal. Among all HSE employees, we've selected those who held a research position as main position marked on the employee's personal page. Further among all researchers we've selected HSE those who as of March 2020, were 39 years old or younger, and who explicitly marked on his/her personal page (or in CV) at least one episode of scientific or educational mobility lasting more than three months. Processing of personal pages and CVs of HSE employees was done in an automatic mode with further manual check and correction of controversial cases. As a result, we have selected the initial sample of 193 young mobile researchers working at HSE University – those who were under 40 year (as of March 2020), held a research position and had at least one episode of international mobility lasting 3 months or more.

To form the group of non-mobile researchers, we've used matched pairs method[3]. The aim was to create two groups for comparison, where members are as close as possible in several significant parameters. For each mobile researcher, a non-mobile "pair" was selected manually from the pool of HSE researchers without mobility experience – a researcher working in the same or close by profile department, of about the same age (the difference in the year of receiving the first diploma was no more than two years). In addition, control was carried out for the region of the first higher education – for mobile researchers who received it in Moscow or St. Petersburg, non-mobile pair with the same educational background were selected. The selection resulted in 119 pairs of mobile and non-mobile researchers.

To analyze whether the length of the mobility episodes makes a difference to research performance, we divided all mobile researchers to two sub-samples – researchers with episodes

[1] See more about HSE University at: https://www.hse.ru/en/info/

[2] Implementation of some measures on openness of data on academic mobility of employees and their publications is observed in the universities participating in the so-called 5-100 project (Russian Academic Excellence Project 5-100. Read more at: https://www.5top100.ru/en/about/more-about/), but none of them had enough data for calculations in the framework of our approach and research design.

[3] This method is widely used in medical research as part of the design of an experiment to study the effectiveness of a particular treatment. In social research it is more often used in non-experimental design. The approach has been applied in studies of science, in particular in the analysis of the relationship between mobility and career achievements of scientists [Bäker 2015; Lawson, Shibayama 2015].

of long-term mobility and researchers with episodes of short-term mobility. As researchers with long-term mobility (long-mobile researchers) we determined those who on their personal pages or in CV marked at least one episode of abroad mobility with the length of one year and more. As a result, we have selected 78 long-mobile researchers (and 78 their non-mobile matched pairs) and 40 short-mobile researchers (and 40 their non-mobile matched pairs). For one researcher we could not detect the length of mobility.

Publication activity data for mobile researchers and their non-mobile matched pairs was taken from the largest international scientific citation database Scopus. If available, Scopus Author Identifiers (IDs) were derived from the personal pages of the studied sample of researchers; otherwise, we have run the search of Scopus author IDs. Further all the Scopus author IDs collected were checked on their correctness and completeness. Due to small size of our sample, author name disambiguation was performed in manual mode. Duplicate author profiles (cases when there are several Scopus author IDs for one author) were merged[4].

Further using the functionality of the Scopus SciVal analytical toolbox, we have created the synchronized corpus of Scopus author IDs for mobile and non-mobile researchers. In this database each row represents a specific mobile or non-mobile researcher from our sample with time series of some key bibliometric indicators like number of publications, number of citations received etc. for this specific researcher.

The preliminary analysis shows that first publications of mobile researchers appeared in 2004. We've further divided the 2004-2020 period onto three five-year sub-periods: 2005-2009, 2010-2014 and 2015-2019. We focus our analysis on 2015-2019 sub-period since during this period mobile and non-mobile researchers have published the highest number of Scopus-indexed publications.

We've integrated further all the publications of mobile and non-mobile researchers into two special corpuses of publications. In each corpus each row represents a single Scopus-indexed publication of mobile or non-mobile researcher with various data on this publication like a year of issue, a number of citation received, name of source issued, CiteScore value of this source etc. Aggregation of information from two corpuses of publications allowed us to calculate some basic bibliometric indicators (like number of publications, number of citations received, share of publication in international collaboration etc.) for two groups of researchers. All the calculations were performed for the Scopus data collected in October 2020.

To analyze the relationship between international mobility and the content of publications of mobile and non-mobile researchers we used data on so-called Scopus Topics Prominence in Science that is available in the SciVal analytical toolbox[5]. Among the various number of bibliometric indicators available in SciVal for each publication of mobile and non-mobile researchers we select for content analysis indicators like Topic Cluster name, Topic Cluster number, Topic name, Topic number, Topic Cluster Prominence Percentile, Topic Prominence. With these data, we can see for each researcher in what topics and clusters he or she has

[4] Merging of author profiles was done in the following cases: different versions of the transliteration of the surname and / or first name of a specific author; combining several author profiles with the same spelling of the surname, but different spelling options for the name and patronymic; combining profiles of the same author with different affiliations; unification of maiden surname and husband's surname for women. In some cases, instead of unification of duplicate profiles, we did the clearing of author profile (exclusion of publications that obviously do not belong to a specific author). Merging of Scopus Au-IDs in different formats and/or clearing of author profiles was done for about 40 cases of mobile and non-mobile researchers.

[5] Assigning of topic prominence in science to Scopus-indexed publications works as follows. To each specific publication indexed in Scopus special clustering algorithm automatically assigns one topic and one topic cluster (broader topic). Assigning of this or that topic to a specific publication is defined in the result of clustering based on direct citation analysis of almost all publications indexed in Scopus. As a result 96000+ topics and 1500+ topic clusters is defined for almost all Scopus-index publications. See more about topic prominence in Science at: https://www.elsevier.com/solutions/scival/releases/topic-prominence-in-science

published papers. The question we are interested in is there a difference in the size of "repertoire" of a researcher (the number of topics and the number of clusters) between mobile and non-mobile groups. Analysis of Scopus topics was done for the whole period: 2004-2020.

Results

Mobility and general research performance

Key results of bibliometric analysis of publication activity of short- and long-term mobile young researchers and their non-mobile matched pairs from HSE University in Scopus in 2015-2019 were summarized in Table 1.

Table 1. Key indicator of publication activity for the studied groups of mobile and non-mobile researchers from HSE University in Scopus for 2015-2019

Group of researchers and Type of mobility length → Indicator name ↓	Publications of mobile researchers			Publications of non-mobile matched pairs		
	All types	Long-term	Short-term	All types	Long-term	Short-term
Number of publications	724	475	250	595	398	185
Number of researchers who had at least one publication in Scopus	113/119	73/78	38/40	112/119	74/78	38/40
Average number of publications per one researcher of a group	6.08	6.09	6.25	5.00	5.10	4.63
Number of citations received	3 393	2 430	945	1 525	1 097	383
Average number of citations per one publications	4.67	5.12	3.78	2.56	2.76	2.07
Average value of field-weighted citation impact of all publications, points	0.96	1.03	0.83	0.70	0.72	0.62
Number of publications in Top 1 Citation Percentile (top-1% of the most cited publications)	3	3	0	0	0	0
Average value of CiteScore[1] of sources[2] where publications are issued, points	2.46	2.70	2.07	1.66	1.81	1.28
Share of publications in Q1 sources[1] by CiteScore (to publications in all sources with CiteScore calculated), %	35.3	37.5	32.3	25.2	26.4	20.8
Number of publications in top-1% sources[1] by CiteScore value	13	11	2	2	1	1
Share of publications in international collaboration, %[2]	42.0	46.5	34.4	19.8	21.3	17.3

Notes. 1. According to methodology of Scopus "Calculating the CiteScore is based on the number of citations to documents (articles, reviews, conference papers, book chapters, and data papers) by a journal over four years, divided by the number of the same document types indexed in Scopus and published in those same four years" – see more at: https://service.elsevier.com/app/answers/detail/a_id/14880/supporthub/scopus/. 2. Vast majority of sources for which CiteScore is calculated are journals, indexed in Scopus, and some conference proceedings, book series and books. 3. As publications in international collaboration we treat publications where the sole author or at least one co-author is affiliated with at least two different countries.

Source: authors' calculations based on Scopus SciVal data collected at October 2020. All types of documents indexed in Scopus are taken into account

Table 1 provides key bibliometric indicators for the corpuses of Scopus-indexed publications for the selected groups of researchers. As we can see from Table 1 almost all mobile researchers as well as their non-mobile matched pairs had at least one Scopus-indexed publication for 2015-2019. Our analysis shows that mobile researchers have in general better research performance indicators of Scopus-indexed publications than their non-mobile matched pairs. Mobile researchers outperform their non-mobile matched pairs by the average number of publications per one researcher.

Mobile researchers are especially stronger than their non-mobile matched pairs in terms of citation indicators, journal quality indicators and involvement in international research collaboration. Mobile researchers have much higher average number of citations per one publication, higher field-weighted citation impact of their publications, and publish their papers in journals with much higher average CiteScore metrics. Mobile researchers also have higher share of publications in Q1 journals and much higher number of publications in top-1% journals by CiteScore value. In addition, mobile researchers authored all publications in "top-1% most cited" category from the studied corpuses of publications. All these prove the first hypothesis (H1) that mobile researchers have better overall researcher performance.

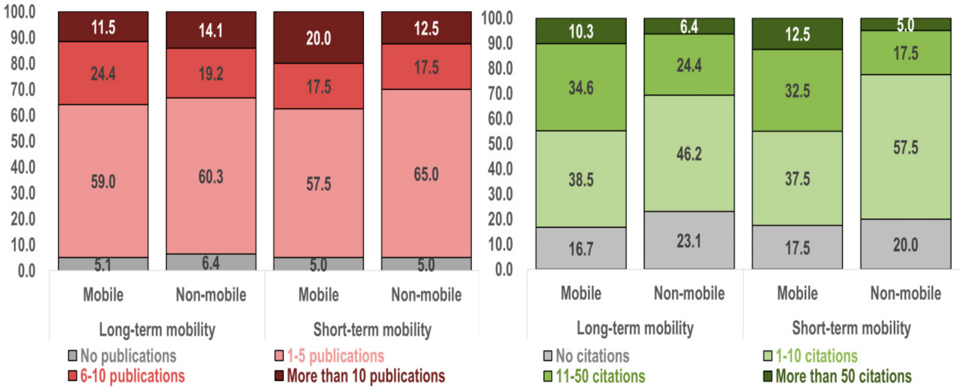
Higher average CiteScore value of journals where mobile researchers publish their work can be caused by a variety of factors. During their work or studying abroad mobile scientists can acquire new competencies that let them make better studies. Among these new competencies one can learn how to select research topics and questions to make the study eligible for publication in high-level international journal. Mobile researchers can also find new collaborators and join new projects producing high quality work. Apart from that mobile researchers could have some first-hand experience with editors or regular authors of high quality journals while working abroad. These social ties can also boost their chances to be published. Some of these possible explanations find evidence in bibliometric data we have.

Mobile researchers are much more actively involved in international research collaboration. It is not surprising that mobile researchers especially strongly outperform their non-mobile pairs by the level of integration into international research collaboration. After returning to Russia, mobile researchers bring their contacts with foreign co-authors, accumulated abroad, to their Russian places of work. The results of our analysis prove the second hypothesis (H2) about much higher collaboration of mobile researchers with foreign colleagues.

We found that that researchers who have in their career longer-than-one-year episode(-s) of international mobility in many aspects have better research performance indicators of their Scopus-indexed publications in comparison to researchers with short-term episodes of international mobility. Short-term mobile have slightly higher average number of publications per one researcher, but they lose in terms of involvement in international collaboration, average citation level and the average value of CiteScore indicator of journals where the publications were issued. We also see that vast majority of publications in top-1% sources by CiteScore value and all publications in Top 1 Citation Percentile are published by long-term mobile researchers. The conclusions that can be derived from the comparison of long-term mobile researchers with short-term mobile are rather limited though. These groups can differ in many aspects significant for publication performance. To analyze how the length of mobility is related to research performance we compared each group of mobile researcher to the appropriate control group of non-mobile researchers (matched pairs).

Differences between mobile and non-mobile researchers

Further we go to the level of individual authors to compare key indicators of publication activity of mobile researchers vs. their non-mobile pairs. Figure 1 shows the distribution of short- and long-term mobile researchers and their non-mobile matched pairs by the number of publications and number of citations received in Scopus for 2015-2019.



Source: authors' calculations based on Scopus SciVal data collected at October 2020. All types of documents indexed in Scopus are taken into account.

Figure 1. Distribution of researchers with long- and short-term mobility and their non-mobile matched pairs by number of publications and number of citation received in Scopus in 2015-2019

As we can see from this graph, the difference between mobile and non-mobile researchers by the level of publications activity is not dramatic. On the other hand, the differences by number of publications for mobile researchers vs. non-mobile pairs are stronger for the group with short-term mobility. Mobile researchers are in general slightly more productive than non-mobile researchers are. Among all groups studied short-term mobile researchers show the highest share of authors with 10+ publications in Scopus for 2015-2019. The differences in the number of citations received between mobile and non-mobile researchers are much stronger. Among mobile researchers, we can see a much less share of non-cited authors and much more share of authors who received 10 and more citations in comparison to non-mobile researchers. Meanwhile, there is no dramatic difference between short-term and long-term mobile researchers in distributions by number of citations received. Non-mobiles pairs of short-term mobile researchers show the "worst" distribution by number of citations received.

Table 2. Results of paired two-sample Student's t-test for mean number of publications and citations received for 2015-2019 in Scopus for mobile vs. non-mobile researchers

Type of distribution →	**Mean number of publications**			**Mean number of citations received**		
Type of mobility length → **Indicator name ↓**	**All types**	**Long-term**	**Short-term**	**All types**	**Long-term**	**Short-term**
N. of pairs	119	78	40	119	78	40
Mean value for mobile group	6.24	6.18	6.45	29.55	32.62	24.30
Mean value for non-mobile group	5.18	5.24	4.95	13.49	14.50	10.60
t-statistics	1.287	0.838	1.344	2.103	1.662	1.705
P-value (T <= t) one-sided	0.100	0.202	0.093	0.019	0.050	0.048
t critical one-sided	1.658	1.665	1.685	1.658	1.665	1.685

Notes: 1. Significance level (alpha-value) for all test is set as 5%. 2. Null hypothesis is that there are no differences in mean values of number of publications and citations received between mobile and non-mobile researchers. 3. Mean values of number of publications in Table 2 differs from Average number of publications per one researcher differs since some publications are coauthored by several from the studied samples.

Table 2 shows the results of the paired two-sample Student's t-test that was used to test the hypothesis about the difference of mean number of publications and citations received for 2015-2019 for two dependent samples of mobile vs. non-mobile researchers. The results of this test support our observations from Figure 1: differences between mobile and non-mobile researchers by number of citations received are stronger than differences by number of publications. The difference in number of publications between mobile and non-mobiles researchers proves statistically significant for short-term mobile group and all mobile, but not for the group of long-term mobile researchers. In case of citations received the difference between mobile and non-mobile is significant for all three groups (all, long-term, short-term).

Publication activity before and after international

The observed difference in bibliometric indicators for the two groups of researchers, even when proved statistically significant, does not automatically mean that it is an effect of international mobility. Despite the matched pairs selection procedure, the difference may be due to other factors that are not directly observable. For example, some personality traits could be the factor of both gaining foreign experience and publication activity.

Availability of data on the publications of researchers, and on the periods of their study and work abroad allows us to conduct additional analysis to partially exclude unaccounted factors. We compared the research performance of mobile and non-mobile researchers in periods before it could be affected by mobility. To do this analysis, for each mobile researcher we take into account only the papers published before the year of the first episode of mobility. For the non-mobile pair of this specific mobile researcher, we also take into account publications issued before the same year (Figure 2). As a result we have detected 102 mobile researchers (and 102 their non-mobile matched pairs) for whom we can detect the year of the first episode of international mobility.

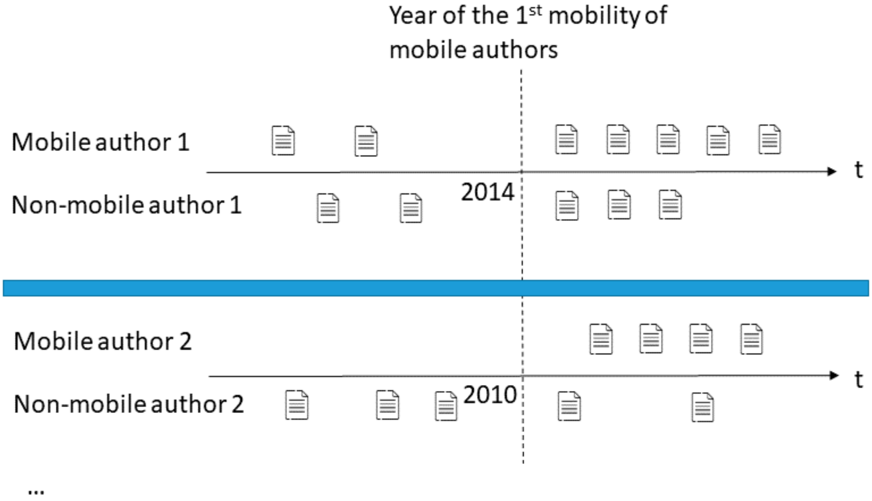


Figure 2. Publication activity of mobile researchers and their non-mobile matched pairs before and after the "treatment" (the first mobility).

Distribution of researchers according to number of papers published during two periods is shown on the Figure 3. On average, mobile researchers published 0.99 papers in Scopus before the first episode of international mobility, while the group of non-mobile researchers had published more intensively during the same periods – a mean is 1.44 publications. The median is 0 papers in both groups, and the difference of the means in not significant (p-value for a t-test is 0.268). As for publications in high-level journals, mobile researchers showed somewhat higher productivity at the start of a career – a mean is 0.22 papers in Q1 journals vs. 0.13 for non-mobile authors, but this difference is also not statistically significant. Thus, the advantage in publication activity of the group of mobile researchers was not noticeable at the start of their careers and appeared definitely after their work or studying abroad.

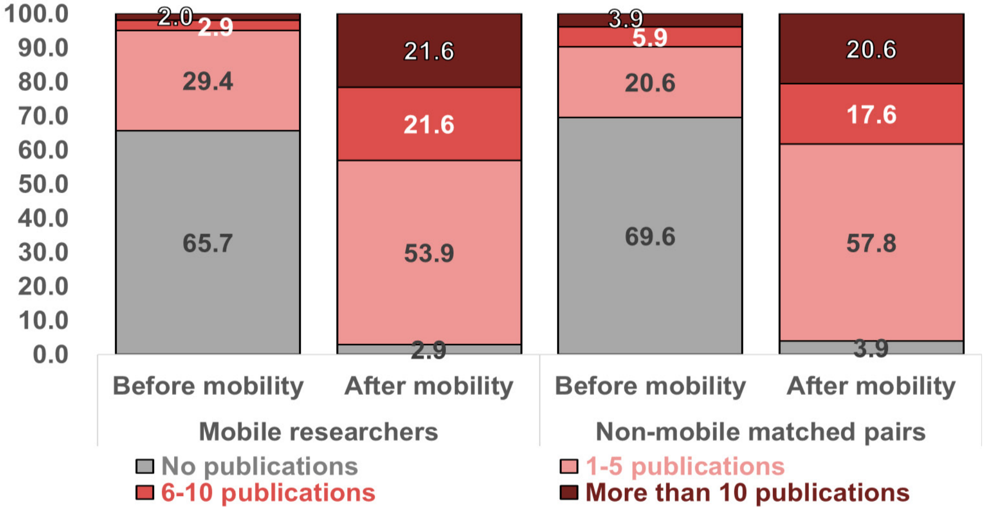

Figure 3. Distribution of mobile researchers and their non-mobile matched pairs according to number of papers in Scopus published before and after the year on the 1st mobility (and the same years for matched pairs).

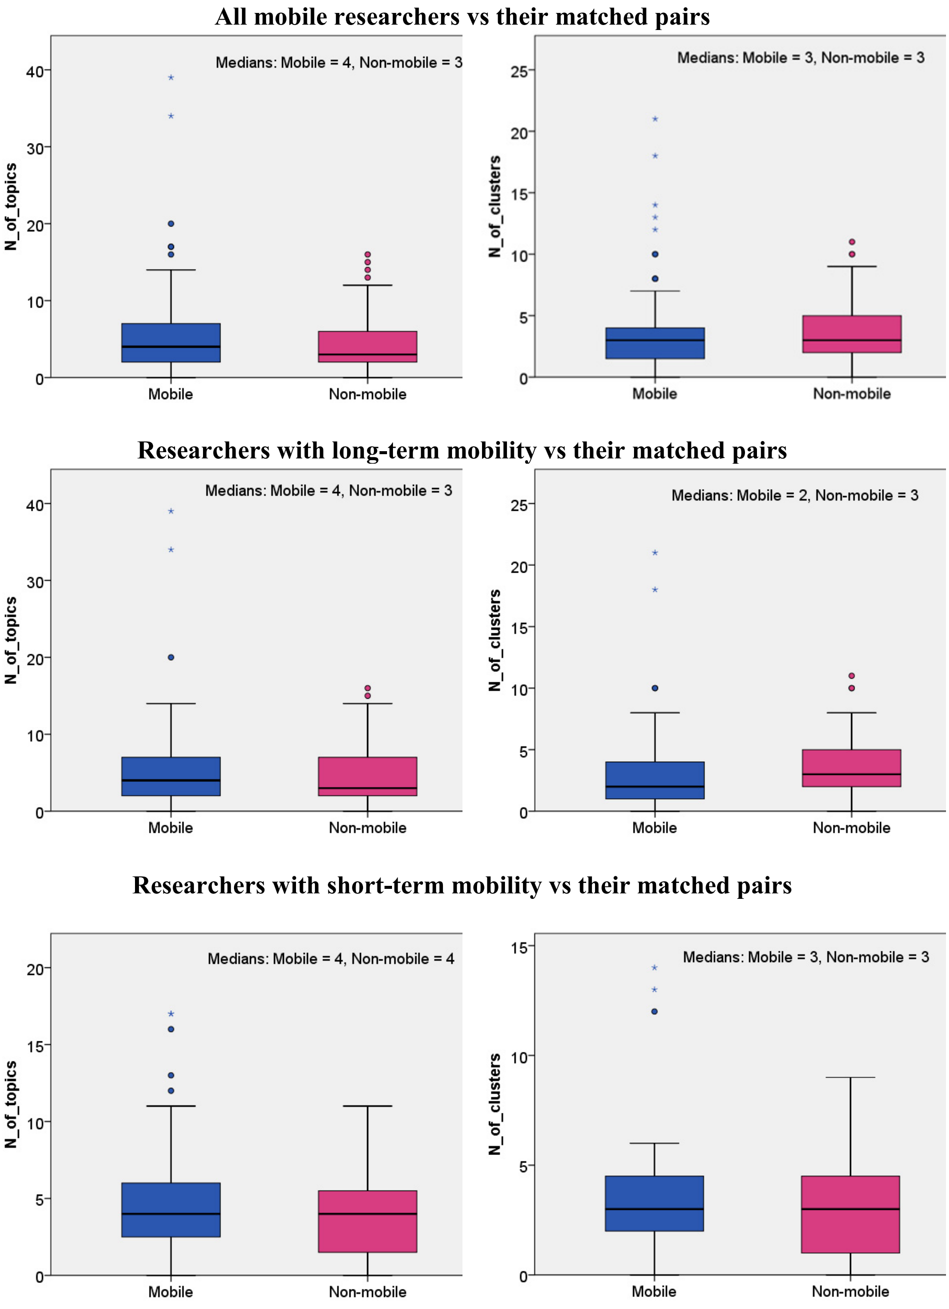
Publication portfolios of mobile and non-mobile researchers

One of our goals was to investigate the difference between publication portfolios of mobile and non-mobile researchers beyond the traditional productivity and impact indicators. Particularly we are interested in research topics. One topic and one topic cluster are assigned to each publication in Scopus. Topic cluster is a group of closely related topics and can be regarded as a broad topic. Figure 4 shows the distribution of researchers in mobile and non-mobile groups by the number of topics and number of topic clusters in their papers.

We see that the distributions are not quite different. Mobile researchers tend to have more topics in their portfolio, than non-mobile. This is true for both long-term mobile researchers (mean number of topics is 5.3 vs 4.8 for non-mobile, medians are 4 vs 3) and short-term mobile ((means are 5.2 vs 3.8, medians are 4 vs 4)). The difference is statistically significant only for short-term mobile researchers (t-test, p-value < 0.09). When topic clusters (broad topics) are considered, there is no much difference in portfolio size of mobile and non-mobile researchers, it is not statistically significant at least. We can conclude that the hypothesis H3 is somewhat confirmed – mobile scientists make research on more diverse subjects than non-mobile – although the difference is not big, and is significant only in case of short-term mobility.

The difference observed does not mean that mobile researchers are actively engaged in research on more topics than non-mobile. On the contrary, the chances are that mobility actually helps researchers to focus, to find an "oilfield" and drill it. To investigate this in detail one need to look how the portfolio changes what a researcher moves to another country. We compared "active portfolios" of mobile and non-mobile researchers – the research topics in relatively recent publications (published in 2015-2019). Mobile group again turned out to have more diverse portfolios (mean number of topics 4.2 vs 3.4 for non-mobile, medians are 3 vs 3; t-test for means shows the difference is marginally significant with p-value =0.108).



All mobile researchers vs their matched pairs

Researchers with long-term mobility vs their matched pairs

Researchers with short-term mobility vs their matched pairs

Figure 4. Distribution of number of topics (left) and topic clusters (right) in papers published by mobile researchers and their matched pairs.

Discussion

In terms of basic indicators of activity, our results can be summarized as follows. Mobile researchers from HSE University have much better indicators of research performance in Scopus than researchers who have never worked or studied outside of Russia. Our findings support the similar others (Franzoni et al., 2015; Gibson & McKenzie, 2014; Gureyev et al., 2020; Netz, Hampel & Aman, 2020) and contradict to some others (Halevi et al. 2016; Cañibano et al. 2008). Moreover, continuing the discussion, opened by (Cañibano et al. 2020), we claimed that the period of mobility matters. Researchers with long episodes of international research or education mobility show even better research performance in Scopus.

In this paper, we open a direction in the analysis of publications of mobile researchers that seems promising to us – research topics analysis. We saw that researchers with mobility experience tend to make research in more topics than non-mobile researchers. The question is: "Whether it was the mobility that pushed the scientists to diversify their research interests?". One way to answer this question, which we hope to develop in future studies, is to analyze how the "repertoire" of researchers evolves over time – what are the most common patterns in research topics change associated with moving to another country. The evolution of the topic's portfolio can be related to a performance advantage, which is often registered for mobile researchers. It also contributes to the discussion about the pattern of change in research practices (Gläser et al. 2014).

We see the possible ways of development of our researcher as follows. One way – to analyze how the career stage when first episode of international mobility occurred matters for the further pattern of researcher performance, following the discussion by (Cañibano et al., 2020). The other way – is the analysis of disciplinary profiles of researchers (i.e. whether the difference between mobile researchers vs. non-mobile researchers is stronger in natural sciences vs. social sciences, following the work by (Laudel & Bielick, 2019).

Avoiding bias when inferring race using name-based approaches

Abstract
Racial disparity in academia is a widely acknowledged problem. The quantitative understanding of racial-based systemic inequalities is an important step towards a more equitable research system. However, few large-scale analyses have been performed on this topic, mostly because of the lack of robust race-disambiguation algorithms. Identifying author information does not generally include the author's race. Therefore, an algorithm needs to be employed, using known information about authors, i.e., their names, to infer their perceived race. Nevertheless, as any other algorithm, the process of racial inference can generate biases if it is not carefully considered. When the research is focused on the understanding of racial-based inequalities, such biases undermine the objectives of the investigation and may perpetuate inequities. The goal of this article is to assess the biases introduced by the different approaches used name-based racial inference. We use information from US census and mortgage applications to infer the race of US author names in the Web of Science. We estimate the effects of using given and family names, thresholds or continuous distributions, and imputation. Our results demonstrate that the validity of name-based inference varies by race and ethnicity and that threshold approaches underestimate Black authors and overestimate White authors. We conclude with recommendations to avoid potential biases. This article fills an important research gap that will allow more systematic and unbiased studies on racial disparity in science.

Introduction

The use of racial categories in the quantitative study of science is so widely extended that it intertwined with the controversial origins of statistical analysis itself (Galton, 1891; Godin, 2007). While Galton and the eugenics movement reinforced the racial stratification of society, racial categories have also been used to acknowledge and mitigate racial discrimination. As Zuberi (2001) explains: "The racialization of data is an artifact of both the struggles to preserve and to destroy racial stratification." This places the use of race as a statistical category in a precarious position: one that both reinforces the social processes that segregate and disempower parts of the population, while simultaneously providing an empirical basis for understanding and mitigating inequities.

Science is not immune from these inequities (Hoppe, et al., 2019; Prescod-Weinstein, 2020; Stevens et al, 2021; Ginther et al., 2011). Early research on racial disparities in scientific publishing relied primarily on self-reported data in surveys (e.g., Hopkins et al., 2013), geocoding (e.g., Fiscella & Fremont, 2006) and directories (e.g., Cook, 2014). However, there is an increasing use of large-scale inference of race based on names (Freeman & Huang, 2014), similar to the approaches used for gender-disambiguation (e.g., Lariviere et al., 2013). Algorithms, however, are known to encode human biases (Buolamwini & Gebru, 2018; Caliskan, 2017): there is no such thing as *algorithmic neutrality*. The automatic racial inferences of authors based on their features in bibliographic databases is itself an algorithmic process that needs to be scrutinized, as it can fall into implicitly encoded bias, with major impact in the over and under representation of racial groups.

In this study, we use the self-declared race/ethnicity from the 2010 U.S. census and mortgage applications as the basis for inferring race from author names on scientific publications indexed in the Web of Science (WoS) database. Bibliometric databases do not include self-declared race by authors, as they are based on the information provided in publications, such as given and family names. Given that the U.S. census provides the proportion of self-declared race by family name, this information can be used to infer US authors' race given their family names. We present several different approaches for inferring race and examine the bias generated in each case. The goal of the research is to provide an empirical critique of name-based race inference and recommendations for approaches that minimize bias. Even if a prefect inference is not achievable, the conclusions that arise from this study will allow researchers to conduct more careful analyses on racial and ethnic disparities in science. Although the categories analysed are only valid in the U.S. context, the general recommendation can be extended to any other country in which the Census (or similar data collection mechanism) includes self-reported race.

Racial categories in the US census

The U.S. census is a rich and long-running dataset, but also deeply flawed and criticized. Currently it is a decennial counting of all U.S. residents, whether citizens or non-citizens, in which several characteristics of the population are gathered, including self-declare race/ethnicity. The classification of race in the U.S. census is value-laden with the agendas and priorities of its creators, namely 18th century White men who Wilkerson (2020) refers to as "the dominant caste." The first U.S. census was conducted in 1790 and founded on the principles of racial stratification and White superiority. Categories included: "Free White males of 16 years and upward," "Free White males under 16 years;" "Free White females," "All other free persons," and "Slaves" (U.S. Bureau of the Census, 1975). At that time, each member of a household was classified into one of these five categories based on the observation of the census-taker, such that an individual of "mixed white and other parentage" was classified into "All other free persons" in order to preserve the "Free White…" privileged status. To date, anyone classifying themselves as other than "non-Hispanic White" is considered a "minority." The shared ground across the centuries of census survey design and classification strata reflects the sustained prioritization of the White male caste (D'Ignasio & Klein, 2020, Zuberi, 2001).

Today, self-identification is used to assign individuals to their respective race/ethnicity classifications (Locke, Blank, & Groves, 2011), per the U.S. Office of Management and Budget (OMB) guidelines. However, the concept of race and/or ethnicity remains poorly understood. For example, in 2000 the category "Some other race" was the third largest racial group, consisting primarily of individuals who in 2010 identified as Hispanic or Latino (which according to the 2010 census definition refers to a person of Cuban, Mexican, Puerto Rican, South or Central American, or other Spanish culture or origin regardless of race). Instructions and questions which facilitated the distinction between race and ethnicity began with the 2010 census which stated that "[f]or this census, Hispanic origins are not races" and to-date, in the U.S. federal statistical system, Hispanic origin is considered to be a separate concept from race. However, this did not preclude individuals from self-identifying their race as "Latino," "Mexican," "Puerto Rican," "Salvadoran," or other national origins or ethnicities (Humes, Jones, & Ramirez, 2011, p. 3). Furthermore, 6.1% of the US population changed their self-identification of both race and ethnicity between the 2000 and 2010 censuses (Liebler, et al., 2017), demonstrating the dynamicity of the classification. The inclusion of certain categories has also been the focus of considerable political debate. For example, the inclusion of citizenship generated significant debates in the preparation of the 2020 Census, as it can generate a larger nonresponse rate from the Hispanic community (Baum, 2019). The aim of this article, however, is to represent the full extent of possible US-based authors. Therefore, we consider both citizens and non-citizens.

In this paper, we design and compare multiple approaches for inferring race based on the given and family names of authors in the WoS database. The social function of the concept of race (i.e., the building of racialized groups) underpins its definition more than any physical traits of the population. For example, "Hispanic" as a category arises from this conceptualization, even though in the 2010 U.S. census the question about Hispanic origin is different from the one on self-perceived race. While Hispanic origin does not relate to any physical attribute, it is still considered a socially racialised group, and this is also how the aggregated data is presented by the Census Bureau. Therefore, in this paper, we will utilize the term race to refer to these social constructions, acknowledging the complex relation between conceptions of race and ethnicity. But even more important, this conceptualization of race also determines what can be done with the results of the proposed models. Given that race is a social construct, inferred racial categories should only be used in the study group-level social dynamics underlying these categories, and not as individual-level traits. Census classifications are founded upon the social construction of race and reality of racism in the US, which serves as “a multi-level and multi-dimensional system of dominant group oppression that scapegoats the race and/or ethnicity of one or more subordinate groups” (Horton & Sykes, 2001, p. 209). Self-identification of racial categories continue to reflect broader definitional challenges, along with issues of interpretation, and above all the amorphous power dynamics surrounding race, politics, and science in the U.S. In this study, we are keenly aware of these challenges, and our operationalization of race categories are shaped in part by these tensions.

Data

This project uses several data sources to test the different approaches for race inference based on the author's name. First, to test the interaction between given and family names distributions, we simulate a dataset that covers most of the possible combinations. Using a Dirichlet process (Teh, 2010), we randomly generate 500 multinomial distributions for given names, and another 500 random multinomial distributions for family names. After this, we build a grid of all the possible combinations of given and family names random distributions (250,000 combinations).

In addition to the simulation, we use two datasets with real given and family names and an assigned probability for each racial group. The data from the given names is from Tzioumis (2018), who builds a list of 4,250 given names based on mortgage applications, with self-reported race. Family name data is based on the 2010 US census (US Census Bureau, 2016), which includes all family names with more than 100 appearances in the census, with a total of 162,253 surnames that covers more than 90% of the population. For confidentiality, this list removes counts for those racial categories with fewer than five cases, as it would be possible to exactly identify individuals and their self-reported race. In those cases, we replace with zero and renormalize. As explained previously, changes were introduced in the 2010 US census racial categories. Questions now include both racial and ethnic origin, placing "Hispanic" outside the racial categories. The racial categories used in both datasets include Hispanic as a category, and all other racial categories excluding people with Hispanic origin, therefore the category "White" becomes "Non-Hispanic White Alone", and "Black or African American" becomes "Non-Hispanic Black or African American Alone", and so on. The final categories used in both datasets are:

- Non-Hispanic White Alone (*White*)
- Non-Hispanic Black or African American Alone (*Black*)
- Non-Hispanic Asian and Native Hawaiian and Other Pacific Islander Alone (*Asian*)
- Non-Hispanic American Indian and Alaska Native Alone (*AIAN*)
- Non-Hispanic Two or More Races (*Two or more*)
- Hispanic or Latino origin (*Hispanic*)

We test these data on WoS to study how name-based racial inference performs on the population of U.S. scientific authors. WoS did not regularly provide first names in articles before 2008; therefore, the data includes all articles published between 2008 and 2019. This results in 21,295,333 articles, 1,609,107 unique first authors, 152,835 distinct given names and 288,663 distinct family names for first authors. Given that in this database, 'AIAN' and 'Two or more' account for only 0.69% and 1.76% of authors respectively, we remove these and renormalize the distribution with the remaining categories. Therefore, in what follows we will refer exclusively to categories *Asian, Black, Hispanic,* and *White*.

Methods

Manual validation

The data is presented as a series of distributions of names across race (Table 1). In name-based inference methods, it is not uncommon to use a threshold to create a categorical distinction: e.g., using a 90% threshold, one would assume that all instances of Juan as first name should be categorized as Hispanic and all instances of Washington as a given name should be categorized as Black. In such a situation, any name not reaching this threshold would be excluded (e.g., those with the last name of "Lee" would be removed from the analysis). This approach, however, assumes that the distinctiveness of names across races does not significantly differ.

Table 1. Sample of family names (US census) and given names (mortgage data).

Type	*Name*	*Asian*	*Black*	*Hispanic*	*White*	*Count*
Given	Juan	1.5%	0.5%	93.4%	4.5%	4,019
	Doris	3.4%	13.5%	6.3%	76.7%	1,332
	Andy	38.8%	1.6%	6.4%	53.2%	555
Family	Rodriguez	0.6%	0.5%	94.1%	4.8%	1,094,924
	Lee	43.8%	16.9%	2.0%	37.3%	693,023
	Washington	0.3%	91.6%	2.7%	5.4%	177,386

To test this, we began our analysis by manually validating name-based inference at three threshold ranges: 70-79%, 80-89%, and 90-100%. We sampled 300 authors from the WoS database, 25 randomly sampled for every combination of racial category and inference threshold. Two coders manually queried a search engine for the name and affiliation of each author and attempted to infer a racial category through visual perception and information listed on their websites and CVs (e.g., affiliation with racialized organizations such as *Black in AI, SACNAS* etc.).

Figure 1 shows the number of valid and invalid inferences, as well as those for whom a category could not be manually identified, and those for whom no information was found. Asian authors were valid at every threshold considered. The inference of Black authors, in contrast, was invalid or uncertain at the 70-80% threshold, but high at the 90% threshold. Similarly, inferring Hispanic authors was only accurate after the 80% threshold. Inference of White authors was valid at all thresholds but improved above 90%. This suggests that a simple threshold-based approach is not equally valid across all races. We thereby move to a weighting-based scheme for analysis that does not provide an exclusive categorization but uses the full information of the distribution.

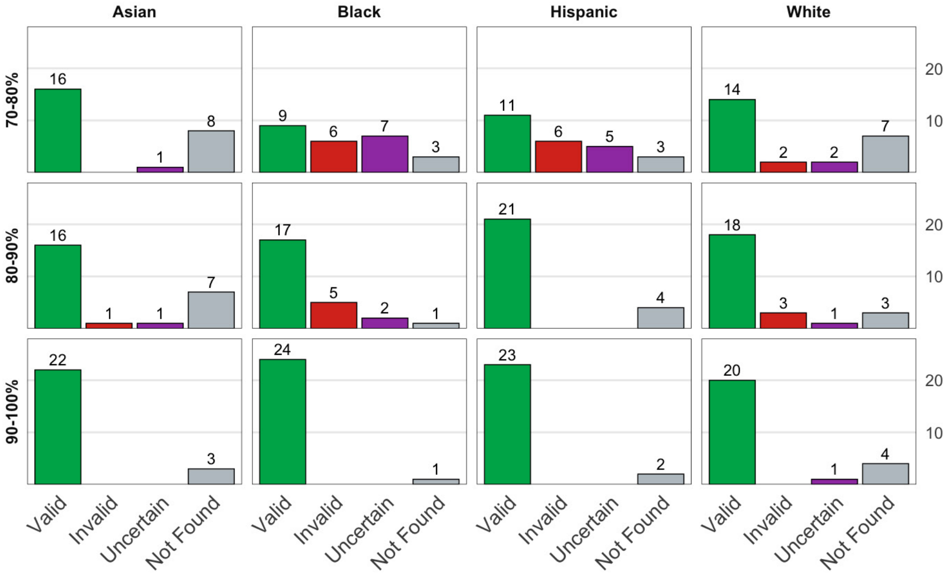

Figure 1. Manual validation of racial categories

Weighting scheme

We assess three strategies for inferring race from an author's name using a combination of their given and family name distributions across racial categories (Table 1). The first two aim to build a new distribution as a weighted average from both the given and family name racial distributions, and the third uses both distributions sequentially. In this section we explain these three approaches and compare them to alternatives that use only given or only family name racial distributions.

The weighting scheme should account for the intuition that if the given (family) name is highly informative while the family (given) name is not, the resulting average distribution should prioritize the information on the given (family) name distribution. For example, 94% of the people with Rodriguez as a family name identify themselves as Hispanic, whereas 39% of the people with the given name Andy identify as Asian, and 53% as White (see Table 1). For an author called Andy Rodriguez, we would like to build a distribution that encodes the informativeness of their family name, Rodriguez, rather than the relatively uninformative given name, Andy. The first weighting scheme proposed is based on the standard deviation of the distribution:

$$sd = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(x_i - \overline{x})^2}$$

With four racial categories, the standard deviation moves between 0, for perfect uniformity, and 0.5 when one category has a probability of 1. The second weighting scheme is based on entropy, a measure that is designed to capture the informativeness of a distribution:

$$e = -\sum_{i=1}^{c} P(x_i) log P(x_i)$$

Using this, we propose the following weight for given names:

$$x_{weight} = \frac{f(x)^{exp}}{f(x)^{exp} + f(y)^{exp}}$$

with x and y as the given and family name. exp is the exponent applied to the function, and is a tuneable parameter. For the standard deviation, using the square function means we use the variance of the distribution. In general, the higher the exp is set, the more skewed the weighting is towards the most informative name distribution.

Figure 2 shows the weighting to the given and family names based on their informativeness, and for different values of the exponent. The horizontal and vertical axes show the highest value on the given and family name distribution, respectively. This means that a higher value on any axis corresponds with a more informative given/family name. The color palette shows how much weight is given to the given names. When the exponent is set to two, both the entropy and standard deviation-based models skew towards the most informative feature, a desirable property. Compared to other models, the variance gives the most extreme values to cases where only one name is informative, whereas the entropy-based model is the most uniform.

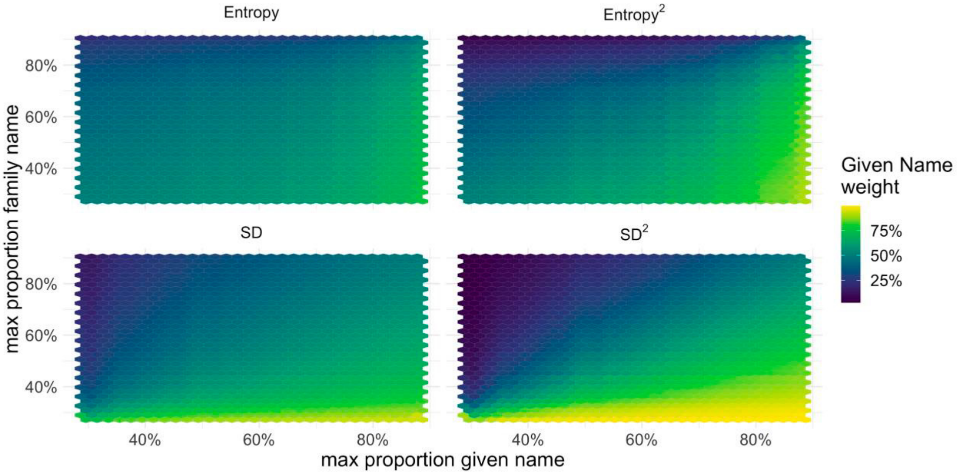

Figure 2. Given names weight distribution by given and family name skewness. Simulated data.

Information retrieval

The above weighting schemes result in a single probability distribution of an author belonging to each of the racial categories, from which a race can be inferred. One strategy for inferring race from this distribution is to select the racial category above a certain threshold, if any. A second strategy is to make use of the full distribution to weight the author across different racial categories, rather than assigning any specific category. Third, we implement a two-step strategy that sequentially uses family and then given names. Given that family names are from census data, we first retrieve all authors which have a family name with a probability of belonging to a specific racial group greater than a given threshold. This retrieves *N* authors. Second, we retrieve the same amount, *N,* of authors as in the first step, but using the given names. Finally, we define a unique set of authors, removing those captured by both steps. This leaves a set between *N* and 2*N* authors, depending on the number of authors retrieved in both steps. Naturally, there are multiple possible changes on this two-step method, for example, a percentage threshold could be used in both steps, instead of a given number. It could be possible also to have a specific percentage threshold for each step. There is not a preferred method in principle, but the proposed configuration relates with our belief that the census data (family names) is of better quality, and therefore we prefer to use it to define the number observations to extract with the lower quality data.

Results

The effect of underlying skewness

Before comparing the results of the proposed strategies for using both given and family names, we present characteristics of these two distributions on the real data, and in relation to the WoS dataset. Table 2 shows the population distribution on the family names, based on the US census, and on the given names, based on the mortgage applications. Considering the US census data as ground truth, we see that the mortgage data highly over-represents the White population, particularly over-represents Asians, and underrepresents Black and Hispanic populations; this likely stems from the structural factors (i.e., economic inequality, redlining, etc.) that prevent marginalized groups from applying for mortgages in the US. People may also choose to self-report a different racial category when responding anonymously to the census bureau than when applying for a mortgage loan. Due to this bias in the distribution of given names, we normalize the given name distribution by applying an expansion factor to each racial group, so that the expanded given name count preserves the racial distribution in the US census.

Table 2. Racial representation of family names (US census) and given names (mortgage data).

Racial group	*Family names*	*Given names*
White	66.1%	82.6%
Hispanic	16.5%	6.9%
Black	12.4%	4.2%
Asian	5.0%	6.3%

Both given and family names share a characteristic not considered in our simulated data: the informativeness of names varies across racial groups. Inferring racial categories based on a set threshold will, then, produce biased results as typical names of one racial category are more informative, and thus more easily meet the threshold, than another. Figure 3 shows how the representation of inferred races changes based on the assignment threshold used. Increasing the threshold results in fewer total individuals returned (top), as some names are not very sufficiently informative. For family names, only a small proportion of the population remains at a 90% threshold. The Asian population is highly over-represented between the 90% and 96% threshold, after which they suddenly become under-represented. The White population is systematically over-represented for any threshold, whereas the Black population is systematically underrepresented. The Hispanic population is overrepresented between the 65% and 92% threshold and underrepresented after. With given names, the White population is systematically overestimated for every threshold until 96%, where the Asian population is suddenly overestimated to a high degree. Similar results are observed based on given names. Again, the Asian population is highly overrepresented after the 96% threshold, whereas the White population is over-represented across nearly all thresholds and the Black and Hispanic population were underrepresented across all thresholds. The fact that Asian, and to some degree Hispanic, populations have more informative given and family names is related with higher differentiation of these two communities; White and Black populations in the United States, in contrast, tend to have more similar names (as verified in Elliott et al., 2009). Given that the White population is larger than the Black population, the use of a threshold (and assigning all people with that name to a single category), generates a Type I error on Black authors, and Type II error on White authors, thereby overestimating the proportion of White authors.

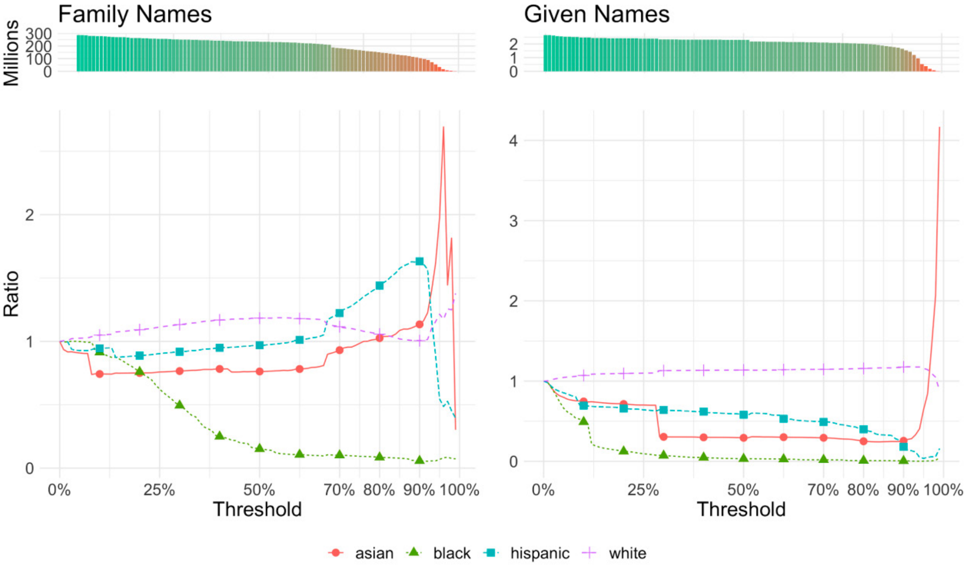

Figure 3. Changes in groups share, and people retrieved, by threshold. Census (Family names) and mortgage (Given names) datasets.

The effect of thresholding

Figure 4 shows the effect of using a 90% threshold on the WoS dataset of unique authors. The first column corresponds to each author counting fractionally towards each racial category in proportion to the probabilities of their name distribution, using family names from the census, i.e., this is the closest we can get to ground truths with the available information. The remaining columns represent (1) inference based on given and family names alone; (2) combination distributions; and (3) the two-steps strategy, using both normalized and unnormalized given names, always with a 90% threshold. All models highly underrepresented the Black population of authors. All models except normalized given names under-represent the Hispanic population. The unnormalized given name, either alone or in the variance model, underrepresents the Asian population. Finally, the White population is overrepresented by all models except family names and the variance with normalized given names.

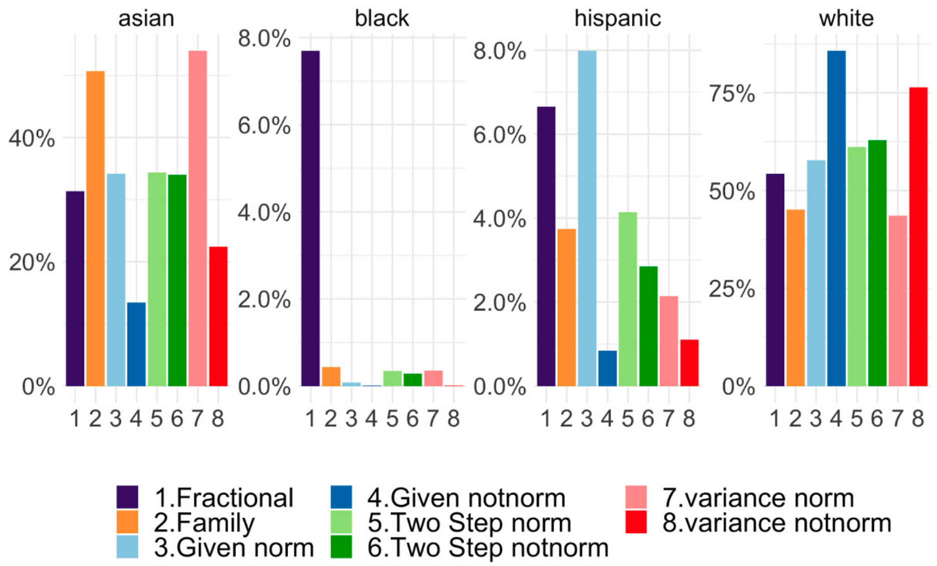

Figure 4. Resulting distribution on different models with 90% threshold. Fractional counting on family names for comparison.

Figure 5 demonstrates how the number of authors in each racial group drops when increasing the threshold. The convexity in the Black authors curve, distinct from the concave curves for other racial groups, explains the underrepresentation of this group under high thresholds. Even at less extreme thresholds, the proportion of Black authors in the dataset is far smaller than the fractionalized counting of White authors (851,843.60). The consequence of this is that a low threshold would grossly over represent White authors, while a high threshold would exclude nearly all Black authors. We conclude from this that a threshold-based approach, while intuitive and straightforward, should not be used for racial inference. Rather, analysis should be adapted to consider each author as a distribution over every racial category; in this way, even though an individual cannot be assigned into a category, aggregate results will remain unbiased.

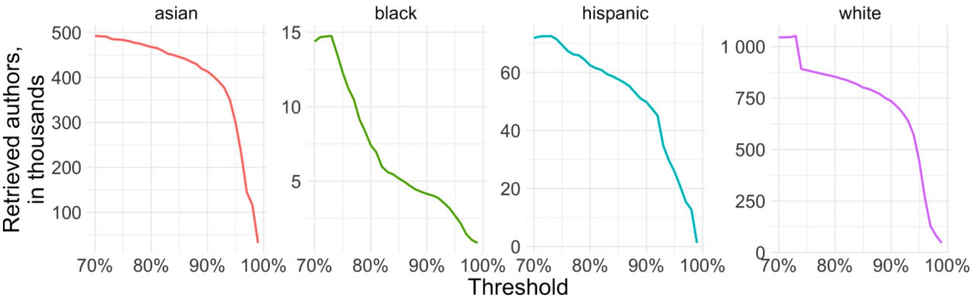

Figure 5. Two-steps strategy retrieval.

The effect of imputation

Another consideration is how to deal with unknown names. As mentioned in the Data section, the family names dataset provided by the census bureau covers 90% of the US population. The remaining 10%, as well as author names not represented in the census, generates 774,381 articles, or 18.75% of the dataset, for which the family name of the first authors has an unknown distribution over racial categories.

An intuitive solution would be to impute missing names with a default distribution based on the racial composition of the entire census. Table 3 shows the distribution among racial groups in the US census and in WoS (for first authors with family names included in the US census data). The Asian population is highly overrepresented among WoS authors, whereas Hispanic and Black authors are highly underrepresented, with respect to the total US population. Imputing with the census-wide racial distribution is, therefore, equivalent to skewing the distribution towards Hispanic and Black authors and underrepresenting Asian authors. Since the ground truth is contingent to the specific dataset in use, the natural imputation would instead be the mean of the population most representative of an individual. For example, in the case of a missing author name in the WoS, the racial distribution of that individual's discipline could be imputed. Our recommendation is, therefore, to first compute the aggregate distribution of racial categories with the dataset in which the inference is intended, and then use this aggregate distribution to impute in those family names missing from the census dataset. Statistically, this preserves the aggregate distribution on this dataset.

Table 3. Racial distribution in US census and WOS US Authors with known family names.

Racial group	*US census*	*US WoS*
White	66.1%	59.4%
Hispanic	16.5%	5.4%
Black	12.4%	7.2%
Asian	5.0%	24.5%

Conclusion

Race scholars (Emirbayer & Desmond, 2011) have advocated for a renewal of Bourdieu's (2001) call for reflexivity in science of science. We pursue this through empirical reflexivity: challenging the instrumentation used to collect and code data for large-scale race analysis. In this paper we manually validate and propose several approaches for name-based racial inference of US authors. We demonstrated the behaviour of the different methods on simulated data, across the population, and on authors in the WoS database. We showed the risks of underestimating highly minoritized groups (e.g., Black authors) in the data when using a threshold, and the overestimation of White authors introduced by given names when they are based on mortgage data. A similar result was identified by Cook (2014), in her attempt to infer race of patent data based on the US census: she found that the approach "significantly underpredicted matches to black inventors and overpredicted matches to white inventors" and concludes that the name-based inference approach was not suitable for historical analyses. From our analysis, we come away with three major lessons that are generally applicable to the use of name-based inference of race in the US, shown in table 4.

Inferring race based on name is an imperfect, but often necessary approach to studying inequities and prejudice in bibliometric data (e.g., Freeman & Huang, 2014), and in other areas where self-reported race is not provided. However, the lessons shown here demonstrate that care must be taken when making such inferences in order to avoid bias in our datasets and studies.

Table 4. General recommendations for implementing a name-based inference of race.

	Do's	*Don'ts*
Given Names	Use only family names from US census to avoid bias.	Do not use given names, except the underlying distribution of your dataset matches that of mortgage data.
Thresholding	Consider each person in your data as a distribution and adapt your summary statistics.	Do not use a threshold for categorical classification of each person, as this underrepresents Black population, due to the correlation between racial groups and name informativeness.
Imputation	Calculate first the aggregated distribution on your dataset, and use this for imputation of missing cases.	Do not use the census aggregate distribution for imputation, except your target population matches the US population.

It has been argued that science and technology serve as regressive factors in the economy, by reinforcing and exacerbating inequality (Bozeman, 2020). As Bozeman (2020) argued, "it is time to rethink the economic equation justifying government support for science not just in terms of why and how much, but also in terms of who." Studies of the scientific workforce that examine race are essential for identifying who is contributing to science and how those contributions change the portfolio of what is known. To do this at scale requires algorithmic approaches; however, using biased instruments to study bias often replicates the very inequities they hope to address.

In this study, we attempt to problematize the use of race from a methodological and variable operationalization perspective in the US context. However, any extension of this work across country lines will necessarily require tailoring to meet the unique contextual needs of the country or region in question. Ultimately, scientometric researchers utilizing race data are responsible for preserving the integrity of their inferences by situating their interpretations within the broader socio-historical context of the people, place, and publications under investigation. In this way, they can avoid preserving unequal systems of race stratification and instead contribute to the rigorous examination of race and science intersections toward a better understanding of the science of science as a discipline. As Zuberi (2001) remarked: "The racialization of data is an artifact of both the struggles to preserve and to destroy racial stratification."

Utrecht University Library, Utrecht University, Heidelberglaan 3, 3584 CX Utrecht (The Netherlands)

Abstract

Preprints have become an important part of the scholarly communication ecosystem. To be able to connect preprints to subsequent journal publications, and thereby have access to the full record of versions of a publication, the existence of reliable links between preprints and subsequent publications, available in an open infrastructure, is important. This paper reports on research in progress investigating, for a subset of COVID19-related preprints, authoritative links between preprints and published papers in Crossref metadata and on preprint servers themselves. It is shown that the coverage of links from preprints to published papers in Crossref metadata is often incomplete compared to links found on preprint servers themselves, underlining the potential for improvement in the update of metadata.

Introduction

In a growing number of scientific disciplines, preprints have become an important part of the way research results are communicated. As an example, over the last year, COVID19-related preprints have been shared on over 35 different preprint servers (Fraser and Kramer, 2020). Some of these are disciplinary preprint servers, most often on a non-profit basis (e.g. bioRxiv, medRxiv (both hosted by Cold Spring Harbor Laboratory), SocArXiv and PsyArXiv (both hosted on the Open Science Framework (OSF)). Other preprint servers are associated with legacy publishers, either directly linked to their submission workflow (e.g. ResearchSquare used by Springer Nature, and JMIR Preprints by JMIR) or also open to preprints independent of submission to the publisher's own journals (e.g. Preprints.org from MDPI, SSRN from Elsevier). Yet another example is ChemRxiv, a disciplinary preprint server backed by a number of scholarly societies including the American Chemical Society (ACS) and the Royal Society for Chemistry (RSC).

In order for preprints to form an integral part of the scholarly record, it is important to be able to link them to subsequent journal publications. This will enable access to the full record of versions of a publication (e.g. to track changes over time), irrespective of where each version is published. Many preprint servers (including all the examples mentioned above) use Crossref to obtain DOIs for their preprints, and consequently, register preprint metadata with Crossref. Crossref notifies preprint servers of potential matches with published articles. Crossref notifies preprint servers of potential matches with published articles. It requires preprint servers to verify the links and add them to the metadata record of the preprint. (Crossref, 2020). In addition, preprint servers also often add links to published papers on the landing pages of preprints.

Open availability of authoritative links from preprints to published papers in a centralized infrastructure (such as with Crossref) as open metadata, without restrictions on use and reuse, makes this information available for other systems to integrate and build upon, e.g. in discovery systems, for evaluation purposes and for transparent analysis on developments in scholarly communication. As such, they contribute to making research publications not only accessible and reusable, but also findable and interoperable (Waltman, 2020).

This research-in-progress investigates, for a subset of COVID19-related preprints, authoritative links between preprints and published papers in Crossref metadata and on preprint servers themselves. Furthermore, it uses these data to look at time between publishing of the preprint and publishing of the published paper for different preprint servers, as well as the destination (at the level of publisher) of published preprints, as these can both influence the observed links to published papers in preprint metadata.

Methods

Corpus of COVID-19 related preprints

As corpus for this investigation, COVID-19 related preprints with Crossref DOIs were used, as collected by Fraser and Kramer (2020). This corpus was collected by querying the Crossref REST API for all records with publication type 'posted content' and posted date between January 1, 2020 and April 11, 2021 indicated. Preprints were subsequently classified as being related to COVID-19 on the basis of keyword matches in their titles or abstracts (where available). The search string was defined as: coronavirus OR covid-19 OR sars-cov OR ncov-2019 OR 2019-ncov OR hcov-19 OR sars-2. Preprints were deduplication within preprint servers (keeping only the earliest posted version) but not between different preprint servers.

Links between preprints and published papers in Crossref

For all COVID-19 related preprints in the corpus defined above, information was collected on links to published papers, by querying the Crossref REST API for all DOIs and retrieving the information in the metadata field 'metadata field relation.is-preprint-of', which contains the DOI of the published paper. Subsequently, information on the published paper (journal, publisher and date of publication) was collected via a separate query on the Crossref REST API.

Links between preprints and published papers on bioRxiv and medRxiv

For COVID-19 related preprints in the corpus defined above that were published on bioRxiv and medRxiv, links to published papers were collected by querying the biorXiv API for all DOIs in our corpus of preprints, based on code used in Fraser et al., 2021. Subsequently, information on the published papers (journal, publisher and date of publication) was collected via a separate query on the Crossref REST API.

Data collection, analysis and data visualization

Following data collection, Data on links between preprints and published papers, time between preprint publication and journal publication and destination of published preprints were analyzed and visualized. Full R scripts for data collection, analysis and visualization are available on Github (Kramer, 2021). All data were collected on April 25, 2021.

Results

Links to published papers in preprint metadata.

Overall, the rate of COVID19-related preprints with links to published papers in Crossref metadata is only 11% (4146 of 36541 preprints with Crossref DOI). A number of preprint servers do not include links to published papers in their metadata on Crossref, including SRRN (n=5862 COVID19-related preprints in this dataset), Authorea (n=1356), and Scielo Preprints (n=312).

Among preprint servers that do include links to published papers in their metadata, the proportion of preprints linked to published papers, ranges from 7.7% (for OSF) to 51.3% (for JMIR) (Figures 1,2).

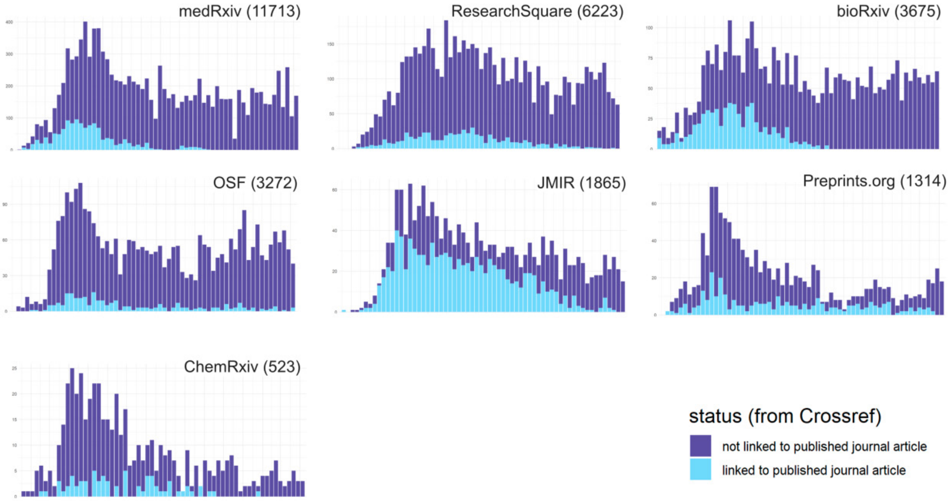

Figure 1. COVID-19 related preprints per week (January 2020-April 2021) with and without links to published papers in Crossref metadata.

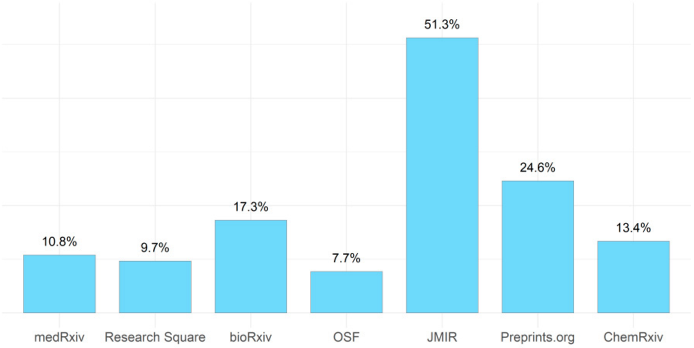

Figure 2. Percentage of COVID-19 related preprints (January 2020-April 2021) with links to published papers in Crossref metadata.

Time to publication

For preprints in this sample with a link to a subsequent journal article, the average time to publication (measured as the difference between the posted date of the first version of the preprint and the publication date of the subsequent journal article in Crossref metadata) is 97 days (close to 3 months). There is no clear difference between preprint servers in time to publication - preprint servers with a relatively high proportion of preprints with a link to a published paper (esp. JMIR) do no have a shorter average time to publication (Figure 3). OSF shows the largest spread in time to publication, which could be due to the variety of preprint servers using the OSF platform, with corresponding differences in publication cultures including (timing of) preprint sharing. Time to publication can also be negative, reflecting cases where the preprint is shared after publication of the journal article.

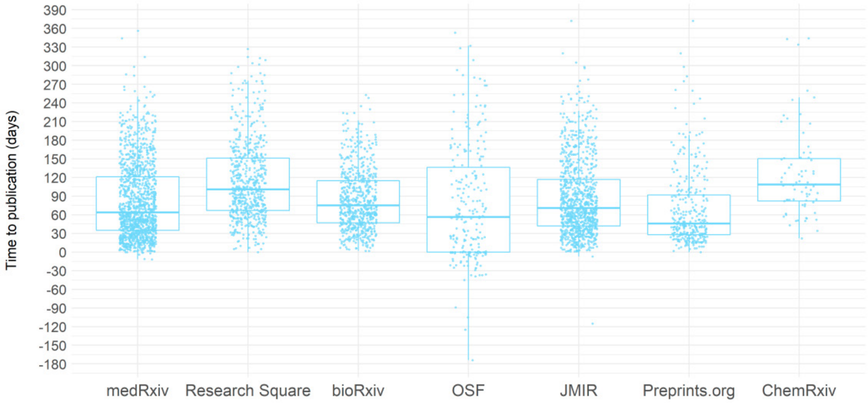

Figure 3. Distribution of time to publication (in days) for COVID-19 related preprints with links to published papers in Crossref metadata, for different preprint servers.

Links to published papers on bioRxiv and medRxiv

Both bioRxiv and medRxiv have more extensive coverage of published articles on their platform itself than recorded in their preprints' metadata: 28.7% vs. 10.5% for medRxiv and 32.7% vs. 17.3% for bioRxiv, for COVID19-related preprints in this sample (Figures 4, 5). NB. There were no cases of preprints with only a link to a published paper in the metadata, but not on the preprint platform.

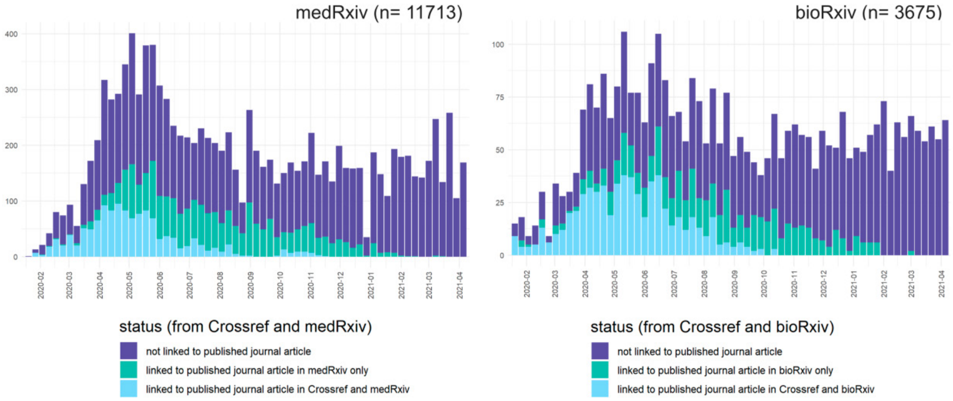

Figure 4. COVID-19 related preprints per week (January 2020-April 2021) on medRxiv and bioRxiv with links to published papers in Crossref metadata, on the preprint platform only, or neither

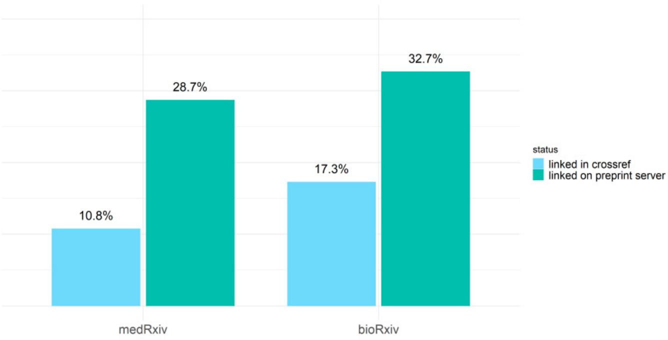

Figure 5. Percentage of COVID-19 related preprints (January 2020-April 2021) on medRxiv and bioRxiv with links to published papers in Crossref metadata or on the preprint platform.

Destination of published preprints

An alluvial plot was made showing the destination of all preprints with links to a published paper in their metadata. As expected, preprints from publisher-associated preprint servers JMIR and ResearchSquare predominantly are published in journals from JMIR and SpringerNature, respectively. However, only a subset of preprints on Preprints.org with a link to a subsequent paper get published in MDPI-journals, with over half being published in journals from other publishers.

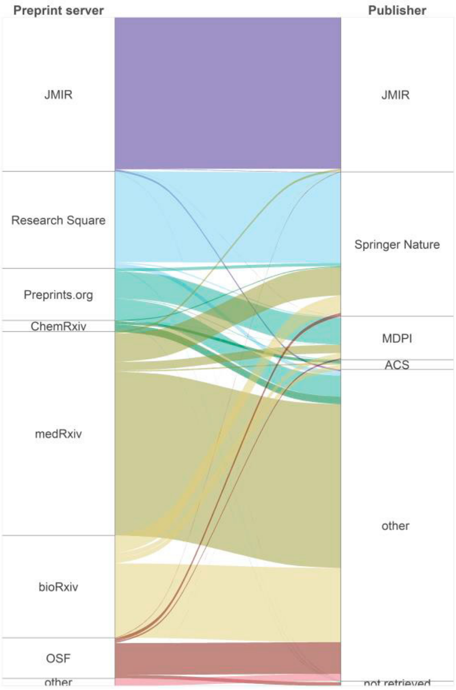

Figure 6. Destination of COVID-19 related preprints (January 2020-April 2021) with links to published papers in Crossref metadata.

Discussion

Coverage of links to published articles in preprint metadata in Crossref is expected to be incomplete. Not all preprint servers include such links in their metadata, and those that do might do so with a time delay and matches might be missed. Among preprint servers that do include links to published papers in their metadata, differences in the proportion of preprints linked to published papers, could reflect both technical workflows (e.g. linking might be easier/quicker when preprint server and journals are from the same publisher) and publication practices (e.g. selectivity of journals, speed of peer review processes, decisions on when to post a preprint).

There appears to be no clear difference between preprint servers in time to publication - preprint servers with a relatively high proportion of preprints with a link to a published paper do not have a shorter average time to publication. It might also be expected that linking preprints and published papers might be easier/quicker when preprint server and journals are associated with the same publisher, and indeed, JMIR, and to a lesser extent Preprints.org and ResearchSquare, have the highest proportion of preprints linked to published papers in the sample studied here.

Both bioRxiv and medRxiv have more extensive coverage of published articles on their platform itself than recorded in their preprints' metadata. The delay in updating this information in metadata records points to the potential for more accurate and complete coverage of links to published papers in metadata of preprints.

Having authoritative links from preprints to published papers available as open metadata will benefit the scholarly communication system. It will also be interesting to investigate the potential of additional similarity-based matching of preprints to published papers (see e.g. Lachapelle 2020, Cabanac et al., 2021), such as in EuropePMC (that links preprints and published papers), Unpaywall (that includes preprints as green open access versions of published papers) and Microsoft Academic (that groups detected versions of a paper in a 'paper family').

Do impact-factor journals make blacklisted journals visible? A systematic citation study

Abstract

Predatory publishing has recently become the most popular and controversial subject in academia. The main reason is the efforts of policymakers to draw a line between predatory and legitimate publishing. While the journals included in the citation indexes are accepted as 'legitimate' by policymakers, the journals in two lists (Beall's and Cabell's), one of which has not been updated for years, are considered blacklisted. Our main aim in this study is to reveal the contribution of the journals accepted as legitimate by policymakers to the visibility of predatory journals. The research in progress presents preliminary findings regarding the first stage of a two-part study. In the first stage, the contribution of impact-factor journals to the visibility of predatory journals will be revealed, and in the second, citations will be examined in terms of their contents. In this study, the indexes (JCR, ESCI or A&HCI) and impact factors of the citing journals are presented. According to the preliminary results of the study, the results confirm the necessity of citation content analysis.

Introduction

Predatory publishing is one of the most discussed topics regarding journal publishing in academia, which crosses over narrow fields of bibliometrics, scientometrics and academic-publishing studies (Frandsen, 2017; Xia et al., 2015). This topic related to publishing in so-called questionable or low-quality journals attracts much attention not only in academia but also outside it (Bohannon, 2013; Sorokowski et al., 2017). Predatory journals, accused of damaging science and diminishing the quality of scholarly communication and trust in science, are trying to be classified and listed. In recent years, the most famous attempt to list predatory journals was initiated by Jeffrey Beall, whose list (henceforth: Beall's list) gained attention from scientists and the media (Krawczyk & Kulczycki, 2020). The second well-known approach is done by the company Cabell's International (henceforth: Cabell's list), which not only lists predatory journals but also offers another product listing 'reputable' journals. Thus, journals listed on Beall's or Cabell's lists are called in this study blacklisted journals in contrast to whitelisted journals (listed for instance in reputable international indexes like Scopus or Web of Science Core Collection).

This study is the first extensive study looking at citations from Web-of-Science-indexed journals to papers published in blacklisted (or predatory) journals. Demir (2018) pointed out the big difference between the largest citation databases: Scopus indexes 53 predatory journals from Beall's lists, but Web of Science indexes only three such journals, and Somoza-Fernández et al. (2016) reported that this difference is small but still visible. This could also suggest a difference in citations to predatory journals in these databases, but previous attempts at analysing such citations were based mostly on Google Scholar data (due to an easier data-acquisition procedure) or Scopus.

In this paper, we will provide a systematic-citation study focussing on journals covered by the WoS products and on citers in terms of their country affiliation. The study aim is two-fold: The first is to analyse the visibility of blacklisted journals, and the second is to understand citation contexts. This paper is the first paper of a bigger endeavour aiming to investigate how papers published in blacklisted journals from the field of social sciences are cited by papers published by journals indexed in the Web of Science Core Collection. This paper will be followed by an upcoming study on the content-based analysis of citations of the blacklisted papers to evaluate the citations in terms of their content (meaning, purpose, shape, array). This is the key reason why we focus on social-sciences journals here: evaluating the content of citations will require expertise in the field (Cano, 1989).

Data and Methods

We have used two blacklists: Beall's and Cabell's lists. Moreover, we have collected journals' ISSNs from their websites and used the ISSN Portal to find variants of journal titles and ISSNs as well as to provide data of the country of publishing. The data on citations of papers published in selected journals were obtained from the Web of Science Core Collection (WoS) using the Cited Reference Search. We focussed on three main WOS products: Journal Citation Reports (JCR) based on the Science Citation Index Expanded and the Social Sciences Citation Index, the Arts and Humanities Citation Index (A&HCI) and the Emerging Sources Citation Index (ESCI). We downloaded PDF files of either paper from blacklisted journals and WoS-indexed journals to collect and verify the country affiliations of the authors. Using the blacklisted journal websites, we collected the data on the number of papers published by each journal.

We have decided to include in the analysis only active journals that have fulfilled the set of criteria: they published at least one paper in each year of the 2012–2018 period, their websites were active at the moment of the start of this study (May 2019), were not indexed in WoS even only for one year in at least one of three selected WoS products during the years 2012–2018, and were classified (on expert-scope decisions of the authors of this study) as social-sciences journals according to their titles and aims and scopes published on journals' websites. In the final sample, we have 74 unique blacklisted journals (37 indexed in Beall's and 37 indexed in Cabell's). Ten of those journals are indexed on both lists.

We have prepared two datasets to analyse citations. The first one consists of the bibliographic data and PDF files of the papers published in the years 2012–2018 in the social-sciences blacklisted journals included in this study and were cited by journals indexed in WoS (henceforth: cited papers). The other dataset consists of data on the papers (i.e., all journal publication types) published in journals indexed in WoS in the years 2012–2019 (henceforth: citing papers) that cited papers from the first dataset. The articles from 9 of 74 journals were not cited by articles from WoS-indexed journals, or their PDF files were missing on journals' websites. This allows us to analyse 3,234 unique cited papers from 65 blacklisted journals and 5,964 unique citing papers (6,750 citations of cited papers) from 2,338 WoS journals. The list of analysed blacklisted journals is in Appendix.

Results

Share of cited papers from blacklisted journals

Sixty-five analysed journals published 25,146 papers between 2012 and 2018, of which 3,234 (13%) were cited by WoS journals.

Figure 1 shows the highest share, i.e., 19%, in 2012 and 2013. The mean number of papers published by a single journal in the analysed period is 53.5 (min=43, max=2,176). On average, 11% of papers published by a journal were cited by WoS journals. The highest shares were found for journals that published 1,748 and 259 papers. The shares are 36% (635 papers) and 35% (91 papers), respectively. In the analysed sample, 8,327 papers were published in journals listed in Beall's list (10.3% of them were cited) and 13,910 papers from journals indexed in Cabell's list (14.7% were cited). 5,587 papers were published by journals indexed in both Beall's and Cabell's lists.

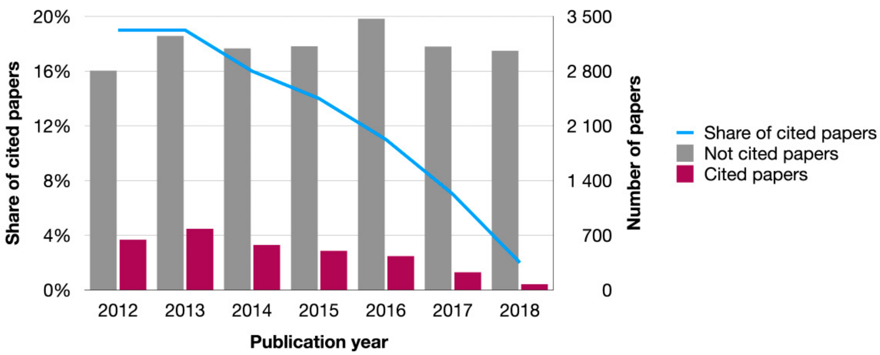

Figure 1. Share and Number of Cited Papers from Blacklisted Journals by WoS Journals

We checked whether 65 analysed journals were covered by Scopus, as this could potentially influence the share of citations. We found that five of 65 were or have been covered: one has been covered by the whole analysed period (24% of papers from this journal were cited), one removed from Scopus before the analysed period (23%), one covered and removed in the analysed period (36% papers), one covered in the last year of the analysed period (19%) and one covered before the analysed period and removed during the period (8%).

Web of Science journals citing blacklisted journals

We found that 2,338 unique WoS journals cited 3,234 blacklisted papers 6,750 times. The average number of citations per blacklisted journal from WoS journals is 2.88 (median=1, minimum=1, maximum=218). Half of the citations were from 261 journals. Eighty-nine of 2,338 journals cited papers from blacklisted journals at least 10 times, and four WoS journals cited over 100 blacklisted papers. In the analysed period, one WoS journal published 183 papers, which cited blacklisted papers from our sample 218 times (all except one published in one blacklisted journal). One of these blacklisted papers was cited 36 times by this WoS journal. We analysed in which WoS product (JCR, ESCI, A&HCI) a journal was indexed when a citing paper was published. We consider the publication year and whether a journal was included in a WoS product in the year in question. We found that 1,152 of 2,338 journals were indexed in ESCI, 35 in A&HCI and 1,047 in JCR. One-hundred and four journals that published 366 citing papers were neither in ESCI, A&HCI nor in JCR, which means that they were either in SCIE or in SSCI indexes but not yet JCR (e.g., waiting for calculation of their impact factor) or dropped from the indexes because of quality issues or manipulations such as citation stacking or excessive self-citation rates. Figure 2 shows how blacklisted journals were cited by WoS journals. Of the 6,750 citations, 2,502 (37%) were from JCR journals, 3,821 (56.6%) were from ESCI journals and 61 (0.9%) were from A&HCI journals.

Impact-factor journals citing blacklisted journals

The fact that a journal has a valid impact factor or is included in citation indexes is used by policymakers and managers to determine the level of that journal. We analysed the relationship between the impact-factor journals and their citations to blacklisted journals. To be able to make accurate statistical analyses, the impact factor of all journals cited in blacklisted journals were gathered with yearly changes. For example, if two articles in the same journal cited the blacklisted journals in 2018 and 2019, JCR 2017 and JCR 2018 were used. As a result, 1,600 impact factors for 1,047 IF journals were obtained.

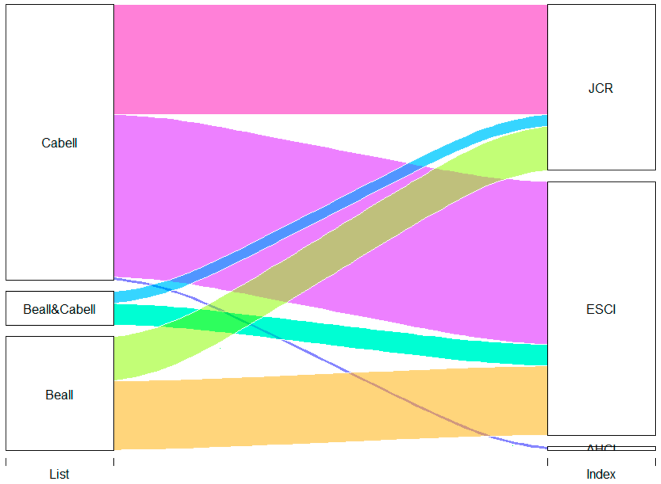

Figure 2. WoS Journals Citing Blacklisted Journals According to Blacklists

Before presenting the comparisons between impact factors and citations to blacklisted journals, it is worth mentioning those journals dropped from citation indexes. Twenty impact-factor journals that cited blacklisted journals 125 times were dropped from JCR or WoS for different reasons. Fifteen of them were dropped from the index without listing any unethical concerns. This means that coverage of the journals did not meet the WoS selection criteria (Clarivate, 2018). *Scientific World Journal* was suppressed from JCR based on citation stacking and four journals (*Business Ethics: A European Review*, *Environmental Engineering and Management Journal, Eurasia Journal of Mathematics Science and Technology Education* and *Industria Textila*) were dropped for their excessive self-citation rates. These five journals cited blacklisted journals 39 times. Furthermore, although they were not indexed in JCR and did not have an impact factor, 15 journals were excluded from ESCI after being indexed for a couple of years in ESCI. All these findings can be commented as questionable journals in WoS cited blacklisted journals; however, statistical tests did not confirm this comment.

The Spearman's Rho correlation coefficient shows that the correlation between journal impact factors and the number of citations to blacklisted journals is very low, at a 99% confidence level (r=0.090, p<0.001). Also, according to the Kruskal-Wallis test results, the differences between journal impact-factor quartiles and the number of citations to blacklisted journals were not significant (χ^2= 7.785, df=3, p=0.051). However, the Mann Whitney U test revealed that the only differences were found between Q1 and Q4 journals' number of citations to blacklisted journals (U=72661.500, Z=-2.648, p=0.008).

The impact-factor range of blacklisted journal citers is from 0 to 27.604 (mean=1.689, median=1.378, SD=1.471, 25%=0.745, 75%=2.252), while the minimum impact factor of the whole JCR between 2011 and 2018 is 0 and the maximum is 244.585 (mean=2.072, median=1.373, SD=3.310, 25%=0.704, 75%=2.462).

Eighty percent of the journals in JCR cited blacklisted journals only one time, and there is a significant difference between the impact factors of one-time citers and the others (U=174977.000, Z=-3.668, p<0.001). However, the surprising result is that the average impact factor of journals that cited blacklisted journals more than once is 1.896 (median=1.634), and this is higher than that of one-time citers (mean=1.639, median=1.318).

Table 1 shows the main features of 10 impact-factor journals that cited blacklisted journals more than 20 times.

Table 1. Ten Impact-Factor Journals that Cited Blacklisted Journals more than 20 Times

Journal name	*IF 2019*	*N of articles citing blacklisted journals*	*N of citations to blacklisted journals*	*Publisher country*	*Journal self-citation rate of the journal*
ACTA MEDICA MEDITERR	0.249	25	126	Italy	63.7%
SUSTAINABILITY-BASEL	2.576	56	56	Switzerland	38.9%
SAGE OPEN	0.715	16	45	USA	2.8%
SYSTEM	1.979	31	34	England	12.4%
FRONT PSYCHOL	2.067	24	26	Switzerland	15.5%
EGIT BILIM	0.493	19	25	Turkey	14.0%
PLOS ONE	2.740	25	25	USA	5.1%
COMPUT EDUC	5.296	21	22	England	11.6%
INT J BANK MARK	2.800	11	21	England	33.7%
COMPUT HUM BEHAV	5.003	20	21	USA	11.4%

All the test results on impact-factor journals prove that it is impossible to evaluate the blacklisted journals by looking at the impact factors or impact-factor percentiles of the journals because no pattern is identified. The impact factor is neither a descriptor of the quality of a paper nor the quality of citation. Therefore, it reveals the importance of content-based analysis in understanding the purpose of citations to blacklisted journals.

Discussion and Conclusions

The main aim of our study is to reveal the contributions of citation indexes, which are accepted as the authority in research evaluations, to the visibility of blacklisted journals, whose scientific levels are always considered quite low in academia. According to the results, 13% of the blacklisted articles were cited by Web of Science journals and 37% of these citations came from the impact-factor journals. If we accept being cited from authority-citation indexes as a tool for visibility, it is obvious that the indexes help the blacklisted journals to be visible regardless of the name of the index, whether SSCI, A&HCI or ESCI. The question to be asked at this point is: Do citations to the blacklisted journals make citation indexes questionable, or do these citations require a closer look at articles published in blacklisted journals? It is easy to accept all the papers published in blacklisted or questionable journals as low-quality, but without answering the question, it is difficult to draw a boundary for the definition between high and low quality. The findings show that there are no significant differences between the impact factors and the number of citations to the blacklisted journals. All the statistical tests conducted using journal-level statistics in our study confirm the emerging need to analyse the citations to blacklisted journals at the article level.

This is the first study in which a large-scale analysis of citations to predatory journals is conducted using WoS. When compared to the different results present in the citation studies based on Scopus, it is difficult to assess differences in terms of citing predatory journals in these two databases. However, taking into account that only 13% of articles in our study are cited, we can be sure that citations to the predatory journal are much more frequent in Google Scholar because it was reported there that 43% of articles were cited (Björk et al., 2020). Since we did not assess the quality of cited papers published in blacklisted journals, there are two possible interpretations of the main result of our study: 1) up to 13% of worthless articles in predatory journals can still leak to the mainstream literature legitimised by WoS, and 2) up to 13% of papers published in blacklisted journals are somehow important for developing scholarly legitimate discussion in social science. Unlike Oermann et al. (2020), we are not so sure that the important conclusion of the studies on predatory journals is to stop citing them completely. We prefer to leave the question raised by the result of our study open.

Our results indicate that there is no connection between the value of JIF of a given journal and this journal's citations to predatory journals. Although the number of such citations is relatively small, it could be another argument against treating JIF as a measure of journals' quality.

Abstract

The academic funding system has been under criticism for many years. While there are some on-going experiments trying to improve the system, there isn't any clear conclusion or guideline. On the other hand, modeling is a cost-effective way to facilitate the discussion. In this paper, we present a construction of analytical and simulation models to study the relation between the amount of funding and the efficiency of the funding system. In many of the settings, we show that there could exist some optimal amounts of funding to maximize the efficiency. The results are useful to reflect on the funding system in the real world.

Introduction

Issues in the academic funding system are attracting a lot of attention in the recent years. As an essential part of academia, the funding system is one of the major factors contributing to over-competitiveness in academia (Carson et al., 2013). Though a certain level of competitions may improve the resource allocation process, over-competitiveness may do more harm than good. Reports claim that scholars are pressured to seek out external funding, or even to change their focus of research to increase their chance of funding success (Roberts, 2007). As a result, rather than doing actual research, researchers may dedicate a large amount of effort to writing funding applications.

Several proposals were made to address this problem in the funding system. A well-known example is the introduction of a lottery for awarding funding (Fang & Casadevall, 2016. The Health Research Council of New Zealand has run an experiment on implementing a lottery system (Adam,2019). While some people are positive about the approach, some researchers oppose such an allocation method. Most researchers who applied to a funding program with a lottery element reported that the lottery did not decrease their preparation time (Liu et al., 2020). These experiments are useful to test different possibilities for implementing alternative funding allocation modes. However, running experiments is quite expensive and time-consuming, limiting the number of alternatives that are explored. In contrast, modeling and simulations provide a low-cost and flexible methodology for exploring alternatives. Some earlier studies have used analytical models (Gross & Bergstrom, 2019) or agent-based models (Avin, 2015; Geard & Noble, 2010) to model different aspects of the academic funding system.

We are interested in better understanding the efficiency of the funding system. In particular, our central question is how the efficiency changes with the amount of funding. To attempt to answer this question, we develop and present several analytical models. We provide analytical results, but for more complex cases we provide results based on extensive simulations. We here construct models of the funding system, starting from the simplest case and gradually adding more realistic elements. Our results suggest that under some conditions increasing the amount of funding may decrease the efficiency by increasing the competition too much.

Although our models only capture a small portion of the possible dynamics, having a systematic construction may improve our understanding of the results. Additionally, our approach may enable us to relate our models to previous studies and study the differences. Finally, it may facilitate extending and modifying the models to study other closely related problems.

Models

We model the funding system in a utility-based framework. Scholars make their decision on whether they are going to apply for the funding, or how much time they are going to spend for the application which determines the qualities of their proposals. They receive a certain payoff based on whether their grant application will be funded or not. We will initially start from the simplest case focusing on an isolated scholar. We then gradually build up the model by adding other scholars and interaction between scholars into the model.

Isolated scholar

Suppose there is one scholar, named scholar i. Following Gross & Bergstrom (2019), we assume that scholar i has a certain quality q_i and can submit a proposal with strength s_i. The cost that it takes a scholar of quality q_i to submit a proposal with strength s_i is denoted by $c(q_i, s_i)$. The application of scholar i with a strength s_i is funded with probability $a(s_i)$. If the application is funded, he receives a payoff $y(q_i, s_i)$, the payoff depends on the proposal strength s_i since a good proposal may improve the actual research. If the application is not funded, he receives no payoff.

The payoff $y(q_i, s_i)$ can be interpreted as a combination of funds, prestige, career position, et cetera, that may result from receiving funding. The cost $c(q_i, s_i)$ can be interpreted as the time spent into preparing the application. If scholar i would not prepare a grant application he may do research instead, which could be interpreted as also providing a certain payoff to scholar i. Such opportunity costs can be considered to be part of the cost of preparing a grant application, and we assume this is included in the cost function $c(q_i, s_i)$.

The expected payoff of scholar i applying for funding is

$$a(s_i)y(q_i, s_i) - c(q_i, s_i).$$

To simplify the problem, we assume that the probability that the funding application is funded is dominated by a specific polynomial term,

$$a(s_i) = a_0 s_i^k,$$

where $a_0 > 0$ is some constant such that $a(s_i) \leq 1$ and k can be interpreted as the accuracy of the funding allocation process with respect to the proposal strength. The higher k, the larger the difference between the success probability of high-quality scholars and that of low-quality scholars.

Similarly, for the cost of writing the grant application, we may assume that

$$c(q_i, s_i) = c_0 s_i^{l_s} q_i^{l_q},$$

where c_0 is again a normalizing constant and l_s and l_q represent how costs scale with strength and quality.

Finally, we assume that the payoff from a successful application is simply proportional to the scholar's quality q_i

$$y(q_i, s_i) = y_0 q_i,$$

where y_0 can be interpreted as an abstract representation of the amount of funding.

Under these simplifying assumptions the expected payoff of scholar i is

$$E_{single} = a_0 s_i^k y_0 q_i - c_0 s_i^{l_s} q_i^{l_q}.$$

The astute reader may observe that a_0 and y_0 are degenerate in the model. We retain them here separately to clarify the role of each variable.

To maximize the expected payoff, scholar i would prepare a proposal with a strength s_i such that

$$\frac{d(a(s_i)y(q_i, s_i) - c(q_i, s_i))}{ds_i} = 0,$$

which implies

$$s_i = \left(\frac{c_0 l_s q_i^{l_q - 1}}{a_0 y_0 k}\right)^{\frac{1}{k - l_s}}.$$

The optimal proposal strength s_i is proportional to $q_i^{\frac{l_q - 1}{k - l_s}}$ Fig. 1 (left) visualizes the optimal proposal strength as a function of scholar's quality under different sets of parameters.

We are interested in studying the efficiency of the funding system. There are various possible definitions of efficiency. Gross and Bergstrom (2019) define efficiency as the ratio of the expected gain and the expected cost. Here we use an alternative definition of efficiency, since it is possible to have zero expected cost in some models and the efficiency is not well normalized when the cost expected cost is close to zero.

We propose the following definition of efficiency:

- Perfect allocation configuration: only scholars with the highest payoff apply for the funding, see Fig. 1 for an example.
- Efficiency: ratio of the expected payoff of the system and the payoff from the perfect allocation configuration.

Our definition of efficiency is meaningful only for models with more than one scholar, so we do not calculate it for the isolated scholar model. On the other hand, if we assume there is a distribution of the scholars, the efficiency can be computed, see (Lai, 2021) for the solution.

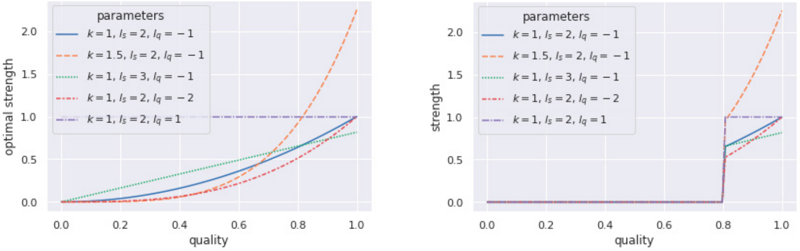

Figure 1. Isolated scholar model with parameters $a_0 = 1$, $y_0 = 2$, $c_0 = 1$, (left) optimal proposal strength versus scholar's quality, (right) the perfect allocation configuration where only some high-quality scholars submit their proposals

Two scholars, discrete choice

In reality, scholars do not apply for funding in isolation. Rather, multiple scholars typically have to decide simultaneously to apply for funding. If more scholars apply, this typically decreases the overall chances for an individual scholar to receive funding. We now add one additional scholar to the model. Although in reality there will be more than two scholars applying for funding, limiting it to two scholars still enables us to obtain some analytical understanding. At the same time, this simple model allows us to understand how interaction between two scholars affects the efficiency of the system.

The probability of receiving funding depends on the number of applicants and their proposal strength. In the model of an isolated scholar, we derived an expression for the optimal proposal strength. However, in the two-scholar model, there are two proposal strengths involved, leading to a non-linear differential equation system which is not easy to solve. For simplicity and analytical tractability, we therefore assume that scholars choose between two options: applying for funding or not. In case they do apply for funding, we assume the cost of applying is proportional to their quality, i.e., $s_i = q_i$. This is motivated by the fact that the optimal proposal strength increases with scholar's quality in the isolated scholar model (see Fig. 1). Though the relation is not exactly linear in the isolated scholar model, $s_i = q_i$ can be viewed as an approximation to the case where the scholars follow the suggestion from the isolated scholar model. In case they do not apply for funding, we may assume that no costs are incurred. This can be achieved by a proposal strength $s_i = 0$. In short, scholars will choose between $s_i = 0$ and $s_i = q_i$. The setting reduces the system into a simple game theoretical system.

Consider a model of 2 scholars, where for each scholar $i = 1{,}2$

$$a(s_i) = a_0(s_1, s_2)s_i^k,$$
$$y(q_i, s_i) = y_0 q_i,$$
$$c(q_i, s_i) = c_0 s_i^{l_s} q_i^{l_q}.$$

Suppose there is only one grant available, for which the two scholars compete. Then if at least one scholar applies the probability to be funded is $a(s_i) = \frac{s_i^k}{s_1^k + s_2^k}$. Clearly, if only one scholar applies, that scholar is guaranteed to be funded. The model can be expressed as a normal-form game, where scholar 1 is the row player, and scholar 2 is the column player.

The payoff matrices for scholar 1 and 2 are given by

$$\begin{array}{cc} & \begin{array}{cc} N & A \end{array} \\ \begin{array}{c} N \\ A \end{array} & \begin{pmatrix} 0 & 0 \\ y_0 q_1 - c_0 q_1^l & \frac{q_1^k}{q_1^k + q_2^k} y_0 q_1 - c_0 q_1^l \end{pmatrix} \end{array}, \quad \begin{array}{cc} & \begin{array}{cc} N & A \end{array} \\ \begin{array}{c} N \\ A \end{array} & \begin{pmatrix} 0 & y_0 q_2 - c_0 q_2^l \\ 0 & \frac{q_2^k}{q_1^k + q_2^k} y_0 q_2 - c_0 q_2^l \end{pmatrix} \end{array}.$$

where $l = l_s + l_q$. A positive l can be interpreted as scholars spend their time on something to receive a payoff that is proportional to their quality, while a negative l can be interpreted as higher quality scholars less time or less effort to prepare a grant proposal.

The first row corresponds to the choice of scholar 1 to *not* apply (N), while the second row corresponds to the choice of scholar 1 to apply (A). The first column corresponds to the choice of scholar 2 to *not* apply (N), while the second column corresponds to the choice of scholar 2 to *not* apply (A).

When a scholar applies, we say he follows strategy A, while if he does not apply, he follows strategy N.

Strategy N is a dominant strategy for scholar 1 if

$$y_0 q_1 \leq c_0 q_1^l,$$

while strategy A is a dominant strategy for scholar 1 if

$$\frac{q_1^k}{q_1^k + q_2^k} y_0 \geq c_0 q_1^{l-1}.$$

Similarly, strategy N is a dominant strategy for scholar 2 if

$$y_0 q_1 \leq c_0 q_1^l,$$

while strategy A is a dominant strategy for scholar 2 if

$$\frac{q_2^k}{q_1^k + q_2^k} y_0 \geq c_0 q_2^{l-1}.$$

If no strategy is dominant, the system is characterized by a mixed Nash equilibrium with 0 payoff.

At every Nash equilibrium, whether it is a pure or mixed equilibrium, we can compute a payoff $E_{2-scholar}$. If at least one scholar applies, we can define the expected payoff from the perfect funding allocation configuration as

$$E_{perfect2-scholar} = max\left(y_0 q_1 - c_0 q_1^l, y_0 q_2 - c_0 q_2^l\right),$$

where only the scholar with the highest payoff applies for the funding.

We then define the efficiency as

$$\epsilon_{2-scholar} = \frac{E_{2-scholar}}{E_{perfect2-scholar}}.$$

If the dominant strategy for both scholars is to not apply, we define the efficiency to be 0.

n scholars, discrete choice, unlimited number of grant per scholar

To extend the two-scholars model to a n scholar model, suppose there are n scholar and m grants available. We here allow scholar i to receive all m grants to produce a simple model to compare with the two-scholars model. Similar to the previous section, we assume that scholar i can only choose between $s_i = 0$ or $s_i = q_i$. Let Q_A be the set of all qualities of scholars who choose to apply, i.e., $Q_A = \{i \mid s_i = q_i\}$. We have

$$a(s_i) = 0 \text{ or } \frac{m s_i^k}{\sum_{j \in Q_A} \left(s_j^k\right)},$$
$$y(q_i, s_i) = y_0 q_i,$$
$$c(q_i, s_i) = 0 \text{ or } c_0 q_i^l,$$

note that $a(s_i)$ here can be interpreted as the expected number of grants received, rather than the probability of receiving a grant.

Unfortunately, analytical results are difficult to obtain for this model, and we therefore rely on the polynomial weight algorithm (Roughgarden, 2010) to try to find equilibria. Though learning algorithms may not be able to find the Nash equilibrium (Daskalakis et al., 2010), the equilibrium found by the algorithm may still be realistic if we relate the models with the real world.

After simulating the strategy choices and payoffs of individual scholars, the expected total payoff $E_{n-scholar,unlimitedgrant}$ can be obtained by adding payoffs from all scholars and then take an average over a few steps. As before, the perfect allocation configuration is that only scholars with the highest quality q_h apply for the funding while others do not. The perfect allocation payoff is then

$$E_{perfectn-scholar,unlimitedgrant} = m y_0 q_h - c_0 q_h^l.$$

We again define efficiency as the ratio between the actual expected total payoff and the perfect allocation payoff, which we take to be zero if no scholars apply at all.

n scholars, discrete choice, one grant per scholar

In the previous model, we allow scholars to accumulate an unlimited number of grants. Although this model has a relatively straightforward definition of the probability to be funded (which is actually an expectation), most funding schemes only allocate a single grant to a scholar. We assume there are m grants available, where $m \leq n$, and each scholar can only get one grant at most. We again assume a discrete choice, and scholar i can choose $s_i = 0$ or $s_i = q_i$. We then obtain

$$\begin{aligned} a(s_i) &= 0 \text{ or } A(q_j \in Q_A, k), \\ y(q_i, s_i) &= y_0 q_i, \\ c(q_i, s_i) &= 0 \text{ or } c_0 q_i^l, \end{aligned}$$

where Q_A is the set of all qualities of scholars who choose to apply as before.

We again need to solve the mixed strategies of this model computationally. Since the success probability $A\left(q_j \in Q_a, k\right)$ of the one grant per scholar model is related to the weighted random sampling with a reservoir problem (Efraimidis & Spirakis, 2006), it is not efficient to compute the probability and the payoffs. Therefore, we use the partial information model (Roughgarden, 2010) to simulate the efficiency in a more agent-based modeling flavour.

The expected total payoff $E_{n-scholar,1grant}$ is computed by averaging the sum of individual payoffs for a few time steps. Let Q_h be the set of m highest scholars' qualities. The perfect allocation payoff is then

$$E_{\text{perfect n-scholar, 1 grant}} = \sum_{q_j \in Q_h} \left(y_0 q_j - c_0 q_j^l\right).$$

We again define efficiency as the ratio of the two.

Results

We have constructed three models:

- a two-scholar model,
- a n-scholar unlimited grant, and
- a n-scholar one grant per scholar model.

We now analyse how the efficiency in these three different models depend on the total amount of funding. The total amount of funding is represented by the variable my_0 ($m = 1$ for the two-scholar model), and the efficiency is defined as the ratio of the expected total payoff and the payoff from the perfect allocation configuration. For each model, we present results for some specific sets of parameters. If we have any analytical results, we will simply present those. Alternatively, if we are unable to obtain analytical results, we will present numerical approximations from simulations. In that case, we always perform 10 runs of the simulations and present averages and deviations thereof.

Efficiency in the two-scholars model

There are 6 free variables in the two-scholars model. Without loss of generality, we assume that $q_2 > q_1$. We choose $q_1 = 0.3$, $q_2 = 0.7$, and $c_0 = 1$. We set $k = 1$, so that the probability of being funded is proportional to a scholar's quality. We set $l = 1$, so that the cost of applying is proportional to a scholar's quality.

Since the payoffs received by scholar 1 and 2, if both of them apply for the funding, are closely related to their dominant strategies A, we plot Fig. 2 to show how those payoffs vary with the amount of funding y_0, if the payoff is greater than 0, then always applying is a dominant strategy for the scholar.

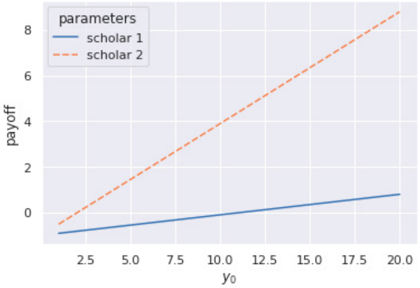

Figure 2. The payoffs scholar 1 and 2 receive as a function of the amount of funding y_0, assuming that both scholar 1 and 2 apply for the funding.

Multiple Nash equilibria may exist in a 2-player game, where they may have different efficiencies. We use the two equilibria with the highest and lowest efficiency to bound the efficiency in this model. Fig. 3 plots the efficiency of those equilibria as a function of the amount of funding y_0. It is interesting to note that we can discern three distinct phases, a feature that does not exist in the single scholar model with a distribution (Lai, 2021). The first phase corresponds to a "no dominant strategy" region, where mixed Nash equilibrium with 0 payoff is allowed. Increasing the funding y_0 we transition towards the second phase, where the dominant strategy for scholar 2 is to always apply for funding, which forces scholar 1 to not apply for funding (because $q_2 > q_1$). This produces a 100% efficient configuration. As the amount of funding further increases, we transition towards the third phase, where applying for funding also becomes a dominant strategy for scholar 2, leading to a sudden drop in efficiency.

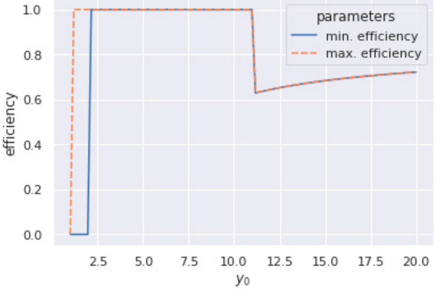

Figure 3. Maximum and minimum efficiency in the two-scholars model as a function of the amount of funding y_0.

The middle phase, which is most efficient, can be enlarged by increasing k or by decreasing l. Increasing k means that the higher quality scholar is more likely to receive funding if both scholars apply. We can interpret this as the accuracy of peer review, in the sense that peer review would be expected to be able to identify the higher quality scholar. In that case, the lower quality scholar requires an even larger funding amount y_0 in order to also apply (thereby entering the third phase), because the probability he is funded is lower with higher k. Increasing k therefore shifts the threshold between the second and third phase to higher funding amounts y_0. On the other hand, the higher quality scholar has a higher probability to get funded, so a smaller y_0 is needed to reach the dominant strategy A, thus the threshold between the first and second phase shifts to lower funding amount y_0.

Decreasing l means that the cost of applying becomes relatively lower for higher quality. In this case, the lower quality scholar requires an even larger funding amount y_0 in order to also apply (thereby entering the third phase), because the relative cost of applying is higher with lower l. Increasing l therefore shifts the threshold between the second and third phase to higher funding amounts y_0.
