Why H-index. This paper use H-index as the standards for highly influential scholars. Although there are certain problems in adopting H index, there are three reasons that support the adoption in this paper. Firstly, H index is more suitable for the summative evaluation of the whole academic career of a scholar. The method validation requires the tracking of a scholar for 20-30 years, which means the scholar should have reached the academic golden age of 45-55 at this time, hence H-index is a more appropriate index to measure his/her academic achievements. Secondly, some studies have shown that although the H-index standards of important scholars in different fields may vary, but H-index, generally speaking, is positively correlated with the academic level of researchers. Some scholars believe that those with H-indexes of 40 or even higher could be regarded as outstanding scientists, and those with H-indexes of 60 or even higher could be regarded as unique scholars (Meho Li, 2007). Therefore, it is reasonable to use H-index to reflect the relative situation of scholars in the academic golden period. Finally, the calculation of H-index is simple and comprehensible, facilitating its promotion and application.

Time periods. The choice of time T2 should consider the time period when the potential of the beginner may be best reflected. This paper selects two time periods to train the samples: the intervals between time T1 and time T2 are 5 and 10 years, and mapping these two time periods into the feature indicators respectively. Since H-index is more suitable to reflect scholars with a long academic history, the choice of time T3 should be able to reflect the real level of scholars more accurately. This paper uses the 30th year in a scholar's academic career as time T3 for two reasons: the 30th year of a researcher's academic career corresponds to his/her biological age of about 60, making it objective to use H-index to judge the level of scientific research achievements at this time; considering the integrity of data collection, the data in the early stage of database construction may have non-standard data format and missing data items, which is not conducive to analysis and modeling.

Prediction algorithm

This paper uses Pairwise ranking algorithm for supervised learning. Two of n beginners from the set of beginners A are combined into a group, i.e. sample is (X_1, X_2),

(X_1, X_3),...(X_i, X_j)...(X_n, X_{n-1}); and h(X_i- X_j) is prediction function of the ranking pair; X_i and X_j are eigenvalues of beginner $a_i$and a_j at time T1-T2; $y_i$and y_j are H-index of beginner $a_i$and $a_j$at time T3. The input of learning model is <X_i, X_j,sign(y_i- y_j)>, where $i \neq j$, $y_i \neq y_j$. sign(x) is a sign function, as shown in Equation 3.

$$\mathrm{sign}(y_i - y_j) = \begin{cases} 1 \quad if\ y_i > y_j, \\ \text{Larger probability of becoming a rising star for } a_i \text{ compared to} a_j \\ -1 \quad if\ y_i < y_j, \\ \text{Smaller probability of becoming a rising star for } a_i \text{ compared to } a_j \end{cases} \qquad \text{(Formula 3)}$$

The prediction target here is to enable h(X_i- X_j) to infinitely approximates sign(y_i- y_j). Therefore, the ranking issue is converted into a binary prediction issue.

Feature selection

The features here are classified into different groups, including author, publication, institution, and time increment. This paper uses 5-year and 10-year data, with feature indicator set R1 and R2 respectively, as shown in Appendix 1. For the publication here, periodical / meeting level proposed by subject matter experts is used to represent paper quality. For the institution, existing and recognized ranking of institutions is used as a basis of institutional grade.

Model testing

As a binary issue, the binary performance index is used for measurement. The final output of the model would be a list of ranking for rising stars. Consequently, ranking-type performance index can be used for measurement as below:

- *Accuracy, precision, recall rate & F1*

$$\text{Accurancy (Accurancy rate)} = \frac{TP + TN}{TP + FP + FN + TN} \qquad \text{(Formula 4)}$$

$$\text{Precision (Precision rate)} = \frac{TP}{TP + FP} \qquad \text{(Formula 5)}$$

$$\text{Recall (Recall rate)} = \frac{TP}{TP + FN} \qquad \text{(Formula 6)}$$

$$\text{F1} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \qquad \text{(Formula 7)}$$

(TP is the number of positive real values and prediction values; FP is the number of negative real values and positive prediction values; FN is the number of positive real values and negative prediction values; TN is the number of negative real values and prediction values.)

- *Hit Ratio (HR) of Top K ranking*

Among Top K ranking, HR is the probability of hitting prediction value among Top K.

$$\text{HR} = \frac{N\text{umber of Hits}}{N\text{umber of Sample}} \qquad \text{(Formula 8)}$$

Validation

Validation of indicator data. The RStarRank will eventually obtain the ranking list of the probability of beginners becoming rising stars. For the top beginners in the ranking sequence, three indicators H-index, total amount of papers and the number of citations after 30 years (in the later period of their academic career) are investigated. In the later stage of academic career, these indicators are important indicators of scholars' academic influence. Therefore, if the predicted ranking result is better, the indexes of scholars at the top of the predicted ranking sequence should also be higher 30 years later.

Verification of "future" academic achievements. Scholars in the later stages of their academic career can be verified by their academic achievements, including but not limited to the organizations they work for, the honors and the titles they have won.

Comparison of effectiveness of the methods. The existing rank-based methods with similar data size and computation cost to RStarRank are selected for comparison. This study intends to select PubRank method, as this method shares similar algorithm complexity with RStarRank, the calculation amount is also close to the complexity of the late RStarRank application, and the data used is similar to RStarRank method.

As it is the comparison of two ranking prediction results of academic beginners, the ranking comparison is carried out from two aspects. The first is to examine the H-index, total number of papers and the number of citations of academic beginners at the top of the ranking. The second is to compare the accuracy of the size of all the pairwise relation of the predicted ranking. Since predicted ranking results are obtained in both algorithms, the accuracy of the ranking is considered to be measured. The size of all pairwise relations in the ranking is used to represent the ranking, and it is compared with the pairwise size of the scholar's H-index 30 years later to calculate the accuracy. The calculation is shown in Formula 9.

$$\mathrm{HIT} = \frac{\delta(\mathrm{P}, \mathrm{P}')}{N * (N-1)} \qquad \text{(Formula 9)}$$

Experiment and results

This paper selects the computer science field to conduct an empirical analysis.

Data source and pre-processing

The dataset of Academic Social Networks (https://www.aminer.cn/data#Science-Knowledge-Graph) is used as literature data (Tang, Zhang, Yao, Li, Zhang& Su, 2008). For publication data, institutional data from CCF proposed Directory of CCF Recommended International Academic Conferences and Periodicals (2015, 4th edition) is used. ArnetMiner (https://www.aminer.cn/ranks/org) is used to rank the global scientific research institutions in the computer science field as basis of the index “institutional grade”. According to the ranking, if the top 1 institution is x among institutions of a scholar a_i, then its institutional reputation is y, as shown in Formula 10.

$$\mathrm{y} = \mathrm{f(x)} = \begin{cases} 1, & \text{x rank in } 001 - 200 \\ 2, & \text{x rank in } 201 - 400 \\ 3, & \text{x rank in } 401 - 600 \\ 4, & \text{x rank in } 601 - 800 \\ 5, & \text{x rank in after } 801 \\ 6, & \text{x did not enter the ranking} \end{cases} \qquad \text{(Formula 10)}$$

This paper selects the time from 1984 to 1988 (5 years) and from 1984 to 1993 (10 years) for extracting features of beginners. The extraction time for label information is set to 2014. The original label information y is H-index of beginners 30 years later, and label value of beginners (X_i, X_j) is sign(y_i- y_j), i.e. sign symbol of H-index difference between $X_i$and X_j. Pairwise ranking algorithm is pair prediction for beginners. Therefore, it is necessary to make pre-processing for eigenvalues of beginners. For beginners X_i and X_j, the input forming learning model is <X_i, X_j,sign(y_i- y_j)>. Here, a new group of features are obtained through subtracting eigenvalues of X_i and X_j, i.e. the new feature is X_{ij} and input of learning model is <X_{ij}, sign(y_i- y_j)>. $X_{ij} = (X_i^1 - X_j^1, X_i^2 - X_j^2, \ldots, X_i^m - X_j^m)$, where m is the number of features.

Empirical workflow

This paper uses two sets of feature data, i.e. those of 5 years and those of 10 years, to verify the effectiveness. These questions are to be answered: (1) Which machine learning algorithm is used? (2) Can 10-years data and 5-years data effectively identify rising stars (over 90%)? (3) Which features are of utmost importance for the identification? (4) How does the setting of different population proportions (k%) of rising stars affect the accuracy of the prediction model? (5) Can a few important features (even just H-index) be used to effectively solve the problem?

Experimental results

According to the requirements of machine learning algorithm in this study, i.e., the classification algorithm with supervised learning, we choose discriminant models, SVM (support vector machine) and XGboost, and generative model NBC (naive Bayesian). The results are shown in Table 2.

Table 2. XGboost, SVM and NBC algorithm performance measurement（10 years）

Model	*Accuracy*	*Precision*	*Recall*	*F1*	*Hit Ratio of Top K*			
					10%	*20%*	*30%*	*40%*
XGboost	0.9111	0.9112	0.9112	0.9111	0.78	0.89	0.76	0.91
SVM	0.6315	0.7039	0.6620	0.6202	0.33	0.65	0.77	0.83
NBC	0.7068	0.7377	0.7254	0.7054	0.66	0.83	0.88	0.83

The results show that the performance of XGboost is the best. XGboost is a kind of decision tree algorithm, which can score the importance of features. Table 3 shows the maximum performance of RStarRank training after adjusting main hyper-parameters.

Table 3. Performance measurement of RStarRank（5 years data/10 years data）

Model	*Accuracy*	*Precision*	*Recall*	*F1*	*Hit Ratio of Top K*			
					10%	*20%*	*30%*	*40%*
5-years data	0.8402	0.8404	0.8401	0.8401	0.70	0.77	0.73	0.89
10-years data	0.9111	0.9112	0.9112	0.9111	0.78	0.89	0.76	0.91

In terms of the performance indexes of the two models, training effect of the 10-year model is better than the 5-year model. The prediction accuracy can reach over 90% for the 10-year model. Therefore, this model can effectively predict rising stars. When ranking beginners, this model indicates a high HR for top 20% and 40% beginners, reaching over 90%. However, the prediction accuracy is 84% for the 5-year model and therefore it cannot perform effective prediction. Nevertheless, when ranking top 40% beginners, this model demonstrates an accuracy rate of about 90% HR.

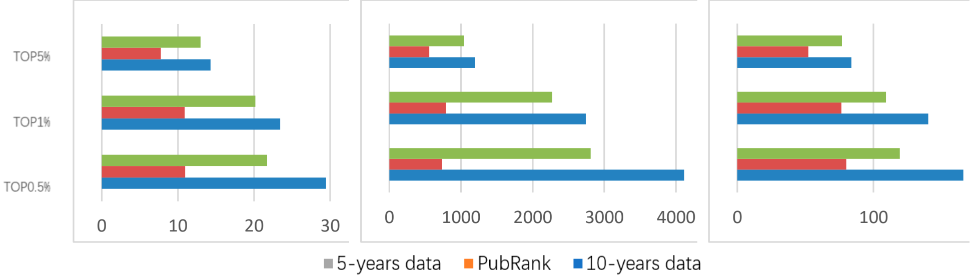
Verification for effectiveness

Method verification. There are a total of 3993 beginners in 1983. According to test data, the accuracy of the model remains stable for different years. The accuracy reaches over 90% for 10-year model and over 80% for 5-year one, and other performance indexes are similar to those obtained in 1984. So, this model indicates certain prediction effects for different years. In terms of the number of papers and citations, Top 20 scholars are leading. The mean of H-index is 27.9 and minimum H-index is 15 (as shown in Appendix 2, Table 4 shows the Top 10). Therefore, they are influential scholars. In addition, in the field of computer science, most of these scholars are professors from top universities, with multiple awards and fellowships of IEEE and ACM. Therefore, it is considered that those beginners in 1983 have grown into outstanding talents after 30-year growth, complying with standards for recognizing rising stars.

Table 4. Results of rising stars identification Top 10（year 1983）

Ranking	*Name*	*Total No. of Paper*	*Total No. of Citations Received*	*H-index*	*Academic Achievements*
1	Rakesh Agrawal	172	15757	43	National Academy of Engineering, ACM and IEEE Fellowship; Former Microsoft Technical Researcher; Former IBM Researcher
2	Brad A. Myers	272	4926	36	Professor and Senior Research Scientist at Carnegie Mellon University; 2017 ACM SIGCHI Lifetime Research Achievement Award winner; co-chaired several journals, conferences, and projects
3	Victor Vianu	126	3033	26	Professor of Computer Science, University of California, San Diego; International President of INRIA
4	Chris Faloutsos	347	9386	50	Professor of Carnegie Mellon University; Chairman/Co-Chairman of ACM SIGMOD, KDD, LDB, etc; In 2004, one of his research was rated as one of the top 50 educators in the field of information technology
5	Mark Hill	139	3894	36	Emeritus Professor of University of Wisconsin-Madison; Eckert Mozili Award (one of the most influential awards in the field of computer science) winner
6	R Tamassia	222	2471	22	Professor of School of Computer Science, Brown University; AAAS, ACM and IEEE Fellowship; IEEE Computer Society Technical Achievement Award winner
7	M. Horowitz	128	2688	27	Professor of Stanford University; IEEE and ACM Fellowship, IEEE Donald O. Pederson Award winner
8	Keith D. Cooper	76	1540	26	Professor of Rice University
9	Robert E. Kraut	135	2519	29	Professor emeritus at Carnegie Mellon University; Former professor at the University of Pennsylvania, Cornell University, and research scientist at Bell Laboratories
10	William Buxton	142	3971	36	Professor of University of Toronto, Canada; CHCCS/SCDHM Achievement Award winner

Method comparison. In order to verify advantages of proposed method, this paper compares its prediction results with existing results obtained with PubRank method. Moreover, this paper uses the data of a total of 3993 beginners in 1983 as test data for verification of the 5-year model, 10-year model and PubRank respectively.



(a) H index (b) Counts of citation paper (c) Counts of paper

Figure 2. Comparison of RStarRank and PubRank prediction results

－Comparison of prediction results in H-index, number of papers and citations. Figure 2 shows the results of Top 5%, Top 1% and Top 0.5% scholars with each method respectively. The two algorithms here rank scholars with high H-index, citations and total number of papers at top positions in prediction. Specifically, the 10-year model is 268.95%, 214.95% and 184.25% higher than PubRank in terms of H-index for Top 0.5%, Top1% and Top5% scholars. Similarly, the 10-year model is 559.04%, 347.88% and 213.85% higher than PubRank in citations; 207.69%, 183.32% and 160.56% higher than PubRank in total number of papers.

－Comparison of accuracy of all relationship pairs in predicted ranking sequence. There are 7970028 relationship pairs, since there are total 3993 beginners in 1983.

Table 5. Accuracy Comparison of All Relationships for Prediction Result Series

Model/Algorithm	*Total No. of relationship pairs*	*Correct No. of relationship pairs*	*Accuracy*
10-years Data	7970028	6816064	85.52%
PubRank	7970028	3843763	48.23%
5-years Data	7970028	6466687	81.14%

The results indicate accuracy of the proposed method reaches over 80%, much higher than 48% of PubRank. Therefore, the proposed method has certain advantages.

Feature analysis

XGboost algorithm can determine importance of each feature. The results are show in Appendix 3. For the 5-year model, “publication” and “time increment” are not considered significant. However, academic level of the co-author is more important, instead of number of co-authors. For the 10-year model, the index “institution” in 10-year model is not as important as the one in 5-year model. However, academic level of co-author is more important than number of co-authors. “Publication” and “time increment” are not completely reflected in two models, while “institution” is more important in early recognition for beginners.

Optimization

H-index as the only feature indicator. As seen from the feature analysis, the H-index is more important than other features. Can the results be analyzed based on the characteristics? The accuracy is 0.72 when H-index in the 5th year is used as the unique feature in the 5-year model, and the accuracy is 0.82 when H-index in the 10th year is used as the unique feature in the 10-year model. Compared to original model, accuracy of these two models have greatly declined.

Five feature indicators. This paper selects the 5 most important indicators to optimize the method and reduce the difficulty in data collection and the amount of calculation. The accuracy of the two data sets decreased slightly, and the hit rate of Top K ranking is basically the same, with ups and downs in some of the K rankings. In general, the prediction level of the method with only five characteristic indicators does not decrease significantly.

Table 6. Performance Measurement of RStarRank（5 features）

Model	*Accuracy*	*Precision*	*Recall*	*F1*	*Hit Ratio of Top K*			
					10%	*20%*	*30%*	*40%*
5-years data	0.8364	0.8369	0.8366	0.8364	0.69	0.79	073	0.89
10-years data	0.9064	0.9068	0.9066	0.9064	0.80	0.88	0.77	0.90

Model analysis

Feasibility analysis. RStarRank method can be used in multiple scenarios. The practicability of this method is different according to the two variables of research field and time.

Table 7. Scenario application of RStarRank

Time period *Research field*	*Same time period*	*Different (Approximate) time period*	*Different (Non-approximate) time period*
Same	Applicable	Applicable	Not applicable
Different	Not applicable	Not applicable	Not applicable

The model is trained based on original data of the computer science field and has verified the effective in computer science. Pairwise ranking algorithm is the foundation of the model, it translate the data to relative values among beginners and will not influence its feasibility due to differences in different fields, for example, the value of “citations” in biological field is higher than the one of computer science field.

Advantage analysis. The advantages mainly include: (1) The prediction accuracy reaches over 90% for the 10-year model and over 84% for the 5-year model, showing certain advantages compared to PubRank method. (2) The model can predict for different tasks, based on data conditions and using a few feature indexes. Besides, the data of these feature indexes have high availability. (3) The model provides ranking of probability of becoming rising stars. It is to compare the relative correlation of beginners in the same field, and there is no limitation for data scale. Therefore, this model can be used practically in selection of youth reviewers, recruitment of research institutions, and introduction of youth talents, etc. (4) The dependency on field shows the field feasibility of the model. Therefore, it can be used to evaluate beginners of the same field.

*Weakness analysis.*The weaknesses mainly include: (1) 5-year model depends on institutional reputation of beginners to some extent. Hence, a relatively persuasive ranking of institutions is required for different fields. (2) The accuracy of 5-year model has not reached 90%. (3)The model cannot conduct comparable ranking for beginners in different fields.

Conclusions

This paper has provided a new method for recognizing rising stars based on machine learning theory and conducted an experiment in computer science field. According to experimental results, the proposed model provides a higher prediction accuracy and can make predictions for different tasks based on data conditions or use a few feature indexes to make a prediction;

moreover, the data of these feature indexes are highly available. Without strong dependency on field, the model can be used in multiple problem-solving tasks. However, this study has some limitations. First, the achievement still emphasizes academic paper which will be investigated for general field of study. Therefore, academic paper is featured with generalization. However, some fields of study such as engineering, humanities and social sciences may investigate books and software works by a scholar. In addition, investigating personalized awards is also an important content. This paper has demonstrated the feasibility of recognizing rising stars with above problem definition from the view of overall framework, which is significant for solving general problems. However, the problem model shall be adjusted to solve some special problems. Second, it is necessary to prepare a large-scale data for early model training. The model here uses machine learning method, so that data scale is one of foundations for reaching model accuracy. Under the same model, the more training data it uses, the higher the model precision will be. Therefore, a large amount of data is required for early model training.

Abstract

Knowledge diffusion based on disciplinary citation is similar to disease propagation via the actual contact. Inspired by the disease-spreading model in complex networks, the paper classifies disciplines in the process of knowledge diffusion in the disciplinary citation network into 5 states, namely potential knowledge recipients, potential knowledge diffusion disciplines, knowledge diffusion disciplines, knowledge skeptics and knowledge immunes. The classifications of disciplines can transform from one state to another with certain rate (α, β, ω, γ, θ and μ respectively). Then the evolution rules of knowledge diffusion in the disciplinary citation network are made. Furthermore, the knowledge diffusion model of differential dynamics in the disciplinary citation of non-uniformity network is formed, and then the evolution process of knowledge diffusion is further discussed, so as to reveal the dynamic mechanism of knowledge diffusion in the disciplinary citation network. The research has shown that: the knowledge diffusion state evolution of disciplines in the disciplinary citation network is affected not only by the evolution states of adjacent disciplines in knowledge diffusion, but also by the relative citation weight (knowledge contact intensity).

Introduction

Knowledge diffusion, the intermediate link and intermediary process of knowledge production and knowledge application, is the exchange and dissemination of knowledge through different media, the transition of knowledge from production behavior to consumption behavior, and the transfer of knowledge from creation subject to learning subject. The ultimate goal of knowledge diffusion is the utilization and innovation of knowledge. Knowledge acquisition, distribution, transformation, innovation and application also need be realized through knowledge diffusion. In the age of Big Science, the disciplinary boundaries are becoming fuzzier with more and more frequent knowledge flow and exchange among disciplines, which greatly promote the collaboration, integration, innovation and development of the disciplines. The study of disciplinary knowledge diffusion law and its dynamic evolution mechanism is an effective way to clarify discipline development and knowledge exchange mode, predict innovation field and developing trend, and promote discipline construction and sci-tech progress.

The study of dynamic evolution mechanism of disciplinary knowledge diffusion shall be started from model building. The common idea is to learn from mature models in disciplines such as infectious diseases, complexity science, sociology, etc. The process of disciplinary knowledge diffusion is accompanied by the generation and evolution of the knowledge diffusion network, and construction of the model relies on the tangible or intangible carrier network of disciplinary knowledge diffusion. Literature is the carrier of knowledge, and the literature citation process is accompanied by the diffusion, transfer, inheritance and innovation of knowledge. Disciplinary citation network is one of the commonly used media to measure the diffusion of disciplinary knowledge. The current knowledge diffusion models include citation path model (Lu & Liu, 2013; Yu, Lu & Liu, 2014; Yan, 2014; Liu & Kuan, 2016), epidemic-like model (Bettencourt, Cinron-Arias & Kaiser, 2006; Bettencourt, Kaiser & Kaur, 2008; Kiss, Broom & Craze, 2009; Yang, Hu & Liu, 2015; Wang, Guo & Yang, 2015; Li, Zhang & Man, 2017; Yue, Xu & Yuan, 2019), network structure model (Cowan & Jonard, 2004; Kim & Park, 2009; Ozel, 2010; Liu, Rousseau & Guns, 2013; Liu, Jiang & Chen, 2015; Luo, Du & Liu, 2015), individual behavior model (Klarl, 2014), citation temporal series network model (Gao & Guan, 2012), co-citation clustering model (Wang, Zhao & Liu, 2013), etc.

Knowledge diffusion based on disciplinary citation is similar to disease propagation. In the process of disciplinary citation, knowledge exchange and diffusion can take place with literature citation among disciplines, while disease is usually propagated among organisms through physical contact, such as air, contact, matrix, blood, and so forth (Anderson & May, 1991).

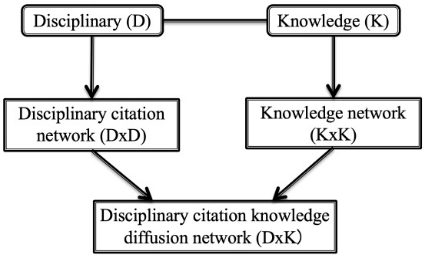
In consideration of the similarity between knowledge diffusion based on literature citation and disease propagation via actual contact, and inspired by the disease-spreading model in complex networks, the paper defines 5 states of disciplines in the process of knowledge diffusion in the disciplinary citation network which can transform from one to another with a certain rate. Then the evolution rules of knowledge diffusion in the disciplinary citation network are made. Furthermore, the disciplinary knowledge diffusion model of differential dynamics in non-uniformity networks is formed and verified, and then the evolution of knowledge diffusion in the disciplinary citation network is further discussed. In this way, the effect of disciplinary citation attribute and the evolution rules of knowledge diffusion are further clarified and knowledge diffusion laws based on literature citation explored so as to reveal the dynamics mechanism of knowledge diffusion in the disciplinary citation network.

Theoretical Model

Knowledge diffusion network based on disciplinary citation

Bibliographies have long been the canonical form of data storage for recording information of scientific activities in a field or across fields. Bibliographic records contain essential summary information of the knowledge diffusion activities in a discipline, revealing 3 different yet interrelated sets of relations: (1) interactive relations among disciplines; (2) semantic relations among subject words which reveal discipline contents; (3) cognitive relations which reveal cognitive structures of disciplines.

In the process of knowledge diffusion activities based on literature citation, the sets of relations correspond to 3 different yet interrelated networks, i.e., disciplinary citation network, knowledge network and knowledge diffusion network based on disciplinary citation. The 3 networks can be described as follows:



Disciplinary (D)
Knowledge (K)
Disciplinary citation network (DxD)
Knowledge network (KxK)
Disciplinary citation knowledge diffusion network (DxK)

Figure 1. Construction of knowledge diffusion network based on disciplinary citation.

Disciplinary citation network (DxD) is a network formed by mutual citation of literature among disciplines. Its unit value represents the frequency of mutual citation of those disciplines and reflect the integration degree of disciplinary knowledge.

Knowledge network (KxK) is a network formed by the co-occurrence among knowledge. Its unit value represents the number of times that different knowledge appears in the same literature in pairs, reflecting the correlation relationship of different knowledge units.

Disciplinary citation knowledge diffusion network (DxK) is formed by the co-occurrence of disciplines and knowledge. The unit value represents the amount of corresponding knowledge in a certain discipline and reflects the distribution or diffusion of knowledge in the discipline (i.e., the cognitive state of the discipline). Construction of the above networks is the basis for analyzing and exploring the essence of knowledge diffusion in the disciplinary correlation network with the aid of literature citation.

Knowledge diffusion process of the disciplinary citation network

Many studies of the behavior dynamics mechanism of propagation and diffusion are based on the classical SIR epidemic model, in which individual diffusion states are defined to be the susceptible state (S), infective state (I), and recovered/immune state (R). They can transform from one state to another in a unidirectional way with a certain rate. During the actual evolution process of knowledge diffusion in the disciplinary citation network, however, there are 3 special phenomena: (1) When receiving certain knowledge, a discipline tends not to spread the knowledge immediately. Instead, there exists a certain period of time in which it digests the knowledge. After the discipline absorbs and converts the knowledge into intrinsic knowledge, it will spread the knowledge to others. (2) The citation behavior is often affected by a variety of factors, such as the rational factors, social factors and random factors, etc. (Ma & Wu, 2009). There are passive or negative citations in some disciplinary literature, where the opinions or works in those citations are criticized because of certain shortcomings or even negated. Then the knowledge in the discipline might be questioned and spread the knowledge further hindered. (3) As the evolution and development of science, a discipline may not diffuse knowledge anymore. However, this kind of immunity is temporary for some disciplines, because they will accept and diffuse the knowledge again in the future. Therefore, this paper argues that the SEIZRS epidemic model, which has a certain latent state (E), skeptical state (Z), and feedback mechanism (R to S), is more consistent with the nature of the knowledge diffusion process in the disciplinary citation network, and is more suitable to function as the basic model of differential dynamics for knowledge diffusion in the disciplinary citation network.

States of disciplines in the knowledge diffusion process of the disciplinary citation network

In terms of characteristics of disciplinary citation and diversity of citation motives, we define that disciplines in different states of knowledge diffusion in the disciplinary citation network fall into 5 categories:

(1) Potential knowledge recipients (S): disciplines which have not known the knowledge or have known but not acquired it yet.
(2) Potential knowledge diffusion disciplines (E): disciplines which have acquired the knowledge but not diffused it yet.
(3) Knowledge diffusion disciplines (I): disciplines which have mastered the knowledge and are diffusing it to the potential knowledge recipients.
(4) Knowledge skeptics (Z): disciplines which have acquired the knowledge but disapprove of it and even question it.
(5) Knowledge immunes (R): disciplines which have acquired the knowledge but are immune to it now. They have lost interest in the knowledge and will not continue to diffuse it.

Process of knowledge diffusion in the disciplinary citation network

In the initial phase, there are only small numbers of knowledge diffusion disciplines in the network, while others are potential knowledge recipients. The number of potential knowledge diffusion disciplines, knowledge skeptics, and knowledge immunes is zero. As time goes on, knowledge begins to be diffused in the following ways:

When knowledge diffusion disciplines transmit knowledge to potential knowledge recipients, the recipients begin to accept it with a certain rate (α) and become potential knowledge diffusion disciplines, while some potential knowledge recipients who disapprove of the knowledge become knowledge skeptics with θ. If potential knowledge diffusion disciplines are interested in the knowledge, they will continue to diffuse it with β and become new knowledge diffusion disciplines. Knowledge diffusion disciplines lose interest in the knowledge with ω and turn into knowledge immunes. Meanwhile, when knowledge skeptics thoroughly reject the knowledge with μ, they also transform into knowledge immunes. Knowledge immunes become knowledge recipients again with γ and take in the knowledge to which they have been immune.

Evolution rules of knowledge diffusion in the disciplinary citation network

At a certain time in the knowledge diffusion process in the disciplinary citation network, which could be marked as t, a discipline can only be in one of the states mentioned above. At time t, we can define the proportion of disciplines that are in a certain knowledge diffusion state as follows.

(1) s(t): the proportion of potential knowledge recipients to all disciplines in different states of knowledge diffusion at time t.
(2) e(t): the proportion of potential knowledge diffusion disciplines to all disciplines in different states of knowledge diffusion at time t.
(3) i(t): the proportion of knowledge diffusion disciplines to all disciplines in different states of knowledge diffusion at time t.
(4) z(t): the proportion of knowledge skeptics to all disciplines in different states of knowledge diffusion at time t.
(5) r(t): the proportion of knowledge immunes to all disciplines in different states of knowledge diffusion at time t.

Here, s(t)+e(t)+i(t)+z(t)+r(t)=1.

According to the above description of the knowledge diffusion process in the disciplinary citation network, a schematic paradigm of the dynamic state evolution rules of disciplines in knowledge diffusion is presented as follows (Figure 2).

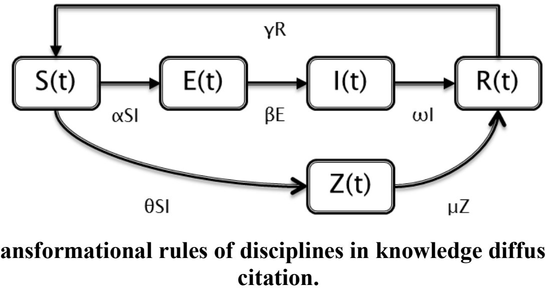


Figure 2. State transformational rules of disciplines in knowledge diffusion of disciplinary citation.

When there is citation relationship between potential knowledge recipients and knowledge diffusion disciplines in the process of disciplinary citation, the former could become potential knowledge diffusion disciplines with the rate of α, and become knowledge skeptics with θ; potential knowledge diffusion disciplines become knowledge diffusion disciplines with β; knowledge diffusion disciplines turn into knowledge immunes with ω; knowledge skeptics turn to be knowledge immunes with μ; and knowledge immunes generate feedback with γ, and become potential knowledge recipients.

Modeling of knowledge diffusion in the disciplinary citation network

The disciplinary citation network is a kind of complex networks with obvious scale-free features. Disciplines with different citation weight (knowledge contact intensity) play different roles in the process of knowledge diffusion. According to the evolution rule of knowledge diffusion in the disciplinary citation network mentioned above, the disciplinary citation knowledge diffusion model of differential dynamics in the non-uniformity network is formed on the basis of the disease-spreading equation of SEIZRS and structural attribute of the citation network. The SEIZRS model equations are as follows.

$$\begin{cases} \frac{ds_i(t)}{dt} = -\alpha\sum_j w_{ji} i_j(t) s_i(t) - \theta\sum_j w_{ji} i_j(t) s_i(t) + \gamma r_i(t) \\ \frac{de_i(t)}{dt} = \alpha\sum_j w_{ji} i_j(t) s_i(t) - \beta e_i(t) \\ \frac{di_i(t)}{dt} = \beta e_i(t) - \omega i_i(t) \\ \frac{dz_i(t)}{dt} = \theta\sum_j w_{ji} i_j(t) s_i(t) - \mu z_i(t) \\ \frac{dr_i(t)}{dt} = \omega i_i(t) + \mu z_i(t) - \gamma r_i(t) \end{cases} \qquad (1)$$

In the equation set above, t is the time step; $s_i(t)$, $e_i(t)$, $i_i(t)$, $z_i(t)$, and $r_i(t)$ indicate the proportion of disciplines at time t, and their knowledge diffusion states are S, E, I, Z, and R, respectively; $w_{ji} = \frac{W_{ji}}{\sum_j W_{ji}}$ represents the standardized weight of knowledge diffusion from discipline "j" to "i", and W_{ji} is the number of citations from discipline "i" to "j".

Model simulation and verification

Based on Model 1, the simulation experiment of the disciplines' state evolution of knowledge diffusion in the disciplinary citation network from t_1 to t_v is conducted by employing MATLAB. The initial conditions of the model are that when t=0, i(0)>0, s(0)=1-i(0)>0, e(0)=0, z(0)=0, r(0)=0.

Parameter estimation

We adjust the parameters (α, β, ω, γ, θ and μ) constantly to gain the best fitting model, namely, the supreme fitness between the output of the model and the actual value that is the proportion of knowledge diffusion disciplines in the disciplinary citation network. According to the distributing characteristics of the theoretical and practical data values, the Likelihood function is employed in this paper for parameter estimation.

The Likelihood function in this model is:

$$L = \frac{1}{v}\sum_{t=t_1,t_2,\ldots\ldots,t_v}\left(-\log\left(\prod_{j=1}^{N}\left(i_j(t)\right)^{Y_j(t)}\left(1-i_j(t)\right)^{1-Y_j(t)}\right)\right)$$

（2）

where v is the total number of time steps. $Y_j(t)$ is an indicator function with a value of one, denoting that a discipline j is spreading knowledge at time t, and a value of zero denoting that j is not a knowledge diffusion discipline. According to Formula 2, the set of parameters that gain the minimum value for L is the optimal parameter set of the fitting model.

Model building

The optimal parameters of the fitting model will be plugged into Model 1 to form the knowledge diffusion model of differential dynamics eventually.

Model verification

The optimal fitting model can continue to be used through iteration of time steps to predict the changing trend of the quantitative proportion of the knowledge diffusion disciplines. By comparing the gained data with the actual data from t_{v+1} to t_m, the consistency can be further checked. If they are consistent, the model is correct; otherwise, it will be revised.

Empirical Research

Selection of research object and data acquisition

As a new sociological research paradigm, social network theory has been continuously deepened in different disciplines such as Psychology, Sociology, Anthropology and so on, and knowledge transmission and diffusion in this field are very active (Wang & Liu, 2007). Social media is a platform for users' social communication and information sharing. It has become an important kind of media for obtaining current information, interpersonal communication, self-expression, social sharing and social participation, through which people form certain loose or close social network connections (Xu & Jin, 2013). There are many similarities between social network and social media in theory, technical methods and applications, so the studies of them present an overlapping, mutually permeating, and inseparable trend.

Therefore, the knowledge point "social media" in the field of social network is selected as the research object to form and verify the knowledge diffusion model of differential dynamics that simulates the knowledge diffusing process of social media in the disciplinary citation network of social network, and the research results are further analyzed and explained. Because the knowledge point "social media" in the field of social network emerged in 2008, the research period of this model is set from 2008 to 2019.

In this paper, TS="social network*" is set as the searching strategy to collect articles in SCI-EXPANDED and SSCI of Web of Science from 2008 to 2019. After data cleaning, 35,397 articles are obtained. In terms of classification of disciplines according to Web of Science Categories and on the basis of the citation data, the multimap of journals and disciplines is used and temporal evolution networks of knowledge diffusion in disciplinary citation during the period is extracted to construct the knowledge diffusion network based on disciplinary citation. The classification of disciplines is not exclusive. In the multimap of journals and disciplines, when a journal has mapping relationships with more than one disciplines, the journal is classified into all those disciplines.

State evolution of knowledge diffusion disciplines

In this paper, we define disciplines in the state of knowledge diffusion disciplines at a certain time as the disciplines that publish papers containing the knowledge point "social media" in the social network field at that time. The total number of members in the disciplinary citation network is 226. The quantity and proportion of knowledge diffusion disciplines from 2008 to 2019 are shown in Table 1.

Table 1. Quantity and proportion of knowledge diffusion disciplines during 2008–2019.

Year	Quantity	Proportion
2008	3	0.013274
2009	13	0.057522
2010	33	0.146018
2011	41	0.181416
2012	66	0.292035
2013	77	0.340708
2014	93	0.411504
2015	104	0.460177
2016	92	0.40708
2017	102	0.451327
2018	116	0.513274
2019	118	0.522124

It can be seen from the table that the proportion of disciplines in the state of knowledge diffusion disciplines (in other words, disciplines that are diffusing knowledge) is growing continually (from 1.3274% to 52.2124%), though the proportion declines in 2016.

Model construction and validation

In the original state (i.e., in 2008), there were 3 knowledge diffusion disciplines of social media in the network (i.e., Computer Science, Artificial Intelligence; Computer Science, Information Systems; and Computer Science, Theory & Methods). The others were all potential knowledge recipients, without any potential knowledge diffusion disciplines, knowledge skeptics and knowledge immunes.

Parameter determination

On the basis of Model 1, we simulate the theoretical model by using MATLAB, adjust parameters (α, β, ω, γ, θ and μ) with a step length of 0.1 and values from 0 to 10, and calculate Maximum-Likelihood estimation (L) between the output values of the model with different parameters and actual values (i.e., proportions of knowledge diffusion disciplines of social media) from 2008 to 2017, respectively, to determine the optimal parameters of the fitting model (Table 2).

Table 2. Optimal parameter set of the fitting model and its L value.

α	β	ω	γ	θ	μ	L
2	10	0.2	0.9	1	0.4	6.51677095

Model building

Evolution curves of the theoretical and actual proportions of knowledge diffusion disciplines in the optimal fitting model are shown in Figure 3.

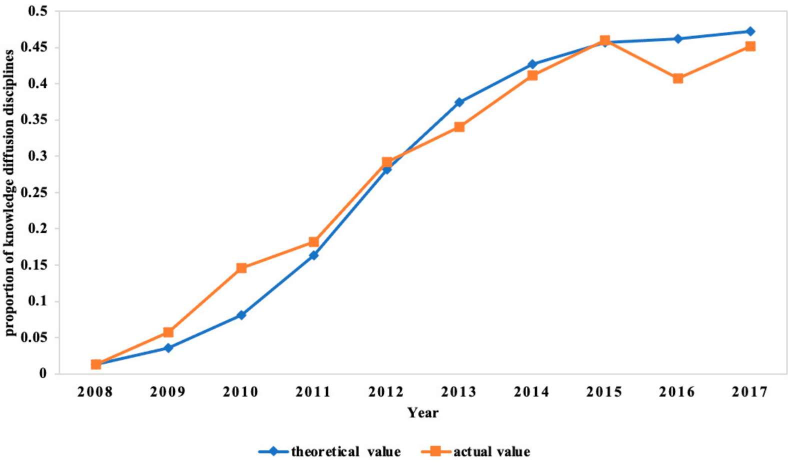

Figure 3. Evolution curves of theoretical and actual proportion of knowledge diffusion disciplines with the optimal fitting parameters.

In the disciplinary citation network of social network, under the conditions that potential knowledge recipients become potential knowledge diffusion disciplines with a state transition parameter of 2 and knowledge skeptics with that of 1, potential knowledge diffusion disciplines become knowledge diffusion disciplines with a parameter of 10, knowledge diffusion disciplines turn into knowledge immunes with a parameter of 0.2, knowledge skeptics become knowledge immunes with a parameter of 0.4, and knowledge immunes revert to being potential knowledge recipients with a parameter of 0.9, the model can simulate the knowledge diffusion process of social media in the disciplinary citation network of social network and reflect the dynamic nature and inherent law of knowledge diffusion in the disciplinary citation network. Therefore, the knowledge diffusion model simulating the knowledge diffusion of social media in the disciplinary citation network of social network can be described as follows.

$$\begin{cases} \frac{ds_i(t)}{dt} = -2\sum_j w_{ji} i_j(t) s_i(t) - \sum_j w_{ji} i_j(t) s_i(t) + 0.9 r_i(t) \\ \frac{de_i(t)}{dt} = 2\sum_j w_{ji} i_j(t) s_i(t) - 10 e_i(t) \\ \frac{di_i(t)}{dt} = 10 e_i(t) - 0.2 i_i(t) \\ \frac{dz_i(t)}{dt} = \sum_j w_{ji} i_j(t) s_i(t) - 0.4 z_i(t) \\ \frac{dr_i(t)}{dt} = 0.2 i_i(t) + 0.4 z_i(t) - 0.9 r_i(t) \end{cases} \qquad （3）$$

The model illustrates that the state evolution of knowledge diffusion disciplines in the disciplinary citation network is affected not only by the evolution states of adjacent disciplines in knowledge diffusion, but also by the relative citation weight (knowledge contact intensity).

Model verification

In accordance with Model 3, the proportions of disciplines that are diffusing knowledge from 2018 to 2019 are predicted by the iteration of time steps (Table 3).

Table 3. Predicted value of the proportion of knowledge diffusion disciplines from 2018 to 2019 in theory.

Year	Predicted value	Actual value	Deviation
2018	0.48261152	0.51327434	-5.974%
2019	0.48641531	0.52212389	-6.839%

The table shows that the deviations between the theoretical value and actual value of the proportion of knowledge diffusion disciplines predicted from 2018 to 2019 are -5.974% and -6.839%, respectively. The closeness between the values illustrates the validity of the model.

A comparison of SEIZRS model and SIR model

In order to further verify the validity of the introduced knowledge latent mechanism, skeptical mechanism and feedback mechanism in the paper, a comparison analysis is performed between the evolutionary fitting effects of SEIZRS model and classic SIR model from 2008 to 2019 (Figure 4).

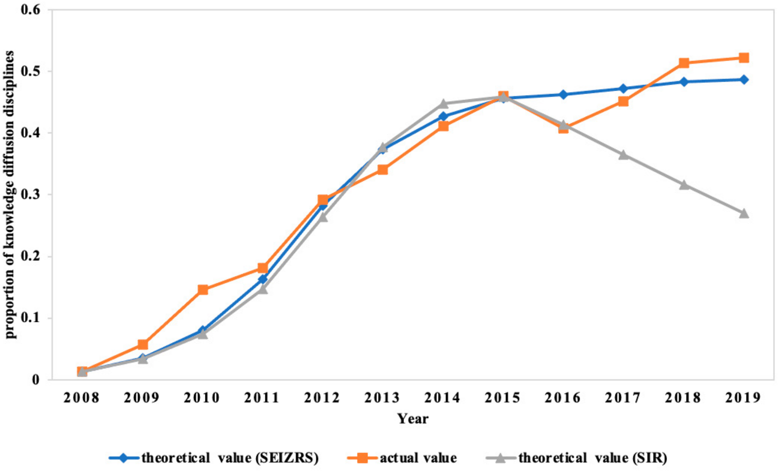

Figure 4. Evolution curves of theoretical and actual proportion of knowledge diffusion disciplines in the optimal fitting model with SEIZRS and SIR type transmission respectively.

Before 2016, the SIR model could relatively effectively reflect diffusion process of the knowledge points "social media" among disciplines by drawing on literature citation in the field of social network. However, its fitting ability has declined rapidly since 2017, and the gap between the theoretical output value of the model and the actual proportion value of knowledge diffusion disciplines has become increasing larger.

From 2008 to 2019, the performance of SEIZRS model is more consistent with the knowledge diffusion process in the disciplinary citation network, which shows that the knowledge latent mechanism, skeptical mechanism and feedback mechanism introduced in this paper can more effectively reveal the essential mechanism and dynamic mechanism of knowledge diffusion in the disciplinary citation network.

Evolution analysis of knowledge diffusion in the disciplinary citation network

From 2008 to 2019, the state evolution of disciplines diffusing the knowledge of social media in the disciplinary citation network of social network is shown in Figure 5.

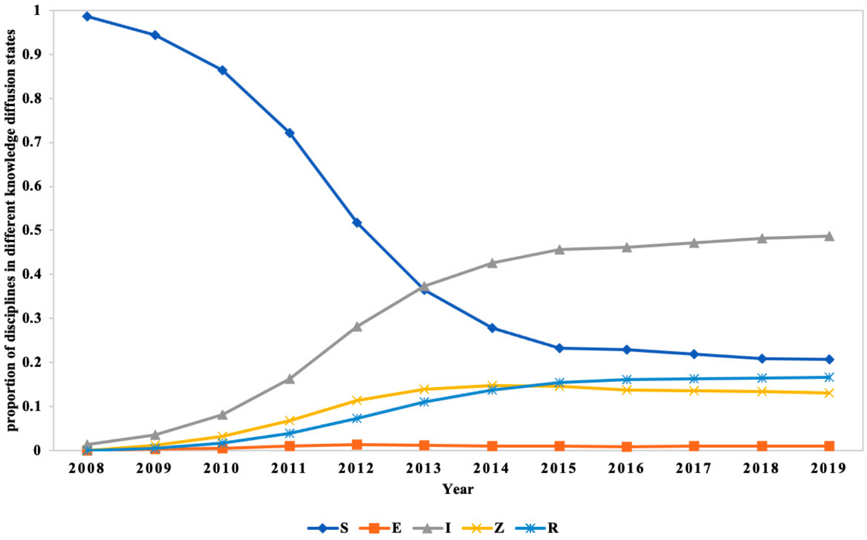

Figure 5. Evolution curves of disciplines in different knowledge diffusion states in the disciplinary citation network.

With the passage of time, it is shown from the perspective of the overall evolution trend of knowledge diffusion as follows: the proportion of potential knowledge recipients in the disciplinary citation network decreases continuously; the proportion of knowledge diffusion disciplines and knowledge immunes is increasing; the proportion of knowledge skeptics climbs first and then decreases gradually; and the proportion of potential knowledge diffusion disciplines shows a slight growth trend. From the perspective of the evolution speed, it is shown that the proportions of potential knowledge recipients, knowledge diffusion disciplines, knowledge skeptics and knowledge immunes in the disciplinary citation network all change rapidly at first and then slow down, while the change of the proportion of potential knowledge diffusion disciplines is relatively insignificant. In terms of the evolution acceleration of knowledge diffusion, the changes of potential knowledge recipients are the fastest, followed by knowledge diffusion disciplines, knowledge skeptics and knowledge immunes in succession, and changes of potential knowledge diffusion disciplines are the slowest.

In addition, according to the evolution trend of the proportion of knowledge diffusion disciplines (showing a logical growth trend), it can be judged that the diffusion of the knowledge point "social media" in the field of social network has entered a relatively mature stage, and the diffusion scale has been steady.

Discussion

From the perspective of evolution of knowledge diffusion process, differential dynamic model of knowledge diffusion in the disciplinary citation network is built in this paper to further reveal the particular dynamics mechanism of knowledge diffusion in the disciplinary citation network according to the attribute of the disciplinary citation network by improving traditional dynamics model, such as introducing knowledge latent mechanism, skeptical mechanism and feedback mechanism and considering the network heterogeneity. The research has shown that:

(1) The hypothesis that knowledge can be diffused with the aid of disciplinary citation is justified, and the knowledge diffusion model constructed in this paper is rational and reasonable.

(2) The knowledge diffusion state evolution of disciplines in the disciplinary citation network is affected not only by the evolution states of adjacent disciplines in knowledge diffusion with citation relationship, but also by the relative citation weight (knowledge contact intensity).
(3) When the state transition parameter meets the conditions that α=2, β=10, ω=0.2, γ=0.9, θ=1, and μ=0.4, the knowledge diffusion model of differential dynamics can better simulate the knowledge diffusion process of social media in the disciplinary citation network of social network.
(4) The diffusion of the knowledge point "social media" in the field of social network has entered a relatively mature stage, and the diffusion scale has been steady.
Knowledge diffusion process of "social media" in the disciplinary citation network of social network is taken as an example to verify the validity of SEIZRS model. However, there are still some questions for further exploration and discussion. What about the applicability of the model for various knowledge points of different fields? Is the speed of diffusion constant across knowledge points? What about the effect of changing parameters on the knowledge diffusion process in the disciplinary citation network?
In order to achieve different evolution effects of knowledge diffusion and control the diffusion process in the disciplinary citation network, the structure and parameters in state transition of disciplinary citation network could be regulated through various means, so as to promote or inhibit knowledge diffusion among disciplines. In addition, the future trend of knowledge diffusion could be predicted timely and accurately according to the current disciplinary citation network, so that the management and regulation of knowledge diffusion in the disciplinary citation network could be realized from the perspective of differential dynamics according to actual needs.

Network Analysis of Econometric Society Fellows

Tolga Yuret[1]

[1] *tyuret@gmail.com*
Faculty of Management, Department of Economics, Istanbul Technical University, Macka,
Istanbul, 34367 (Turkey)

Abstract

We analyze co-author and co-worker networks of 981 Econometric Society Fellows who were elected between 1933 and 2017. The vast majority of Fellows are connected either directly or indirectly. The percentage of connected Fellows has increased through time.

Introduction

Econometric Society was founded in 1933 by a group of distinguished economists. New Fellows of the Society are elected annually by the incumbent Fellows (Hamermesh & Schmidt 2003). Most top-notch economists are Econometric Society Fellows. For example, the vast majority of the Nobel Prize recipients in economics were previously elected as Fellows of the Society (Chan & Torgler 2012).

In this paper, we analyze the connections among all 981 Fellows who have been elected from 1933 to 2017. The Fellows work in a few prestigious institutions so that they have many co-workers who are also Fellows of the Society. The Fellows also publish joint papers. Using these relations, we establish co-worker and co-author networks. We find that the vast majority of Fellows are connected either directly or indirectly in both networks.

We also analyze the development of the networks through time. As the years pass, the number of Fellows has increased and the generational gap among members has widened. Despite this fact, we find that the percentage of connected Fellows has increased through the years.

Data

We collected data for this study and Yuret (2020) at the same time. The latter study analyzes co-author and co-worker networks of 3,587 researchers who published in the top five economics journals in the last ten years. 367 of these researchers are also Econometric Society Fellows. Naturally, the data descriptions of both studies are similar.

We collected publications of all Fellows to establish their co-author network. We searched the names of Fellows from Econ-lit data-base. There is room for name confusion since some authors share the same surname and first name initials. To refrain from this problem, we matched address information in publications with biographical information in CVs. We included articles, review articles, conference proceedings, notes, comments, corrections, replies, and discussions but excluded book reviews, editorials, introductory materials, and announcements.

We collected biographical information of all Fellows to establish their co-worker network. We mainly relied on Fellows' CVs in their home pages and web sites such as Prabook, Wikipedia, and LinkedIn. We only included primary academic positions since visiting information was missing in many cases. We used address information from publications when we could not get biographical information from other sources.

We could not find information about the PhD degrees of 63 Fellows many of whom may not have gotten the degree. There are 21 Fellows that we could not get the institution for their undergraduate degrees. Their biographical information either stated the country of their undergraduate degree or stated their country of birth that we used in place of the country of their undergraduate degree.

Trends in Publications and Residence

Figure 1 shows the cumulative number of Fellows through the years. We do not exclude the retired or deceased Fellows from any of our calculations. There were elections every year except for 1934, 1936, and 1940 through 1943, so the number of Fellows increased every year except for these years. The number of Fellows increased at a higher rate after 1970.

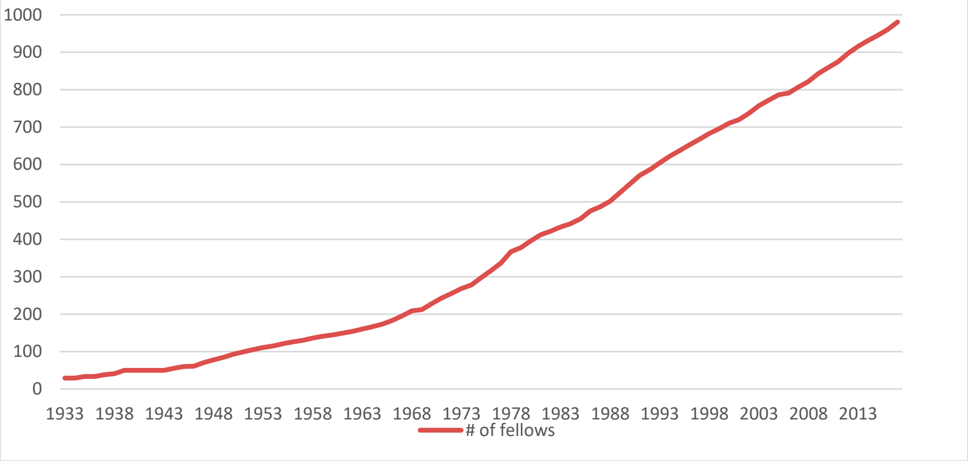

Figure 1. Cumulative number of Fellows through time

Figure 2 gives the age of the Fellows when they are elected. The highest frequency of Fellows are between ages 33 and 50. After age 50, the frequency of Fellows decreases for older age intervals. Therefore, most Fellows were elected before their retirement age.

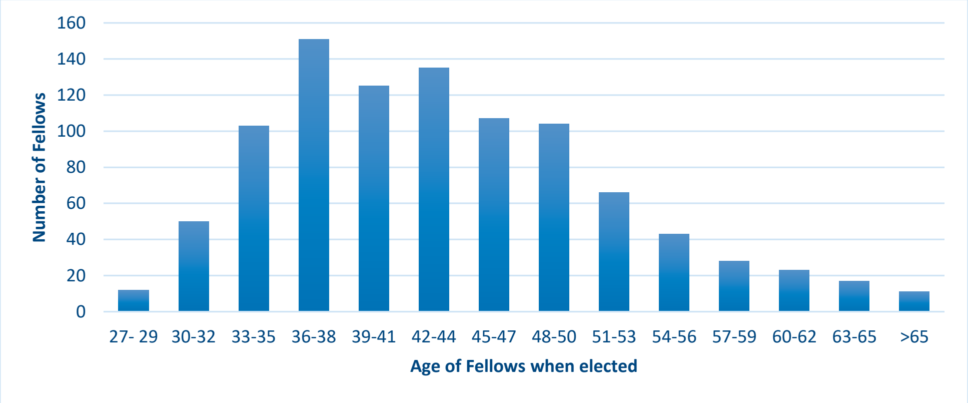

Figure 2. Age of Econometric Society Fellows when elected

Table 1 gives the number of Fellows by the country that they attained their education degrees, and the country of their workplace when elected. There are half Fellows in the workplace category because some Fellows were holding two primary positions in two different countries when they were elected. Ten countries cover more than 80% of the undergraduate and PhD degrees, and workplaces when elected. More than 40% of the undergraduate degrees and more than 70% of the PhD degrees were obtained from the United States. More than 60% of the Fellows were elected while working in a US institution.

Table 1. Number of Fellows by the country of their education and workplace when elected

Total Top 10		800			870			870.5
Total Fellows		981			918			981
Percentage Top 10		81.5			94.7			88.7

Figure 3 shows the percentage of Fellows who were educated and worked when elected in the USA through time. Percentage in a certain year is computed by considering all Fellows who have been elected up to that year. We see that all three percentages were lower in the beginning years of the Society, and there is an increasing trend up until the 1990s. The percentage of undergraduate degrees from the USA decreases, but the other two percentages are stable after the 1990s.

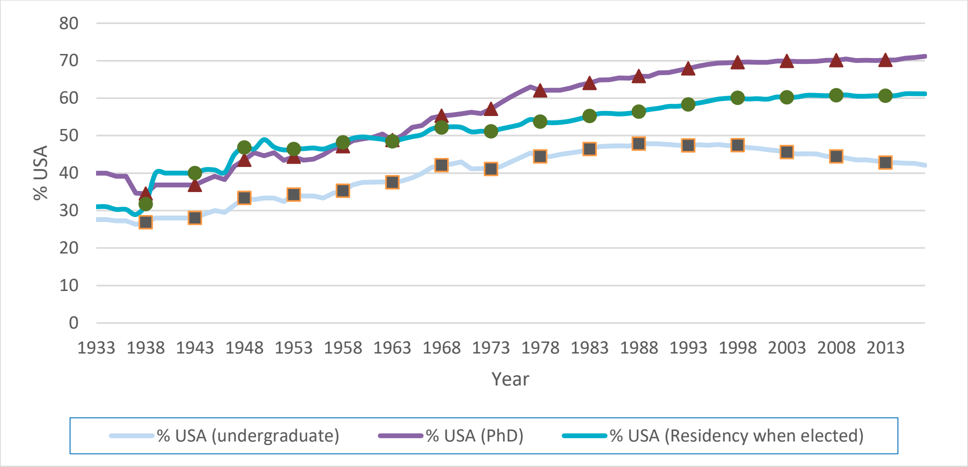

Figure 3. Percentage of Fellows who are educated and worked when elected in the USA.

There is also concentration at the institutional level as we see from Table 2. More than half of the Fellows take their PhD degrees from ten institutions, and more than one-third of the Fellows were working in just ten institutions when they were elected.

Table 2. Number of Fellows by the institution of their education and of workplace when elected

Undergraduate Alumni			PhD Alumni			Workplace when elected		
Rank	Institution	# of Fellows	Rank	Institution	# of Fellows	Rank	Institution	# of Fellows
1	Harvard U	51	1	Harvard U	98	1	MIT	44
2	Cambridge U	34	2	MIT	90	2	Stanford U	42.5
3	Hebrew U	31	3	U Chicago	62	3	U Chicago	41
4	E. Polytech.	26	4	Stanford U	60	4	Harvard U	37.5
5	Yale U	25	5	UC Berkeley	48	4	Northwestern U	37.5
6	U Chicago	21	6	Princeton U	43	6	Princeton U	34.5
7	Princeton U	20	7	Yale U	41	7	U Pennsylvania	33.5
8	ENS	19	8	U Minnesota	27	8	Yale U	33
9	UC Berkeley	18	9	LSE	26	9	LSE	29.5
10	U Tokyo	16	10	Cambridge U	22	10	UC Berkeley	25
Total Top 10		261			517			358
Total Fellows		960			918			981
Percentage Top 10		27.2			56.3			36.5

Co-author and co-worker networks

We assign each of the 981 Fellows to a node. In the co-author network, we connect two nodes with an edge if they have ever been co-authors in a paper. In the co-worker network, we connect two nodes if they worked in the same institution for three years at the same time. Because most PhD students work as teaching or research assistants during their graduate studies, we included this period when we established co-worker links.

Table 3 presents statistics of both networks as of 2017. Average degree is the average number of direct neighbors in a network. Therefore, each Fellow has on average 4.4 co-authors and 57.2 co-workers who are also Fellows of the Society. Isolated nodes are the nodes that do not have any direct connection to other nodes. Therefore, 18.3% of Fellows did not write any joint papers with any other Fellow, whereas only 3.0% of the Fellows were not co-workers with any other Fellow.

Network density divides the number of edges in a network to the maximum possible number of edges in that network. Since both networks have 981 nodes, the maximum possible number of edges in both networks is C(981,2) where C is the combinatorics function. In other words, the denominators for both networks are the same. Therefore, we can say that there are more than ten times (0.058/0.005) more edges in the co-worker network.

Giant component is the largest component where all nodes are connected either directly or indirectly. For example, two nodes are connected even if they only have a common co-author who is also a Fellow. The distance, in this case, is two since we have two edges between these two nodes. The maximum distance between two nodes in the giant component is 11 in both networks. The average distance is 4.4 in the co-author network and 2.4 in the co-worker network.

Yuret (2020) also finds that the co-worker network is much denser than the co-author network for the researchers who have published in the top five economics journals in the last ten years. Giant components are larger in that study, possibly because Fellows span more generations than the authors of the top five economics journals in the last ten years.

Table 3. Network statistics for co-author and co-worker networks

	Co-author	Co-worker
Nodes	981	981
Average Degree	4.4	57.2
Isolated Nodes	180 (18.3%)	29 (3.0%)
Network Density	0.005	0.058
Giant Component	783 (79.8%)	939 (95.7%)
Distance in Giant Component		
Maximum	11	11
Average	4.4	2.4

Figure 4 gives the size of the giant component and the size of isolated nodes as a percentage of all nodes through time. We start with 1937 and repeat the exercise for every decade. For example, when we compute the network for 1957, we consider Fellows who have been elected up until 1957 and use their co-authorship and co-worker relations that have been established up until 1957. We see that the size of giant component has grown and the size of isolated nodes has become smaller relative to the number of nodes through time.
Goyal et al. (2006) compute the giant component for co-authors in all journals indexed in Econlit. They also find an increasing giant component through time.

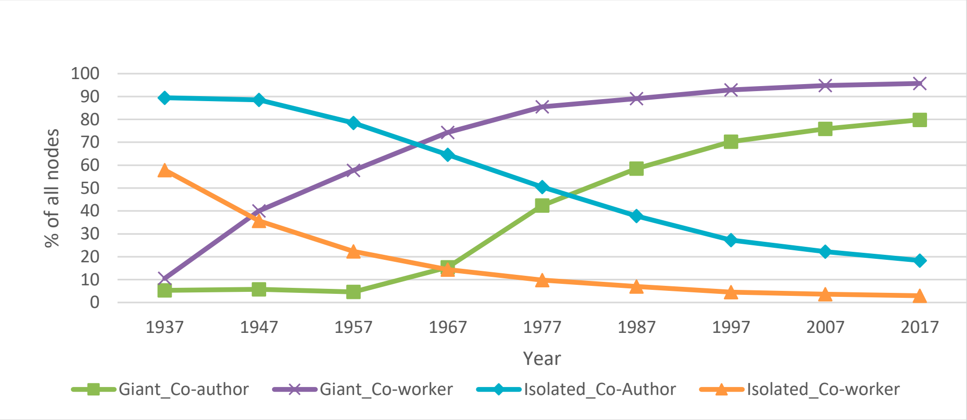

Figure 4. Size of Giant Component and Isolated Nodes

Conclusion

As the years pass, the Econometric Society is growing with newly elected Fellows. The Fellows establish more connections although the generational gap between Fellows widens. The Fellows publish more publications that strengthen their co-author links, and they continue to work in a few prestigious institutions that strengthen their co-worker links.

Abstract

Patent indicators are widely employed in the identification and prediction of disruptive technologies; however, extant research lacks analysis and evaluation of the applicability and effectiveness of these indicators. Therefore, it is necessary to investigate the patent indicators that best match disruptive technologies' salient characteristics. This study uses decision tree algorithms and correlation analysis to compare the characteristics presented by patent indicators found between disruptive and traditional technology fields to derive key indicators, and then verify the indicator research results to check the indicators' applicability and effectiveness. It shows that the changes in the number of patent applications can reveal the development and evolution of disruptive technologies to a certain extent; in terms of other indicators, number of patent family country, duration of patent examination, number of non-patents cited in patents, number of claims, number of patents cited by other patents, and the IPC (International Patent Classification) number are all key indicators. Besides, the index of patent text discrepancy can be used as an effective supplementary component to the above indicators. Finally, this study verifies the feasibility of the above indicators in identifying disruptive technologies in other patent collection fields, and these indicators can provide indicator references for subsequent related research.

Introduction

The rapid development of science and technology (S&T) is reshaping the world's competitive landscape. Among these elements, technological innovation has become the main focus. Bower and Christensen (1995) proposed the concept of disruptive technology for the first time by analyzing technological changes in small and medium-sized enterprises, thereby highlighting that disruptive technology can often replace existing mainstream technology in unexpected ways by not only opening up new markets but also forming new value systems. At present, many instances have revealed that in comparison to traditional or mainstream technologies, disruptive technologies have novel features, functions, development paths, etc., and can have a significant impact on technology paradigms, business models, and competitive situations. Therefore, disruptive technologies attract attention from the government and industry. For example, the Defense Advanced Research Projects Agency has developed a disruptive technological innovation management model to detect disruptive technologies (Cao et al. 2019). For companies, to maintain a competitive advantage in the market, they must rely on new technologies that have the potential to increase revenue (Taşkin, Adali, and Ersin 2004). In short, the identification and prediction of disruptive technologies have important societal, economic, and research significance.

Patent documents contain a wealth of technical information. The patent citation can reflect the ex post impact (Fleming 2001) or the market value (Gambardella, Harhoff, and Verspagen 2008) of the disruptive technology, and it can also be used to analyze the priori characteristics of the disruptive technology (Ahuja and Lampert 2001). Therefore, indicators designed for patent data are widely used to identify disruptive technologies or even predict their likely development (Momeni and Rost 2016). However, in the current practice of disruptive technology identification, the design of patent indicators is quite different. A unified standard for indicator evaluation has not yet been formed and the existing patent indicators mostly come from traditional qualitative technology identification such as foreseeable research. However, it does remain be further verified whether these indicators meet the essential characteristics of disruptive technologies. Besides, in current research, topic identification of disruptive technologies based on patent features is still relatively crude, and hence, it is vital to discuss how to adopt patent feature indicators that are more in line with disruptive technical features for identification. Given the above limitations, this study explores using patent data and machine learning methods to deeply excavate the the core characteristics and regular patterns of salient disruptive technologies from objective data and then build identification indicators of disruptive technology features that provide references for future follow-up work.

Related Work

Concept Development of Disruptive Technology

Initially, the concept of disruptive technology was aimed at managers who made investment or purchase decisions in the company and emphasized the impact of technology on developing existing products or markets (Christensen 1997). Then, the concept of "disruptive innovation" was proposed; it posits that the effects brought about by disruptive technologies are not limited to the technology itself but may also have a significant wider impact due to the introduction of new business models (Christensen and Raynor 2013). Although Christensen distinguished and explained the connotation of disruptive technology and innovation, these two concepts are often found to be used in combination without strict categorical boundaries in subsequent related studies (Dan and Chieh 2008). With disruptive technology's widespread in other fields, scholars have defined it from different perspectives, thereby expanding and enriching its significance (Table 1).

Table 1. Conceptual development of disruptive technology

Perspective	*Main points*	*Main viewpoints and representative scholars*
Market perspective	Emphasize the improvement and replacement of existing products	Disruptive technologies often provide a larger set of product performance combinations or differing performance implementation methods (Thomond and Lettice 2002; Huang and Sošić 2010).
	Pay attention to the relationship between disruptive technology and enterprise development	Defined from the perspective of latecomer companies occupying the market through disruptive technologies or in improving corporate competitiveness (Danneels 2004; Schmidt and Druehl 2008).
	Pay attention to customer needs, consumer behavior, etc.	Defined with consumer needs as the core and believes it can change market standards, consumer expectations, and destroy old markets or create new ones (Nagy, Schuessler, and Dubinsky 2016).
Technical perspective	Emphasize technological change and development	Disruptive technologies are combinations of existing technologies or brand-new technologies whose application will lead to a major paradigm shift (Kassicieh et al. 2002). Disruptive technology is a new dominant technology "derived" or "evolved" from established and technological systems, which can replace existing technologies and produce fundamental changes (Shaffer 2005).

A comprehensive analysis of the above concepts proposed by Christensen and subsequent scholars demonstrates that the definition of disruptive technology is mainly divided into two categories: one is based on Christensen's theory, focusing on the impact of technology on existing products or markets, and emphasizing the improvement or replacement of the existing market trends, and the second is to explain disruptive technologies from the perspective of the development of technology, focusing on the path of technological change and the related development, mode, and the significant impacts and changes thereby produced.

Table 2 Disruptive technology identification index based on patent characteristics

Technical features	*Identification index*	*Identification content*	*Identification features*
Technological breakthrough	Patent cited	The frequency of patent citations and changes	Reflects the influence of disruptive technology
	Patent technical topic	Topic similarity and difference of patent technology	Analyzes technical content such as patent abstracts and specifications, and evaluates technological breakthroughs
	Patent status	Including patent examination time, maintenance time, and litigation.	Reflects the cutting-edge breakthrough of technology
Technical Integration	IPC number	IPC quantity, IPC number combination, etc.	Cross-field or new field application of evaluation technology
	Number of patentees	Cross-field layout of related technologies owned by patentees	Assesses technology combination and integration capabilities
Technology development and diffusion	Number of applications	Number and changes of patent applications	Determines the period of technology
	Number of patents in the same family	Country count of patent family.	Reflects the market and technical value that can evaluate the feasibility of the technology
	Number of claims	Including the average number of claims, independent claims, and dependent claims	Reflects the feasibility of the technology entering the market
	Patent cited	The frequency of patent citations and changes	Reflects the influence, development, and diffusion of disruptive technologies
	Duration of patent examination	Time from patent application to authorization	Reflects the degree of recognition of patented technology

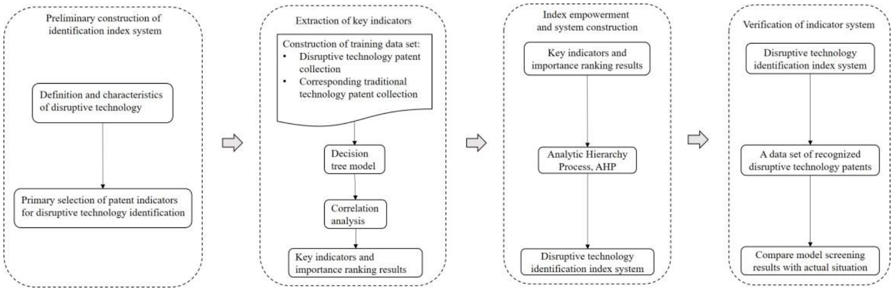
Literature Review of Disruptive Technology Identification Index Based on Patent Features

This study primarily focuses on the technological research perspective wherein research methods are mainly quantitative analysis, such as bibliometrics and patent analysis. Kostoff, Boylan, and Simons (2004) associate literature to identify disruptive technologies by integrating existing features and expert opinions for identification. After 2009, research on identification based on patent characteristics has gradually increased. Buchanan and Corken (2010) used patentee indicators to identify and evaluate whether a given technology can be said is disruptive. Dotsika and Watkins (2017) used keywords to construct a co-occurrence network to establish disruptive technology identification indicators, such as degree of centrality and intermediate centrality. Above all, as an essential source of information for technological innovation, patents are often used by scholars to explore, reveal, and assess the direction of or trend on technological development.

According to the definition of disruptive technology and relevant scholars' research, its main characteristics can be summarized into six aspects, namely, uncertainty, forward-looking, mutation, non-competitiveness, proliferation, and user value orientation (Brimley et al. 2013; Govindarajan and Kopalle 2006; Manyika et al. 2013). This study focuses on identifying disruptive technology topics from the perspective of patent characteristics and uses patent data to identify disruptive technologies' salient characteristics. Patent indicators, are generally divided into internal content feature and external feature indicators; the former includes the number of patent applications, patent citations, and patents of the same family, while the latter mainly involves the analysis of patent text content (Table 2).

Methods

This study's method is divided into four parts: a) the preliminary construction of the identification index system of disruptive technical characteristics, b) the identification of the critical indicators in the initially constructed index system, c) the construction of the evaluation index system, and d) the verification of the identification system (Figure 1).



Preliminary construction of identification index system
Definition and characteristics of disruptive technology
Primary selection of patent indicators for disruptive technology identification

A data set of recognized disruptive technology patents
Compare model screening results with actual situation

Figure 1. Research framework

Preliminary Construction of Indicators

This study uses the decision tree algorithm to extract features that can distinguish between disruptive and traditional technology at the patent features level. The decision tree algorithm is a classic algorithm deployed in data mining and machine learning. It mainly addresses the classification problem through the layered reasoning of the tree structure. Its root node is the sample set, i.e., the patent data set in this study. Its internal nodes can be used to determine the attributes of the sample, i.e., the assessment of various indexes of patents. Its leaf node is the output of the decision result. The nodes in the decision tree are generated by the features found with the largest information gain. Therefore, the decision tree model can be used to obtain those indicators that have a greater influence on the identification of disruptive technology patents. Compared with other traditional classification algorithms, the results of the decision tree model are easy to interpret, and the classification rules can be directly extracted. Compared with deep learning models such as neural networks, decision tree models are more suitable for small and medium data sets and require fewer parameters, and the results are more in line with the human analysis of problems. Decision tree generation algorithms include ID3, C4.5, and CART (Du, Wang, and Gong 2011; Yi, Lu, and Liu 2011). In the process of decision tree model training, this study uses the Light Gradient Boosting Machine (LightGBM) model to perform a five-fold cross-validation on the training results to provide a foundation for selecting the best model results.

Extraction of Key Indicators

After a preliminary ranking of the indicators' importance, it is crucial to use correlation analysis to filter the indicators with a higher degree of correlation due to the correlation between these indicators. This study explicitly measures the Spearman correlation coefficient, the Pearson correlation coefficient, and the partial correlation coefficient of the above indicators. In the calculation, the subversion potential of related patents representing disruptive technologies is assigned a value of 1, while the subversion potential of related patents representing traditional technical fields is assigned a value of 0. Generally, the greater the value of the correlation coefficient, the stronger the correlation between the two given variables. As the above-mentioned patent indicators are derived from scientific metrological analysis, they will inevitably have the specific relevant characteristics. Therefore, merely measuring the relevance of each indicator from the correlation coefficient may cause individual deviations. Therefore, this study adopted the partial correlation analysis algorithm for index analysis and considered the potential subversion variable as the control variable to measure the actual degree of correlation between the indicators. In brief, this study used three indicators to measure the degree of correlation of the disruptive technology theme identification indicators and provide a screening criterion for the indicators obtained through the decision tree model.

Model Validation

After obtaining the corresponding indicators, the indicators' applicability needs to be verified. Specifically, after the decision tree model training input data, the best model is selected through a five-fold cross-validation of the model results. The model is then used to train the patent data set in a specific field (including the disruptive technology patent data set) to deduce whether it can discern it.

Experiments

Data

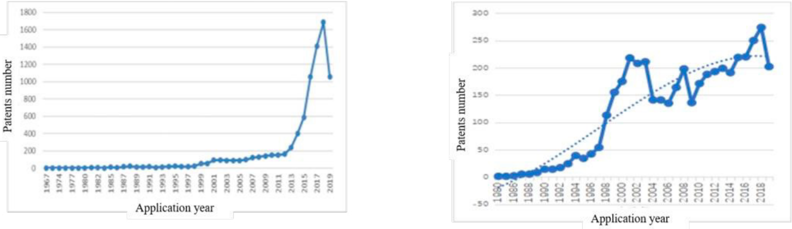
This study compared the disruptive technology's topic characteristics from the perspective of patent data by comparing the patent collections that have been identified as disruptive technologies and the parallel patent collections of traditional technologies. In terms of a specific selection of empirical fields, it selected biology as a valid disruptive technology paradigm and gene targeting technology as an exemplar of traditional technical field. The basis for choosing synthetic biology includes the fact that synthetic biology is a branch of biological sciences that only emerged in the 21st century. It originated from the reference to electronic circuits, which can imply that "humans can assemble organisms like assembled machines" becomes a reality (El Karoui, Hoyos-Flight, and Fletcher 2019). Synthetic biology is hailed as the third revolution in life sciences and has now been recognized as a disruptive technology. In recent years, synthetic biology has been widely used in many fields, including developing more effective vaccines and new drugs; improving drug production and development biological manufacturing, and biological management; and creating biosensors to detect toxic chemicals (Cameron, Bashor, and Collins 2014).

Synthetic biology is an interdisciplinary science, and its knowledge base and technical impetuses encompass the fields of chemistry, physics, information science, biological sciences, etc. It is not easy to correspond with the traditional technology of the development of synthetic biology. However, this study found that synthetic biology's hotspots are mainly gene editing to develop the programming of life systems, modular processing of metabolic pathways, and optimizing combinations between components, etc. Therefore, this study explored and selected the central corresponding traditional technology in this direction. Through literature research and expert consultation, it is found that gene targeting technology mainly uses screening markers and recombinases as the core to integrate external DNA into a specific position on the target cell's genome or site-specific mutations at predetermined target sites. It can be used to change a class of methods for cells' genetic characteristics (Capecchi 1989). Since its development, the new genome editing technology has the advantage of being a more efficient and straightforward technology, especially in the insertion and regulation of large-segment gene clusters. It has significantly improved the ability to change the cell genome accurately, which has led to the gradual development of traditional gene targeting technologies being supplemented (Meng and Ellis 2020). Based on this observation, this study aimed at researching synthetic biology-related technology patents and patents related to gene targeting technology and then construct a feature identification comparison to develop an indicator index.

After determining the empirical objects, Clarivate Analytics' Thomson Innovation (TI) database is used as a data source to procure data. This study focused on the themes of synthetic biology and gene targeting technology and used the database search function to search for relevant keywords to form the research data set. The time range of data collection is from the earliest application date retrieved in the database up to 2019. After obtaining the initial data, this study manually performed data deduplication, invalid data deletion, abnormal record screening, etc., to obtain the final patent data set, comprising 8195 patents related to synthetic biology from 1967 to 2019 and 4362 patents relate to gene targeting technology from 1980 to 2019.

Scientometric Analysis

The number of patent applications is often used to determine disruptive technologies' early neglected features. This study investigated the development trend of synthetic biology and gene targeting technology from the perspectives of changes in patent applications and changes in patent citations. By comparing these variables, it is noted that the development trend of the two is different, as shown in Figure 2.



Synthetic Biology

Gene targeting technology

Figure 2. Changes in the number of patents in synthetic biology and gene targeting technology

The development of synthetic biology techniques can be roughly divided into three stages based on the quantitative change trend:
Stage I: From 1967 to 2000, the number of synthetic biology-related patents was maintained at a low level. There are no more than 100 patent applications worldwide. It can be observed that its development has gone through a long process of incubation.
Stage II: From 2000 to 2007, the number of patent applications showed the first sudden change.
Stage III: Since 2008, the number of patents has increased exponentially. Moreover, it maintained a continuous upward trend and entered a rapid expansion stage, which saw a sudden marked upward trend in patent applications.

The changing trend of the number of patent applications for gene targeting technology can be fitted to the life cycle S curve: a) From 1980 to 1990, the number of patent applications increased gradually, which can be regarded as in the domain being in its infancy. This trend is different from the initial trend characteristics found in disruptive technologies. b) In 1994, gene targeting technology patents saw a significant increase for the first time and reached a peak in 2002, which was a period of rapid growth. c) From 2002 to 2007, the number of patent applications declined rapidly, reaching a trough in 2007; thereafter, the number of patent applications rose in fluctuations. Comprehensive qualitative research and expert consultation, in gene targeting technology, is currently in a mature development stage or perhaps even declining.

The changing trend of the patent applications number can reveal the development and evolution of disruptive technologies to a certain extent, including the initial long-term incubation process. When technological development shows a certain influence, the number of patents will undergo mutations. However, in the entire development process of disruptive technology, the number of patent applications has undergone more than one mutation. Therefore, only using the mutation characteristics of the number of patents to identify the embryonic period of disruptive technology will produce some errors, which need to be rectified through other analyses.

Index Construction for Disruptive Technology Identification

Through the previous literature research, 11 patent index features related to identifying disruptive technical topics are obtained. For the convenience of the following description, this study uses symbols to explain, the above indicators (Table 3).

Table 3 Symbol description of disruptive technology topic identification index

Symbol	*Indicators*	*Symbol*	*Indicators*
$F_{nCitPat}$	Number of cited patents	F_{nCla}	Number of claims
F_{nIPC}	IPC Number	$F_{nPatCit}$	Number of patents cited
$F_{nPatFam}$	Patent family number	$F_{nNonPatCit}$	Number of non-patents Cited in Patents
$F_{nPatFamCou}$	Number of patent family country	F_{PatSta}	Patent status (valid/invalid)
$F_{dPatExa}$	Duration of patent examination	F_{nPat}	Number of patentees
		$F_{PatTexTop}$	Patent textual topic

This study uses Python programming language to implement the decision tree classification model, takes the above-built data set and the patent indicators as the model's input items, and uses the technological subversion potential as the model's output items. During model training, the subversion potential of synthetic biology-related technology patents is assigned a value of 1, while the subversion potential of gene targeting technology patents is assigned a value of 0. In the decision tree model building process, first, we try to use only 10 external feature indicators. The accuracy of the cross-validation of training results is about 71% when using the Light GBM model. Then, after applying the TF-IDF (term frequency - inverse document frequency) algorithm and chi-square reduction to extract the patent title's content characteristics and considering text difference index into the model construction, we find that the accuracy of the model increases to 81%.

Using the decision tree model to analyze the results, the main indicators and their rankings that affect the score of technological disruption potential are obtained, which provides a basis for the subsequent construction of an indicator system for technology identification. As the decision tree model cannot distinguish between the importance of the patent's internal content feature and the external feature, only 10 external features' importance rankings are obtained (Table 4).

Table 4 Importance score of external features in disruptive technology topic identification

Indicator	$F_{nPatFamCou}$	$F_{dPatExa}$	$F_{nNonPatCit}$	F_{nCla}	$F_{nPatCit}$	F_{nIPC}	$F_{nCitPat}$	$F_{nPatFam}$	F_{PatSta}	F_{nPat}
Score	712	528	501	421	347	320	287	285	209	92

We used the correlation analysis algorithm in SPSS (Statistical Product and Service Solutions) v26.0 to analyze the index data of the above patent data set. Among them, the patent status index cannot be analyzed due to its unique data characteristics. The results reveal the following finding: a) Using Spearman correlation analysis can establish that the number of IPC, the number of citing patents, and the number of patents in the same family are more related to disruptive technologies' attributes and characteristics. b) Using Pearson correlation analysis can exhibit that the number of IPC numbers is strongly positively correlated with the number of patents in the same family. The number of cited patents is only slightly positively correlated with the number of patents in the same family. The number of citing patents is remotely positively correlated with the number of IPC numbers. The number of the patent family country is slightly positively correlated with the number of patent families. The correlation coefficients among other indicators are not high. c) When using partial correlation analysis to measure the correct degree of correlation between indicators, the results show a strong positive correlation between the number of patent family members and the number of IPCs. The number of cited patents is slightly positively correlated with the number of patent family members. The number of the patent family country is remotely positively correlated with the number of patent families (Table 5).

Combining the results of the correlation analysis of the above indicators, the number of IPCs has a strong correlation with the number of patents in the same family, and the number of cited patents has a marked impact influence on the number of patents in the same family and has a greater impact than the first six indicators. Therefore, this study selected the first six indicators as the key indicators of the identification index system: the number of patent family country, duration of patent examination, number of non-patents cited by patents, number of claims, number of patents cited by patents, and the IPC. After determining the criterion level and sub-criterion level of the index system and their indexes at all levels, the judgment matrix method is used to assign a relative weight to each index. Using the analytic hierarchy process to calculate the relative weight values between the above six external feature indicators, this study combines the important output results provided by the decision tree model and the above matrix scoring standards. After statistical collation, the following judgment matrix is obtained (Table 6).

After constructing the complete judgment matrix, the matrix operation is performed by the square root method to obtain the maximum eigenvalue of each indicator of the judgment matrix. The weight vectors of the matrix calculated by the relevant statistical algorithm are .46, .26, .14, .07, .04, .03 respectively, so the consistency test result is passed (CR = .067337161< .10). Therefore, it is judged that the index system constructed in this study is reasonable. The final technical feature identification system is thus obtained (Table 7).

Indicator Verification

This study uses the patent subset of the genome editing technology patent data set with the IPC number C07K001400 to verify the effectiveness of the above technical indicator system. Genome editing is a technology that uses a targeted modification of the genome to identify targets specifically for gene knockout and replacement. At present, three main genome editing technologies exit: artificial nuclease-mediated zinc finger nuclease technology, transcription activator-like effector nuclease technology, and RNA-mediated CRISPR-Cas9 nuclease technology. CRISPR-Cas9 technology is highly efficient and precise and has become a major milestone in developing genome-editing technology.

This study uses a subset of the IPC number C07K001400 in the genome editing technology patent. This patent subset is mainly related to the patented technology of peptides, which belongs to organic chemistry. A total of 288 related patents were retrieved in the TI database. According to the model's output, it is observed that 92.5% of the patents have attribute feature values higher than .5 points. The top five patents' IPC numbers are CN108610399A, KR2019113677A, CN108822217A, CN108822217A, WO2019185751A1 and CN107474129A. They are all related to the CRISPR-Cas9 system. It can be observed that the model can better identify disruptive technologies in patent concentrations.

Discussion and Conclusion

Following are the main study conclusions: The changing trend of patent applications' number can reveal the law of disruptive technologies' development and evolution to a certain extent; The effect of fusing the internal content features and external features of patent data is better than using only the external features to identify disruptive technologies; Six patent indicators are vital indicators according to decision tree model. These indicators are useful for subsequent use of patent data to identify subversion, while some of these indicators are somewhat different from traditional research. Then, this study further analyzes the significance of these indicators for the identification of disruptive technology:

a) Number of the patent family country: This indicator can reflect the patentee's recognition and confidence in the patent's development potential and market value. At present, in identification research, the number of patents in the same family is often used to measure this characteristic. However, this study revealed that the number of the patent family country may be more targeted.

b) Duration of patent examination: Different patents have different examination times due to their respective innovation development phases. Disruptive technology has the characteristics of being easily ignored or not being recognized in the early stage, which may affect the patent examiner's examination of the technology patent to a certain extent, thus affecting changes in the patent examination time. Currently, patent examination time has been used to research patent quality. This study highlighted that it can also be used in research related to disruptive technologies identification.

c) Number of non-patents cited in patents: The number of non-patents cited in patents reflects the relationship between technology and the S&T literature. When more non-patent literature is cited, it indicates that the technology patent has a sufficient scientific research foundation. This phenomenon is also in line with the long-term gestation and the phased outbursts of disruptive technologies.

d) Number of claims: The number of claims determines the scope of protection required by a patent, which is also a detailed description of the technical achievement characteristics. This indicator can reflect the characteristics of breakthroughs and the higher technological innovation of disruptive technologies.

e) Number of patents cited by patents: The quotations of patents to existing patents reflect the inheritance of technology or improve existing patents that show their innovation. In the overall index importance score, the back-cited features of patents are more important than the front-cited features, thereby illustrating the difference between disruptive technology and highly cited technology patents. Disruptive technologies may become highly cited patent technologies, but highly cited patents are not necessarily imbued with subversive potential. This aspect is also an identification standard that needs to be lucid and defined in identification research.

f) Number of the IPC: This aspect reflects the technical fields involved in the patent, such as reflecting the possibility of technological development or re-innovation of the technology in multiple technical fields and confirming the fact that disruptive technologies are new developments emerging from established and technical systems.

Research Limitations and Future Improvements

This study has the following limitations: (1) The construction of the index system in this article relies on the fields of synthetic biology and gene targeting technology, and the recognition effect in other fields remains to be verified. (2) In terms of extracting patent internal information, this study uses the TF-IDF algorithm, which ignores word position information, and thus, other models can be used to further extract patent text information.

As the development of disruptive technologies involves multiple aspects and types of data, this study will consider fusing patent data and market data to identify disruptive technologies in subsequent future research.

Abstract

Field normalization indicators are not reliable when a short citation time window is used. To solve this problem, two new field normalization indicators called the Weighted Category Normalized Citation Impact (WCNCI) and Total WCNCI (TWCNCI) were proposed by Wang and Zhang (Wang & Zhang, 2020; Wang & Zhang, 2021). The main idea of the two new normalization indicators is that a weighting factor, which is calculated as the correlation coefficient between citation counts of papers in the given short citation time window and in the fixed-length long window, is introduced to represent the degree of reliability of normalized citations. In this study, we conducted a theoretical analysis of the two new indicators. We first compared WCNCI with the crown indicator and new crown indicator in terms of how to handle recent publications. We found that WCNCI has the advantages of both the crown and new crown indicators. Furthermore, we also proved that WCNCI and TWCNCI have the consistency property, and that WCNCI simultaneously has the homogeneous normalization property. Additionally, we discussed how to handle overlapping fields when calculating WCNCI and TWCNCI.

Introduction

The citation count is a significantly important indicator used to measure the impact of publications in research evaluation. In some fields, the average number of citations per publication is much higher than those in other fields because of the inherent differences in citation practice among fields (Waltman et al., 2011b). For example, the citation counts of papers in Molecular Biology & Genetics are generally higher than those in Mathematics. The Essential Science Indicator (ESI) updated in January 2021 reported that the average number of citations per paper in Molecular Biology & Genetics was 24.58, whereas it was only 4.89 in Mathematics (Clarivate Analytics, 2021). Therefore, the citation counts of papers from different fields should not be compared directly. Field normalization methods are recommended in the guiding principles for research evaluation in the Leiden Manifesto (Hicks et al., 2015).

The literature on field normalization is extensive. The main methods include the mean-based method (Lundberg, 2007; Waltman et al., 2011b), *z*-score method (Vaccario et al., 2017), percentile rank method (Bornmann, Leydesdorff, & Wang, 2013; Bornmann & Williams, 2020; Leydesdorff & Bornmann, 2011), reverse engineering method (Radicchi & Castellano, 2012), citing-side method (Leydesdorff & Opthof, 2010; Waltman & van Eck, 2013; Zitt & Small, 2008), and method that combines the citing-side and percentile methods (Bornmann, 2020).

An important problem to solve is that field normalization indicators are not reliable when a short citation time window is used. Recent papers do not have sufficient time to be cited, and their citation counts are not as reliable as those of papers published many years ago. Based on an investigation of Web of Science journal papers published in 1980, Wang (Wang, 2013) found that the correlation coefficient between the citation counts in a 2-year citation time window and those in a more reliable citation window of 31 years was only 0.592 for all fields, and the correlation coefficients were even lower in the fields of Engineering Technology and Mathematics, dropping to 0.466 and 0.386, respectively. According to Nederhof et al. (Nederhof, Van Leeuwen, & Clancy, 2012), longer citation time windows yielded more favorable results than shorter windows, that is, the longer the citation time window, the more reliable the field normalization indicators. However, research evaluation practice is usually conducted in a short time period and cannot wait for decades. To address this problem, Wang and Zhang proposed the following solution (Wang & Zhang, 2020).

The normalization citation count of each paper is assigned a weighting factor to represent its degree of reliability. The weighting factor is calculated as the correlation coefficient between the citation counts in the short citation time window and those in a fixed reliable long citation time window (e.g., 31 years). The new weighted indicator at the aggregation levels (e.g., at the country level, institution level, or research group level) is called Weighted Category Normalized Citation Impact (WCNCI) (Wang & Zhang, 2020) and is an average performance indicator. Average performance indicators are scale free and cannot measure the total performance of a set of publications. Because of this, Wang and Zhang proposed a total performance indicator called Total WCNCI (TWCNCI), which equals the number of publications multiplied by the WCNCI of these publications (Wang & Zhang, 2021).

In this paper, we present a theoretical analysis of WCNCI and TWCNCI. We first compare WCNCI with CPP/FCSm (De Bruin, Kint, & Moed, 1993; Moed, Debruin, & Vanleeuwen, 1995) and Mean Normalized Citation Score (MNCS) (Waltman et al., 2011b) in terms of how to handle recent publications. Furthermore, we particularly pay attention to the consistency property of WCNCI and TWCNCI. Finally, we discuss how to handle overlapping fields when calculating WCNCI and TWCNCI.

Definition of indicators

In this section, we provide formal definitions of the six indicators: (1) average performance indicators: CPP/FCSm, MNCS and WCNCI; and (2) total performance indicators: CPP/FCSm×n (Waltman et al., 2011b), Total Normalized Citation Score (TNCS) (Waltman et al., 2011b) and TWCNCI.

CPP/FCSm is called the “crown indicator” and has been used for more than 20 years, whereas MNCS is known as the new crown indicator and adopts a different normalization mechanism.

CPP/FCSm is defined as

$$CPP\,/\,FCSm = \frac{\sum_{i=1}^{n} c_i / n}{\sum_{i=1}^{n} e_i / n} = \frac{\sum_{i=1}^{n} c_i}{\sum_{i=1}^{n} e_i} \qquad (1)$$

and MNCS is defined as

$$MNCS = \frac{1}{n}\sum_{i=1}^{n}\frac{c_i}{e_i}, \tag{2}$$

where c_i is the raw citation count of publication i. e_i is the expected citation count of publication i, which equals the average citation counts of all publications published in the same field, same year and with the same document type as publication i. n is the total number of publications in a publication set.

The CPP/FCSm indicator is the average performance ratio, whereas MNCS is the average of the individual performance ratios. CPP/FCSm and MNCS are both average indicators that measure the average performance of a set of publications. They cannot measure the total performance of a set of publications. Thus, we use two total performance indicators: CPP/FCSm × n and TNCS.

CPP/FCSm × n is defined as

$$CPP\,/\,FCSm\times n = \frac{\sum_{i=1}^{n}c_i}{\sum_{i=1}^{n}e_i/n} = \frac{n\sum_{i=1}^{n}c_i}{\sum_{i=1}^{n}e_i} \tag{3}$$

and TNCS is defined as

$$TNCS = MNCS\times n = \sum_{i=1}^{n}\frac{c_i}{e_i}. \tag{4}$$

The normalized citation indicator may not be sufficiently reliable when a short citation time window is used because the citation counts of recent papers are not as reliable as those of older papers. To solve this problem, Wang and Zhang introduced a new indicator called WCNCI (Wang & Zhang, 2020), which is defined as

$$WCNCI = \frac{1}{n}\sum_{i=1}^{n}w_i\frac{c_i}{e_i}, \tag{5}$$

where w_i is the weight of publication i, which represents the degree of reliability of the normalized citation count of publication i. w_i is equal to the correlation coefficient between citation counts of publications in the given short citation time window and those in a fixed long citation time window. For instance, if the correlation coefficient between the citation counts of papers published 2 years ago and 31 years ago in chemistry is 0.55, the normalized citation count of a chemistry paper with a citation window of 2 years should be multiplied by 0.55 to obtain its reliable scientific impact. The shorter (longer) the time window after publication, the lower (higher) the correlation coefficient and degree of reliability.

Similar to CPP/FCSm and MNCS, WCNCI also has a corresponding total performance indicator TWCNCI as follows:

$$TWCNCI = WCNCI\times n = \sum_{i=1}^{n}w_i\frac{c_i}{e_i}. \tag{6}$$

How to handle recent publications

How to handle recent publications is an important issue in the process of field normalization. It is not sufficiently reliable to calculate the field normalization indicator with a short citation time window, such as 2 years. Recent papers have not had sufficient time to accumulate citations after publication. However, using a short citation time window to evaluate the recent research performance of journals, researchers, institutions and countries is generally inevitable in research evaluation practice. For example, university rankings are usually published once a year and they generally use recent publications for the paper indicators. Scientific research administrators and policymakers also usually cannot wait for decades to evaluate the research impact of publications in actual research evaluation practice.

CPP/FCSm can be regarded as a type of weighted version:

$$CPP/FCSm = \frac{1}{n}\sum_{i=1}^{n} w_i \frac{c_i}{e_i}, \tag{7}$$

where w_i is given by

$$w_i = \frac{e_i}{\sum_{j=1}^{n} e_j / n}. \tag{8}$$

The weight w_i in CPP/FCSm implicitly allocates more (less) weight to older (more recent) papers because older (more recent) papers naturally have a relatively higher (lower) *e* value. However, w_i in CPP/FCSm simultaneously allocates more (less) weight to papers from fields with a higher (lower) expected number of citations, which is unreasonable and contrary to the original intention of field normalization, which is to eliminate field differences in citation counts and ensure that normalized citations are comparable across fields (Wang & Zhang, 2020). Unlike CPP/FCSm, MNCS gives the same weight to all publications; that is, recent publications play the same role as older publications. According to the opinion of Waltman et al. (Waltman et al., 2011a), the calculation of the MNCS indicator could leave out recent publications published less than 1 year to overcome quite a significant amount of noise in the indicator caused by recent publications.

However, leaving out recent publications may result in the loss of some useful information. Furthermore, leaving out recent publications cannot essentially solve the problem that the field normalization indicator is not reliable when a short citation time window is used because the degree of reliability of citation counts from different citation time windows is different; even the citation count of a paper published 10 years is not reliable compared with a paper published 30 years. Wang and Zhang proposed a new solution to this problem (Wang & Zhang, 2020). The normalization citation count of each paper is assigned a weighting factor to represent its degree of reliability. The weighting factor is calculated as the correlation coefficient between the citation counts in the short citation time window and those in a fixed reliable long citation time window. The shorter (longer) the citation time window, the lower (higher) the correlation coefficient and degree of reliability.

To compare the difference in handling recent publications between CPP/FCSm, MNCS and WCNCI, we consider the following fictitious example. Suppose there are two research units: research unit A and research unit B. Both research units are active in field X and field Y.

Research unit A publishes 10 publications during 10 years in field X and field Y, and so does research unit B. The characteristics of the datasets used to compare the three indicators are reported in Table 1. The numbers in parentheses represent the citation count and expected citation count of a publication. For example, (1, 0.1) means that a publication has been cited once and the average citation counts of all peer publications is 0.1. Peer publications refer to publications published in the same year and field as the publication investigated.

Table 1. Characteristics of the datasets used to compare CPP/FCSm, MNCS and WCNCI.

		Publishing age									
		1	2	3	4	5	6	7	8	9	10
Research Unit A	Field X	(1, 0.1)	—	(2, 3)	—	(5, 4)	—	(7, 6)	—	(8, 7)	—
	Field Y	(2, 0.15)	—	(5, 4)	—	(8, 7)	—	(12, 10)	—	(15, 12)	—
Research Unit B	Field X	(2, 0.1)	—	(10, 3)	—	(15, 4)	—	(20, 6)	—	(25, 7)	—
	Field Y	(3, 0.15)	—	(15, 4)	—	(24, 7)	—	(30, 10)	—	(35, 12)	—

Note: Research units A and B do not publish any papers in some years. This case is indicated by "—."

Weighting factors are necessary when WCNCI is calculated, and they are listed in Table 2. Five citation time windows are used: 1 year, 3 years, 5 years, 7 years and 9 years.

Table 2. Weighting factors of field X and field Y in different citation time windows.

	Citation time window				
	1 year	3 years	5 years	7 years	9 years
Field X	0.10	0.30	0.50	0.70	0.80
Field Y	0.15	0.40	0.65	0.80	0.95

Table 3 presents the values of the three indicators WCNCI, CPP/FCSm and MNCS calculated for research units A and B using two different approaches: including all publications and leaving out publications published no more than 1 year. The fourth column and sixth column show the differences between the two different approaches for the same indicator and research unit.

Table 3. Changes after leaving out recent publications for the three indicators.

Indicator	*Methods*	*Research unit A*	*Difference A*	*Research unit B*	*Difference B*
CPP/FCSm	All papers	1.22	0.05	3.36	0.08
	1-year papers excluded	1.17		3.28	
MNCS	All papers	3.24	2.11	6.71	3.32
	1-year papers excluded	1.13		3.39	
WCNCI	All papers	0.89	0.15	2.20	0.08
	1-year papers excluded	0.74		2.12	

As seen in Table 3, the values of the MNCS indicator change more significantly than those of CPP/FCSm and WCNCI after recent publications are left out. This demonstrates that MNCS is more easily influenced by recent publications than the other two indicators. Clearly, both CPP/FCSm and WCNCI have advantages over MNCS in terms of handling recent publications. Despite this, CPP/FCSm is not recommended because it allocates more (less) weight to papers from fields with a higher (lower) expected number of citations, which is unfair because different fields should be treated equally.

Consistency of indicators

In this section, we prove the consistency of WCNCI and TWCNCI. Consistency is a mathematical property that some indicators have and others do not.

We define some mathematical notation first. A publication can be expressed as an ordered triple (c, e, w), where c and e denote the actual citation count and expected citation count, respectively. The expected citation count of a publication equals the average citation counts of all publications published in the same field, in the same year and with the same publication type. w is the weight of a publication that represents the degree of reliability of the normalization citation count. c is a positive integer, whereas e and w are both positive real numbers. P is defined as the set of all ordered triples (c, e, w). The set including n publications can be represented by a multiset S = { (c_1, e_1, w_1), (c_2, e_2, w_2), … (c_n, e_n, w_n) }, where (c_1, e_1, w_1), (c_2, e_2, w_2), … (c_n, e_n, w_n)$\in P$. $\sum$ is the set of all non-empty multisets S.

WCNCI is an average performance indicator and TWCNCI is a total performance indicator. First, we prove the consistency of TWCNCI.

Definition 1. Let f_T denote a bibliometric indicator of the total performance of a set of publications. f_T is said to have the consistency property if

$$f_T(S_1) \geq f_T(S_2) \Leftrightarrow f_T(S_1 \cup \{(c,e,w)\}) \geq f_T(S_2 \cup \{(c,e,w)\}) \tag{9}$$

for all S_1, $S_2 \in \sum$ and all $(c, e, w) \in P$.

Definition 1 means that an indicator of total performance is consistent if adding the same publication to two different sets of publications never changes the way in which the indicator ranks the sets of publications relative to each other.

We assume that there are n_1 publications in S_1 and n_2 publications in S_2. According to the definition of TWCNCI,

$$\begin{aligned} f_T(S_1) \geq f_T(S_2) &\Leftrightarrow \sum_{i=1}^{n_1} w_i \frac{c_i}{e_i} \geq \sum_{j=1}^{n_2} w_j \frac{c_j}{e_j} \Leftrightarrow \left(w\frac{c}{e} + \sum_{i=1}^{n_1} w_i \frac{c_i}{e_i} \right) \geq \left(w\frac{c}{e} + \sum_{j=1}^{n_2} w_j \frac{c_j}{e_j} \right) \\ &\Leftrightarrow f_T(S_1 \cup \{(c,e,w)\}) \geq f_T(S_2 \cup \{(c,e,w)\}) \end{aligned} \tag{10}$$

TWCNCI has the consistency property.

We now consider the indicator WCNCI, which measures the average performance of a set of publications. For an indicator of average performance, we use a slightly different definition of consistency.

Definition 2. Let f_A denote a bibliometric indicator of the average performance of a set of publications. f_A is said to have the consistency property if

$$f_A(S_1) \geq f_A(S_2) \Leftrightarrow f_A(S_1 \cup \{(c,e,w)\}) \geq f_A(S_2 \cup \{(c,e,w)\}) \tag{11}$$

for all S_1, $S_2 \in \sum$ such that $|S_1| = |S_2|$, and all $(c, e, w) \in P$.

According to Definition 2, an average performance indicator is consistent if adding the same publication to two different but equally large sets of publications never changes the way in which the indicator ranks the sets of publications relative to each other.

We assume that there are *n* publications in both S_1 and S_2. According to the definition of WCNCI,

$$\begin{aligned} & f_A(S_1) \geq f_A(S_2) \Leftrightarrow \frac{1}{n}\sum_{i=1}^{n} w_i \frac{c_i}{e_i} \geq \frac{1}{n}\sum_{j=1}^{n} w_j \frac{c_j}{e_j} \Leftrightarrow \sum_{i=1}^{n} w_i \frac{c_i}{e_i} \geq \sum_{j=1}^{n} w_j \frac{c_j}{e_j} \\ & \Leftrightarrow \frac{1}{n+1}\left(w\frac{c}{e} + \sum_{i=1}^{n} w_i \frac{c_i}{e_i} \right) \geq \frac{1}{n+1}\left(w\frac{c}{e} + \sum_{j=1}^{n} w_j \frac{c_j}{e_j} \right) \\ & \Leftrightarrow f_A(S_1 \cup \{(c,e,w)\}) \geq f_A(S_2 \cup \{(c,e,w)\}) \end{aligned} \tag{12}$$

WCNCI has the consistency property.

The average performance indicator has another property called homogeneous normalization, which was discussed by Waltman (Waltman et al., 2011b).

Definition 3. Let f_A denote a bibliometric indicator of the average performance of a set of publications. f_A is said to have the homogeneous normalization property if

$$f_A(S) = \frac{\sum_{i=1}^{n} w_i c_i}{ne} \tag{13}$$

for all S = { (c_1, e_1, w_1), (c_2, e_2, w_2), … (c_n, e_n, w_n) } $\in \sum$ and $e_1 = e_2 = ... = e_n = e$.

The homogeneous normalization property aims to describe homogeneous sets of publications. In this paper, a homogeneous set of publications means that all publications belong to the same field and were published in the same year. It is not difficult to confirm that WCNCI has the homogeneous normalization property.

To summarize, WCNCI and TWCNCI both have the consistency property, whereas WCNCI simultaneously has the homogeneous normalization property.

How to handle overlapping fields

In this section, we focus on how to calculate the values of WCNCI and TWCNCI in the case of overlapping fields.

Because some journals in the Web of Science database may belong to more than one subject category, if we calculate WCNCI and TWCNCI based on the subject categories in the Web of Science database, we will encounter the problem of handling overlapping fields, that is, when a publication belongs to more than one subject category. Therefore, we need to consider how WCNCI and TWCNCI should be calculated.

We use a fictitious example as an illustration. Suppose there are only three fields: field X, field Y and field Z. Five publications are distributed across the three fields. For each publication, the field it belongs to, number of citations, years since publication and weight representing the degree of reliability of the normalization citation count are listed in Table 4. Notice that publication 5 simultaneously belongs to field X and field Y.

Table 4. Five publications and the fields to which they belong.

	Field	*Citations*	*Publishing age*	*Weight*
Publication 1	X	2	3	0.15
Publication 2	X	3	3	0.15
Publication 3	Y	6	1	0.10
Publication 4	Z	10	5	0.50
Publication 5	X and Y	4	4	0.25

The weighting factors of the three fields are listed in Table 5. Publication 1 belongs to field X, and its weight is 0.15 because the correlation coefficient between the citation counts in the 3-year citation time window and those in the fixed long citation window (31 years) in field X equals 0.15. The weights of publications 2, 3 and 4 equal 0.15, 0.10 and 0.50, respectively. Half of publication 5 belongs to field X and half to field Y. Its weight equals the average weight of field X and field Y, that is, 0.25.

Table 5. Weighting factors of fields X, Y and Z.

	Citation time window				
	1 year	2 years	3 years	4 years	5 years
Field X	0.05	0.10	0.15	0.20	0.30
Field Y	0.10	0.20	0.25	0.30	0.40
Field Z	0.20	0.24	0.32	0.40	0.50

Now we consider calculating the expected citation counts of the five publications. Publications 1, 2, 3 and 4 belong to one field, and it is relatively easy to calculate the expected citation counts. Publication 5 belongs to fields X and Y, and its citations are divided equally between fields X and Y. Both publications 1 and 2 belong to field X, and therefore their expected citation counts equal the average citation counts of all publications published in field X. The expected citation counts of publications 1 and 2 are given by

$$e_1 = e_2 = \frac{2+3+4/2}{1+1+1/2} = \frac{14}{5}. \tag{14}$$

As can be seen, half of the citation count of publication 5 is used in Equation (14) because publication 5 is divided equally between fields X and Y. The expected citation count of publication 3 equals

$$e_3 = \frac{6+4/2}{1+1/2} = \frac{16}{3}, \tag{15}$$

where publication 5 is also divided equally between fields X and Y.

The expected citation count of publication 4 equals 10 because field Z consists of only one publication that is cited 10 times, and e_4 =10.

It is slightly complicated to calculate the expected citation count of publication 5. Two methods exist, which are the arithmetic average and harmonic average of e_1 and e_3 when publication 5 simultaneously belongs to field X and field Y. When the arithmetic average is adopted,

$$e_5 = \frac{14/5 + 16/3}{2} = \frac{244}{15}. \tag{16}$$

Calculating the values of WCNCI and TWCNCI for the set of five publications, we obtain

$$WCNCI = \frac{1}{5}\left(0.15 \times \frac{2}{14/5} + 0.15 \times \frac{3}{14/5} + 0.1 \times \frac{6}{16/3} + 0.5 \times \frac{10}{10} + 0.25 \times \frac{4}{244/15}\right) \approx 0.19 \tag{17}$$

$$TWCNCI = 5 \times 0.19 = 0.95. \tag{18}$$

The other method used to calculate the expected citation count is the harmonic average. Then we have

$$e_5 = \frac{2}{\frac{1}{14/5} + \frac{1}{16/3}} = \frac{224}{61}, \tag{19}$$

which yields

$$WCNCI = \frac{1}{5}\left(0.15 \times \frac{2}{14/5} + 0.15 \times \frac{3}{14/5} + 0.1 \times \frac{6}{16/3} + 0.5 \times \frac{10}{10} + 0.25 \times \frac{4}{224/61}\right) \approx 0.23 \tag{20}$$

$$TWCNCI = 5 \times 0.23 = 1.15. \tag{21}$$

According to Waltman et al. (Waltman et al., 2011b), MNCS has the nature of a baseline. If the value of the MNCS indicator of a research unit equals one, this means that the citation impact of the research unit equals the world average. If the value of the MNCS indicator is greater (less) than one, this means that the citation impact of the research unit is above (below) the world average. Waltman et al. (Waltman et al., 2011b) used the arithmetic average and harmonic average approach respectively to calculate the expected citation counts of publications published in more than one field. They found that the harmonic average approach could ensure that the baseline of MNCS always equals one. They therefore argued that the most appropriate approach to deal with overlapping fields is the harmonic average. The WCNCI indicator also has the nature of a baseline. However, the baseline of WCNCI is not equal to one, as is MNCS, but equals the average of all publications' weights. In our example above, the baseline of WCNCI could be calculated as

$$WCNCI_{baseline} = \frac{1}{5}(0.15 + 0.15 + 0.1 + 0.5 + 0.25) = 0.23. \tag{22}$$

We adopt both the arithmetic average and harmonic average to calculate the average citation impact of different fields in Equations (17) and (20). From the perspective of the baseline nature of the WCNCI indicator, it is obvious that the harmonic average approach is more appropriate for dealing with the problem of overlapping fields. This finding coincides with that of Waltman et al. (Waltman et al., 2011b). However, the arithmetic average approach provides a clear physical meaning and intuitive interpretation of the citation impact of a research unit. The two average approaches above provide opposite choices. In the future, more studies need to be conducted on how to select an appropriate average approach between the arithmetic average and harmonic average in the case of handling overlapping fields.

Discussion and conclusion

There have been several arguments about whether the CPP/FCSm indicator or MNCS indicator is more appropriate. Generally, academics prefer MNCS because it has a clear physical meaning. However, MNCS is not perfect in dealing with publications with different citation time windows. The citation impact of a recent publication is unreliable because recent publications have not had sufficient time to be cited; that is, recent publications and publications published many years ago should be treated in a different way when calculating the normalized citation impact. This is the limitation of the new crown indicator MNCS.

CPP/FCSm can be regarded as a type of weighted version of the MNCS indicator. It implicitly gives more (less) weight to older (more recent) publications. However, CPP/FCSm simultaneously gives more weight to publications from fields that have a higher expected number of citations, which is unfair because all fields should be treated equally.

WCNCI and TWCNCI retain the advantages and avoid the disadvantages of CPP/FCSm and MNCS. The two new field normalization indicators directly give more (less) weight, which is calculated as the correlation coefficient between citation counts of publications in the given short citation time window and those in a fixed long citation time window, to older (more recent) publications.

In this paper, we proved that both WCNCI and TWCNCI have the consistency property and that WCNCI simultaneously has the homogeneous normalization property. We also discussed the problem of handling overlapping fields when calculating WCNCI and TWCNCI. The arithmetic average approach and harmonic average approach are two commonly used methods. Each has pros and cons. There is no consensus on which one is better, so more studies need to be conducted in the future.

Acknowledgments

We thank Zhihui Zhang, PhD, from CNKI for his valuable suggestions on earlier draft of this paper.

Abstract

The classification of scientific literature into appropriate disciplines is one of the essential preconditions of valid scientometric analysis and is significant in the practice of research assessment. In this *research-in-progress* paper, we compared the disciplinary classifications of publications in *Nature* based on three different approaches across three different systems: WoS categories provided by Incites based on the disciplinary affiliation of the majority of its references; FOR major and minor fields provided by Dimensions based on the machine learning techniques; and *Nature* subjects constructed by Springer Nature based on the author-selected subject area tags in the journal's tagging system. The preliminary results show that, the single category assignment in Incites based on the disciplinary affiliation of cited references seems quite unreasonable for a large proportion of papers. The comparison results between Dimensions and *Nature* also show significant differences: only 1322 (16%) publications share the same classification results. Further investigations including a closer look at the "inconsistent" results, a deeper insight and methodological analysis is needed in the completion of the study.

Introduction

The classification of science into a disciplinary structure is as old as science itself (Glänzel & Schubert 2003). Classification systems assign scholarly literature into disciplines, which can help us delineate fields and identify their thematic structures(Young & Belanger 1983), and of great significance on scientific evaluations (Shu et al. 2020).

In the last decades, multiple methods have been developed to identify academic disciplines to which publications belong. For an overview of the history of classification systems, one can refer to Gläser et al. (2017). Most classification systems of publications are based on journal assignment, and it is most commonly adopted by major bibliographic databases such as Clarivate Analytics' Web of Science (WoS) and Elsevier's Scopus. However, using such classification systems, all papers published in a given journal are classified in the same discipline (or set of disciplines), which has been treated as a limitation. As stated by Leydesdorff & Bornmann (2016) and Shu et al. (2019), these journal level categories do not provide sufficient analytical clarity to carry bibliometric normalization in evaluation practices.

There are three main solutions to the classification problem on article level. The first is the citation-based classification approach. Waltman & van Eck (2012) clustered almost 10 million publications to 20 research areas based on their citation relations, and the algorithms are continuously optimized (Traag et al. 2019). Klavans & Boyack (2017) compared the accuracies of topic-level taxonomies based on the clustering of documents using direct citation, bibliographic coupling, and co-citation. The second is the text-based algorithmic approach.

Boyack et al. (2011) clustered over two million biomedical publications based on nine different document-document similarity matrices generated from information extracted from their titles, abstracts and subject headings. Eykens et al. (2019) attempted to classify sociology publications with supervised machine learning algorithms based on the textual information from titles and abstracts. The third is the author-selected-based approach. Chinese library classification (CLC) system has been used at the paper-level by asking authors to provide the CLC code when submitting their manuscript (Shu et al. 2019). McGillivray & Astell (2019) also introduced the subject tagging system constructed Springer Nature based on author-selected subject area tags, which is one of the data sources in this study.

In this study, we attempt to assess how citation-based classification (in this case the Incites WoS categories) and text-based algorithmic classification (in this case the Dimensions Fields of Research, FOR) perform on the individual article level, in comparisons with Springer Nature's subject classification based on author-selected subject tagging.

Data and methods

In this exploratory study, we chose research articles and letters[1] published during 2010-2019 in the multi-disciplinary journal *Nature* as the data sample. The three different classification systems and corresponding methods used in this study are briefly introduced as follows:

1) *Web of Science (WoS) Categories*

The WoS schema comprises 250+ categories, and each journal and book covered by the WoS core collection is assigned to at least one WoS category. Additionally, all articles in theWoS categories: '*Multidisciplinary Sciences*', '*Medicine, General and Internal*' are reclassified into specific categories based on the disciplinary affiliation of its cited papers. The results can be obtained from Incites™. After gathering all cited references, along with the respective WoS categories assigned to the journals in which the cited references occur, the target paper is then reclassified to the most frequently occurring category from this distribution. Finally, one publication is only assigned to one WoS category.

2) *Fields of Research (FOR) classification*

The Fields of Research (FOR) classification is a component of the Australian and New Zealand Standard Research Classification (ANZSRC) system developed in 2008. It contains 22 divisions (broad subject area, FOR2) and 159 groups (detailed subsets of these categories, FOR4). FOR categories are built in Dimensions using emulations of the categorisation systems based on machine learning guided by topic experts. In Dimensions, one publication may be assigned to multiple FOR4 or FOR2 categories with the classifying algorithm. The assignments of FOR classifications to each publication in *Nature* can be obtained from the website of Dimensions.

3) *Nature subjects*

Springer Nature constructed a standardized structure for the subject tagging of its own publications (McGillivray & Astell 2019). The subject tagging system is based on author-selected subject area tags, which are chosen at the point of submission and inserted into the article's XML at publication. There are thousands of subject area tags in *Nature*'s system, and they are aggregated to 95 second-level subjects and 8 top-level subject areas. Publications can have as many subject area tags associated with them as the article's authors choose. This information is available on the article online-page in the website of *Nature*, and all subjects linked to each document are listed in an integrated website[2].

For the comparability across different classification systems, a uniform classification system is needed. Since the mapping correspondence between OECD Fields of Research (FOS) and WoS

[1] The document types, Article and Letter, are defined according to the *Nature*'s website. They are both peer reviewed research papers published in *Nature*.

[2] https://www.nature.com/nature/browse-subjects

categories can be obtained from Incites-Help[3], and the correspondence table between OECD FOS and FoR can be obtained from the Australian Bureau of Statistics (ABS) official website[4], OECD classification was chosen as the uniform classification system here. As for the correspondence between *Nature* subjects and OECD, we made a manual match through the following steps: 1) Direct mapping of *Nature* subjects and OECD sub-fields with specific feature words (for instances, *chemistry*, *materials science*, etc.). 2) For those subjects with unclear feature words (for instances, *risk factors*, *biotechnology*, etc.), we manually mapped them to OECD sub-fields by referring to the *Nature*'s top-level areas and viewing related papers. 3) For the three *Nature* subjects with broad coverage (*Engineering*, *Agriculture,* and *Social sciences*), we further crawled each paper's subject area tags, and assign each paper to the related OECD sub-fields according to their subject area tags. Specific data acquisition and mapping methods are outlined in figure 1.

After combining all data obtained from the above three platforms/databases, we finally got the total data sample with 8232 papers published in *Nature* during 2010-2019.

Results

The comparison between Incites and Nature

Firstly, we divided all publications into three groups according to the comparison results based on OECD "subfields". Note that in Incites, each paper is assigned to a unique subfield, while *Nature* allows multi-assignments. The results are presented in figure 2.

Group 1 (Identical): The OECD subfield mapped from Incites and *Nature* is identical. 2309 publications, accounting for 28% of all publications belong to this group.

Group 2 (Partial identical): 4869 (59%) publications are assigned to more than one OECD subfield in *Nature* system, while the subfield mapped from Incites is only one of the multi-assignments. For example, paper A is classified into subfields *a* and *b* in *Nature* system, and the same paper is assigned to only subfield *b* according to Incites.

Group 3 (Inconsistent): 1054 publications (13%) have completely different classification results of the OECD subfield(s) between Incites and *Nature*. For example, paper A is classified into

[3] https://incites.help.clarivate.com/Content/Research-Areas/oecd-category-schema.htm
[4] https://www.abs.gov.au/AUSSTATS/abs@.nsf/DetailsPage/1297.02008?OpenDocument

subfields *a (or* and *b)* in *Nature* system, and the same paper is assigned to subfield *c* according to Incites.

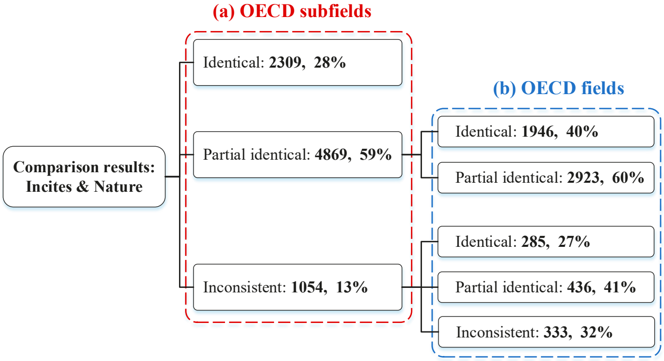

Figure 2. The comparison results between Incites and *Nature* based on mapped OECD (sub)fields

As a second step, we extended the similar comparison based on OECD "major fields" for publications in group 2 and group 3. For publications in group 2, 1946 papers (40%) are with the same OECD major field in both Incites and Nature systems. The rest of publications in this group are assigned to at least two OECD major fields in Nature, and the field assignment from Incites is only one of them. For publications in group 3, 285 papers (27%) are assigned to the same major field across the two systems, and 333 publications (32%) have completely different classifications even when adopting the OECD major fields.

We roughly calculated the proportion of the number of references with the largest subject category to the total number of referenced subject categories in each paper. The proportions of 4217 publications (accounting for 51% of the total sample) are less than 30%, and that of 8076 (98% of the total sample) publications are smaller than 50%, which shows clear unreasonableness of the single category assignment in Incites. Representative examples of publications in group 2 and group 3 have been found to demonstrate the problems of Incites reclassification, but restricted to the length of RIP paper, an in-depth analysis will be provided in the full version. In addition, the categories of cited references are via journals classification. By comparing the journal- and paper- level classifications for the same set of papers and journals, Shu et al. (2019) reported that half of papers could be misclassified in journal classification systems.

The comparison between Dimensions and Nature

All publications are firstly divided into three groups according to the comparison results based on OECD "subfields". Both Dimensions and *Nature* allow multi-assignments, which add to the complexity of comparison. The results are presented in figure 3.

Group 1 (Identical): The OECD subfield(s) mapped from Dimensions and *Nature* are identical. 1322 publications, accounting for 16% of the total sample belong to this group, of which 86% are assigned to one single subfield in both classifications.

Group 2 (Partial identical): This group comprises three sub-groups of publications: 1) The OECD subfield(s) mapped from Dimensions is a subset of subfields mapped from *Nature* (2407 papers, 29% of the total sample). 2) The OECD subfield(s) mapped from *Nature* is a subset of subfields mapped from Dimensions (1350 papers, 16%). 3) The OECD subfield(s) mapped from the two systems are partly identical, but none could be identified as subset of the other (2518 papers, 31%).

Group 3 (Inconsistent): The OECD subfield(s) mapped from Dimensions are completely different with the subfield(s) mapped from *Nature* (635 papers, 8%).

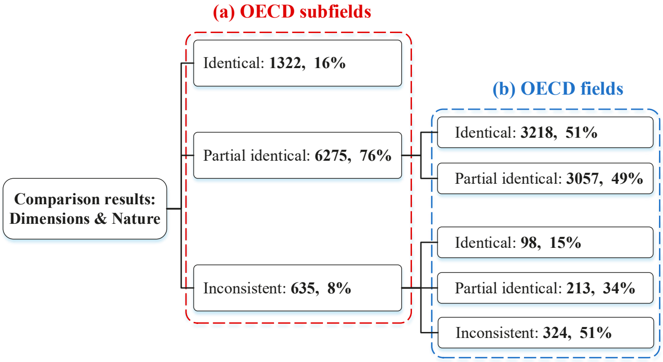

Figure 3. The comparison results of Dimensions and *Nature* based on mapped OECD (sub)fields

We further extended the comparison based on OECD major fields for publications in group 2 and group 3. For publications in group 2, 3218 papers (51%) are with the same OECD major field(s) in both Dimensions and *Nature* systems. 3057 (49%) papers are still partial identical, which can be further divided into: 1) The OECD field(s) mapped from Dimensions is a subset of fields mapped from *Nature* (2405 papers, 79% of the total sample). 2) The OECD field(s) mapped from *Nature* is a subset of fields mapped from Dimensions (565 papers, 18%). 3) The OECD field(s) mapped from the two systems are partly identical, but none could be identified as subset of the other (87 papers, 3%). For publications in group 3, 98 papers (15%) are assigned to the same major field across the two systems, and 324 publications (51%) have completely different classifications even when adopting the OECD major fields. An in-depth analysis of representative publications in group 2 and group 3 will be presented in the full version.

Discussion and conclusion

In this paper, we obtained the disciplinary classifications of publications in *Nature* based on three different approaches across three different systems. The comparison results of Incites and *Nature* show that, the OECD subfield of 2309 (28%) publications mapped from Incites and *Nature* are identical. 4869 (59%) publications are assigned to more than one OECD subfield in *Nature*, while the subfield mapped from Incites is only one of them. And 1054 (13%) publications have completely different classification results of the OECD subfield(s) between Incites and *Nature*. On the one hand, the single category assignment based on the disciplinary affiliation of cited references seems quite arbitrary. On the other hand, the categories of cited references are based on journal-focused solutions. The accuracy has been problematized since the existence of journals that publish papers from multiple research areas and papers published in those journals beyond their fields (Shu et al. 2019; Milojević 2020). Being aware of the characteristics and limitations of the existing categorization of research publications, a bottom-up approach demonstrated in InCites™ Citation Topics was also introduced (Szomszor et al. 2021). Further investigation on this new citation-based, dynamic classification scheme will be performed in future work.

The comparison between Dimensions and *Nature* shows that, there are 1322 (16%) publications whose OECD subfield(s) mapped from Dimensions and *Nature* are identical. 6275 (36%) publications are partial identical. And 635 papers (8%) are completely different. As stated above, the FOR categories are built in Dimensions using emulations of the categorization systems led by supervised machine learning. However, different techniques and methodologies employed in text documents classification have their own limitations. Firstly, the classifier training should be performed on the basis of large number of training text terms, which is very laborious. And if the predefined categories changed, these methods must collect a new set of training text terms. Secondly, most traditional methods haven't considered the semantic relations between words, so the accuracy of related classification methods still remain to be improved. In addition, although it is assumed that the classification of Springer Nature is more accurate than the other two classification systems considering the authors' self-selected subject area tags, the accuracy still needs to be further evaluated.

In this preliminary study, we briefly demonstrate the comparison results of paper-level classifications across Incites, Dimensions and *Nature* subjects. Further investigations including a closer look at the "inconsistent" results, a deeper insight and methodological analysis is needed in the completion of the study. Our final results will be presented at ISSI 2021 if we are given the possibility to do so.

Abstract

Compared to the traditional subscription-based business model, Open Access (OA) publishing has many advantages. It can make science accessible to a wider public and expand individual researchers' influence and increase the potential impact of their research. This study covers all articles and reviews published from China and the USA from 2010 to 2019 with the aim of analyzing the prevalence and impact of different types of OA research articles. We find that the USA has a higher percentage of OA publications than China. American OA articles are more frequently in the Green and Bronze types of OA, while China publishes relatively more in Gold journals covered in DOAJ. Regarding citations, hybrid OA publications from American researchers have the highest impact, while the non-OA publications articles have the lowest impact. Green OA publications from Chinese researchers have the highest impact, while those appearing in Gold DOAJ journals have the lowest impact. The differences can be explained by national research evaluation and OA policies.

Introduction

Open Access (OA) is a policy for change in the international infrastructure of scientific publishing to make publications freely available on the public internet. The change was initiated from university libraries and taken on by research policy at the governmental level. The policy is now partly supported by the international academic communities and fully by the major scientific publishers, who are turning their business model from subscription fees to author payment.

The focus of our study is on the OA development in the two largest contributing countries to the world of science. With its fast and continuous economic and scientific development, China has become a prominent and influential nation in science (Zhou et al., 2008). Since 2016, the number of researchers and scholarly articles in China have surpassed the corresponding numbers of the USA (Tollefson, 2018). As the two largest countries by the number of scientific publications, the policies and developments in the USA and China towards OA play an important role in the change of the scientific publishing infrastructure internationally.

Both American and Chinese authorities have been continuously active in the promotion of OA. In 2013, president Barack Obama's administration introduced a policy that requires taxpayer-funded research to be made freely available online within 12 months of its publication in a journal (Subbaraman, 2019). The National Institutes of Health (NIH) in the USA has also allowed a maximum of 12-month embargo to support Green OA (National Institutes of Health, 2015). In 2014, the National Natural Science Foundation of China (NSFC) and the Chinese Academy of Sciences (CAS) issued a statement announcing that their sponsored researchers should deposit their articles into online repositories and make these articles publicly accessible within 12 months of publication (Van Noorden,2014). At the 14th world OA conference in

Berlin in 2018, China's National Science Library (NSL), National Science and Technology Library (NSTL), and NSFC announced their support for Plan S (Schiermeier, 2018). During the meeting, Xiaolin Zhang, chair of the Strategic Planning Committee of the NSTL, said that the NSFC, NSTL and NSL will all support the government's request to make research papers open immediately after publishing. They also announced their support for a wider range of flexible and inclusive measures to achieve this goal, which means that China could adopt other OA types than Gold OA to achieve Plan S. At the same time, the USA federal agencies stayed with policies developed in 2013. "*We don't anticipate making any changes to our model*," said Brian Hitson of the USA Department of Energy in Oak Ridge, Tennessee, who directs this agency's public access policy (Rabesandratana, 2019). The statement indicated that the USA still prefers the publishing model of Green OA. However, the Scholarly Publishing and Academic Resources Coalition, a group that represents more than 200 USA college and university libraries, said that its members "*wholeheartedly endorse updating current policy and eliminating the unnecessary 12-month waiting period* (Subbaraman, 2019)."

There are some similarities in the OA policies of the two countries. For example, both require researchers to deposit their funded articles online for free within 12 months after publication. But in recent years, some institutions are beginning to adjust their policies to achieve OA as soon as possible after the articles are published.

A comparison has not been made so far of the OA output of the two major publishing countries and the impact of different types of OA publications in relation to national policies. We investigate the prevalence and impact of different types of OA publications from the two countries to answer these questions:

- Q1: What is the prevalence of OA publishing in China[1] and the USA?
- Q2: What types of OA publishing are preferred in the two countries?
- Q3: What is the citation impact of the different types of OA publications in the two countries?

Data and methods

Types of OA

This study is based on information made available in Web of Science by *Clarivate* in collaboration with *Our Research* and their Unpaywall database.

This source of information distinguishes between five types of OA articles according to the license policy of the journals:

1) *DOAJ Gold*. Articles published in journals listed on the Directory of Open Access Journals (DOAJ). To be listed on the DOAJ, all the articles in these journals must have a license in accordance with the Budapest Open Access Initiative.
2) *Hybrid (Other Gold)*. Hybrid open access articles are those identified as having a Creative Commons (CC) license by the Unpaywall Database but are not in journals listed on the DOAJ. Hybrid journals are based on subscriptions but give free access to individual articles against author payment.
3) *Bronze*. The license for these articles is either unclear or is in the Unpaywall Database as articles without CC license that are free-to-read on the publisher's site.
4) *Green*. including Green Published, the final published versions of articles hosted in an institutional or subject-based repository, and Green Accepted, accepted final versions of manuscripts hosted on a repository without the publisher's copyediting or typesetting.
5) *Non-OA*. All other research articles.

[1] China in this paper refers to mainland China.

Data collection and processing

Data for this study were collected from InCites, an analytical tool based on Web of Science[2]. To cover all different types of OA research articles, we selected all articles and reviews published by at least one Chinese author (regardless of the author's position) and all articles and reviews published by at least one American author from 2010 to 2019. The 22 disciplines of the Essential Science Indicators (ESI) were selected for the subject classification. Since InCites does not provide information about the first author/corresponding author and whether there is international collaboration in each document, we added this information by downloading all documents from Web of Science. The data processing procedures are shown in Figure 1.

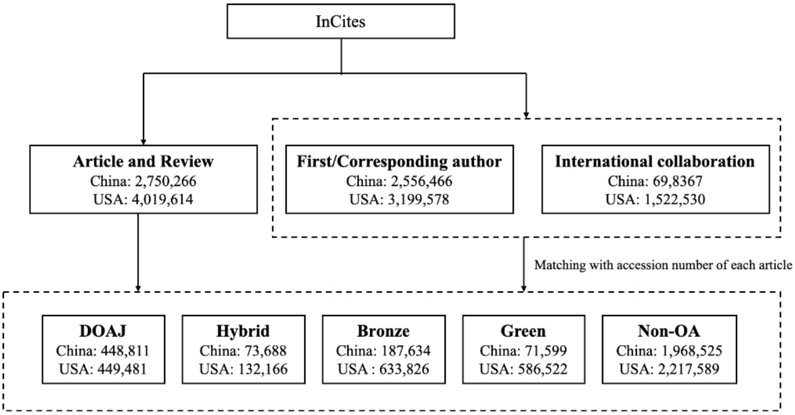

Figure 1. The procedures of data processing.

When multiple open access versions of an article are available, Web of Science prioritizes publisher-hosted content (i.e., gold, hybrid, or bronze), then the most complete version (i.e., for green OA, published version over accepted version over submitted version) (Bosman & Kramer, 2018). Web of Science only includes the 'best' OA location as determined by this algorithm. However, many articles are still classified into multiple OA types, which may affect the analysis. To ensure the accuracy of our study, we relabeled the OA types of all multiple assignment articles to ensure that each article belongs to only one type of OA. Following the example of Piwowar (2019), if an article occurs in both a Gold journal and an OA repository, it is classified as Gold, not Green. Adding other principles from Web of Science[3], the instances of multi-assignment are treated this way in our study: 1) DOAJ in combinations with Green is classified as *DOAJ*; 2) Hybrid in combinations with Bronze or Green are classified as *Hybrid*; 3) Bronze in combinations with Green is classified as *Bronze*.

Results

The prevalence of OA in China and the USA

Figure 2 shows the total number of research articles, the number of OA research articles, and the percentage share of these OA research articles in China and the USA from 2010 to 2019. The OA gap between China and the USA, both in relative and absolute numbers, has gradually decreased and the policy-driven transition to OA is evident for both countries, at least until 2017, after which it stagnated in China and decreased in the USA. This remarkable change will

[2] https://incites.clarivate.com/#/landing. InCites dataset updated Dec 17, 2020. Includes Web of Science content indexed through Nov 30, 2020.
[3] https://clarivate.com/webofsciencegroup/solutions/open-access/

be discussed and analyzed in the following as we have a closer look at the different types of OA research articles.

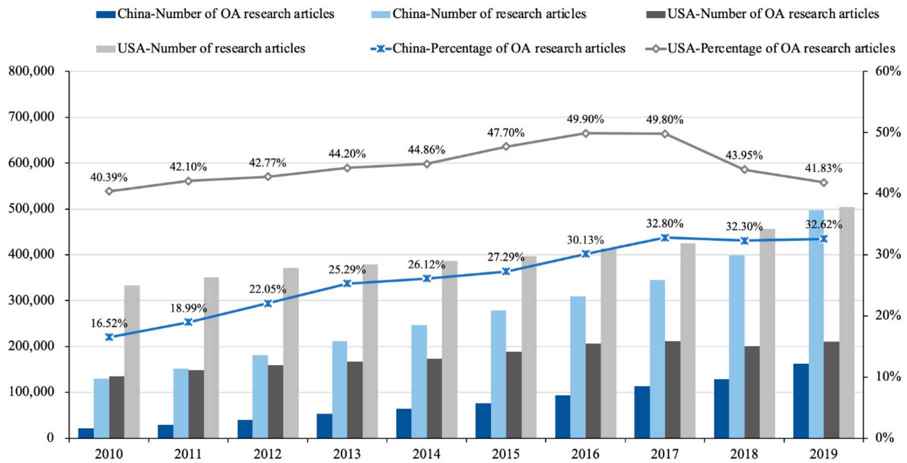

Figure 2. Total number of research articles, number of OA research articles, and the percentage of OA research articles from 2010 to 2019.

The percentage shares among five types of OA research articles in China and the USA from 2010 to 2019 is shown in figure 3. After 2017, the percentage of Green and Bronze OA research articles in the USA began to decrease, while the percentage of DOAJ and Hybrid OA research articles continued to increase. The declining trend may be partly related to the time lag of different types of OA research articles. There is no lag of DOAJ and Hybrid OA because the articles become OA immediately after publication. However, for Green and Bronze OA, the lag is explainable. Authors often self-archive (upload their paper to a repository) months or years after the official publication date of the articles, typically because many journals have policies that authors must wait a certain length of time (the “embargo period”) before self-archiving (Piwowar et al., 2019).

China and the USA, although with similar OA policies, have quite different orientations towards the types of OA research articles. China has the largest percentage of OA research articles in DOAJ journals, while the USA has the largest percentage of OA research articles in Green and Bronze. Some explanations for these differences are available. Firstly, OA policies in China are mostly advisory. Researchers are encouraged to store their publications in the institutional or subject-based repository. There is no mandatory time requirement. The articles can be uploaded at any time. In contrast, some OA policies in the USA are mandatory. For example, the National Institutes of Health Public Access Policy has developed from unofficial regulations to mandatory OA policies to ensure the policy implementation’s legal effect[4]. A second explanation is the impact of research evaluation policy in China. For the last decade, China’s research evaluation and funding policies have had a strong focus on quantitative indicators with incentives to publish in journals covered by the Web of Science (Zhang & Sivertsen, 2020; Quan et al., 2017). Simultaneously, some DOAJ or Hybrid OA journals indexed in WoS (often with high article processing charges) have expanded their annual volume of articles and lowered the threshold for publication, thus affecting Chinese researchers’ choice to a certain extent. The rapidly increasing number of journals in DOAJ (from 300 in 2003 to 15,000 presently) can explain the increasing role of this OA type in both countries.

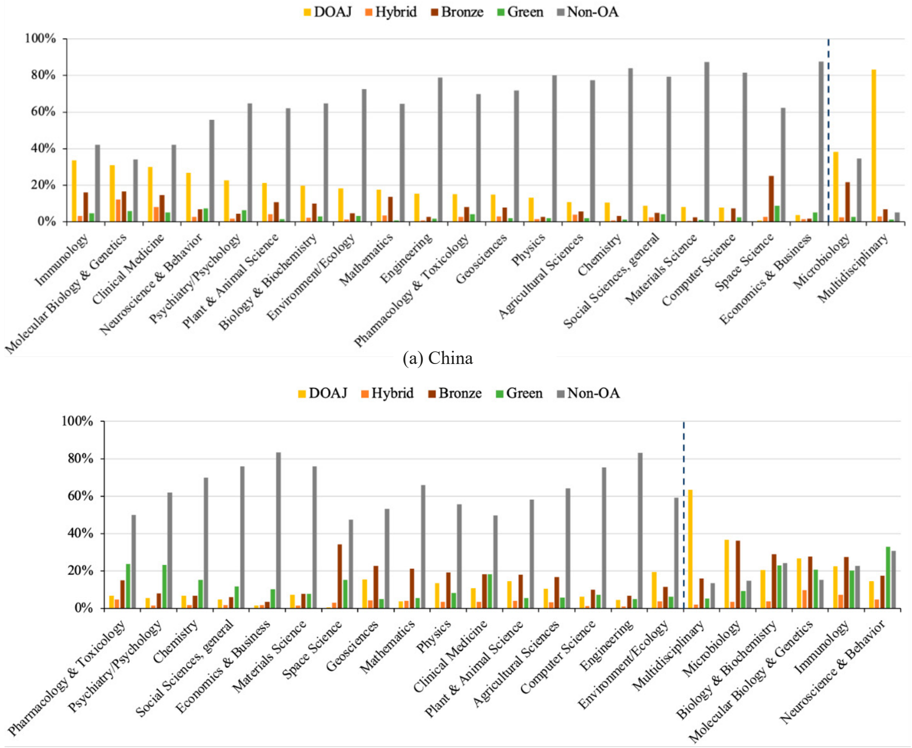
(a) China (b) USA

Figure 3. Percentage of five types of OA research articles from 2010 to 2019.

Figure 4 illustrates the percentage of the different OA types of research articles in the 22 ESI disciplines from 2010 to 2019. Most disciplines mainly publish research articles in the form of Non-OA. Multidisciplinary Sciences (representing e.g. the large DOAJ journal *PLoS One*) and Microbiology have the highest percentage of DOAJ research articles both in China and the USA. Among the OA research articles, DOAJ is the most prevalent type among Chinese researchers in 20 disciplines, while Bronze and Green are more prevalent OA types among American researchers in 20 disciplines.



(a) China

(b) USA

Figure 4. The percentage of the five OA types of articles in different disciplines from 2010 to 2019.

OA research articles with authors from China and the USA in the lead

Generally, the first author or corresponding author can be regarded as having the main responsibility and contribution to an article. We will now consider those articles only where the first author or corresponding author is from China or the USA. Figure 5 shows percentage of the articles within the five types of OA from a country where the authors in lead are from the same country. With this measurement, we can indicate the more typical OA practices of each of the countries. China has more distinctive OA practices towards Non-OA (94.84%) and DOAJ (92.95%). Green OA is less distinctive for China because authors from other countries tend to be in the lead in these articles (see below). Contrary to China, Green OA research articles are distinctive for the USA, while DOAJ and Hybrid OA are not. Our results are consistent with the results of a large-scale questionnaire survey by Professor Carol Tenopir's team (2017). They investigated researchers' attitudes and behaviors towards gold OA in the USA. The results showed that most respondents hold neutral to somewhat negative opinions towards gold OA. They believed that articles published in OA journals are of lower quality than those published in subscription-based journals.

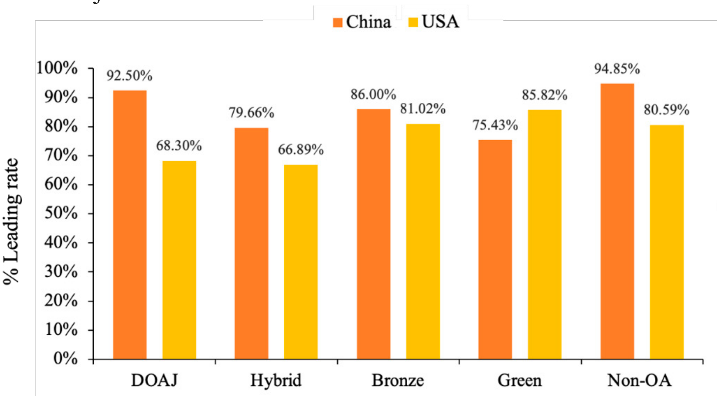


Figure 5. Percentage of the five types of OA research articles led by China and the USA.

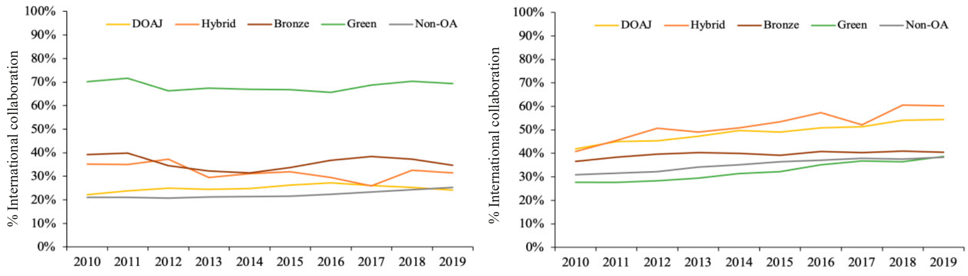
Note: Percentage calculation method: Percentage of the DOAJ research articles led by China= Number of DOAJ research articles with Chinese researchers as the first or corresponding author /Total number of DOAJ research articles published by Chinese researchers * 100%.

In articles with *international collaboration*, the choice of OA type and journal will need to be agreed by co-authors from different countries. These articles may therefore less distinctly represent the OA practices of the USA and China, in contrast to the articles analysed in Figure 5. Figure 6 shows the percentage distribution of articles with *international collaboration* among the five OA types from 2010 to 2019. The proportion of articles with Green OA from China is now highest, far higher than the other four types of articles, indicating that the Green OA practice is mainly due to collaboration with scholars from other countries. The percentage of Non-OA research articles from China is low. This is consistent with the distinctive traits presented above. Non-OA and DOAJ OA are distinctive Chinese practices. The results also confirm that hybrid OA is not a distinctively American practice while Green OA certainly is.



(a) China (b) USA

Figure 6. Proportion of OA types in articles with international collaboration from 2010 to 2019.

The citation impact of different types of OA research articles in China and the USA

We have selected four citation impact indicators from InCites to compare the five types of OA research articles and the two countries:

- *Average Citation*. The average number of citations per paper.
- *%Documents in Top1%*. Percentage of publications in the top 1% most highly cited publications in the world, based on citations by category, year, and document type.
- *Category Normalized Citation Impact (CNCI)*. Citation impact (citations per paper) normalized for the subject, year, and document type.
- *Journal Normalized Citation Impact (JNCI)*. Citation impact (citations per paper) normalized for the journal, year, and document type.

Figure 7 shows the four impact indicators among the five types of OA research articles. Figure 7(a) indicates that the average citation impact within all five types of research articles is higher for the USA than for China. Green OA research articles have the highest impact in both countries followed by Bronze OA articles. These types of OA can be related to traditional subscription-based journals. The same is true for Hybrid OA. The higher impact of these categories compared to Non-OA, is therefore remarkable, particularly for the USA. OA seems to provide more impact. The impact of DOAJ OA research articles is relatively low for both countries, particularly for China where this type of OA is a distinctive and abundant practice.
Moving from average citation impact to the field-normalized indicators in Figure 7 (b) (extremely high impact articles) and Figure 7 (c) (all articles), the picture slightly changes. By these indicators, Hybrid OA research articles score the highest among articles from the USA while Green OA research articles score the highest among articles from China. We already know from the results above that these OA practices are the less distinctive types for both countries and that they are most influenced by international collaboration. Articles with international collaboration are in general more cited. The largest differences in citation impact between the two countries are now found in the Hybrid and Bronze types while there is almost no difference in the Green and Non-OA types. This is a remarkable finding showing the need for further investigation of APC costs related to OA in the publishing practices of different countries. We will follow up in another study.
The JNCI indicator is a similar indicator to the CNCI indicator used above, but instead of normalizing per subject area or field, it normalizes by the average citation rate of articles in the journal in which the article was published. This indicator is valuable for comparing the two countries within journals with the same OA policy. Figure 7 (d) shows that this indicator tends to level out the differences between the two countries in citation impact in all OA types except Hybrid. Again, the least distinctive OA type depending the most on international collaboration (Hybrid for the USA, Green for China) is the most favourable when comparing the two countries. More generally, on the background of the results of the three other citation indicators

presented above, this last indicator indirectly shows that the two countries tend to publish in *different* journals within the *same type* of OA. As an example, we observe that the differences in citation impact between the two countries within DOAJ in Figure 7a-c diminishes in Figure 7d where citations are normalized relative to the articles in the same journal. It seems that the articles from China in DOAJ are published in journals with lower impact.

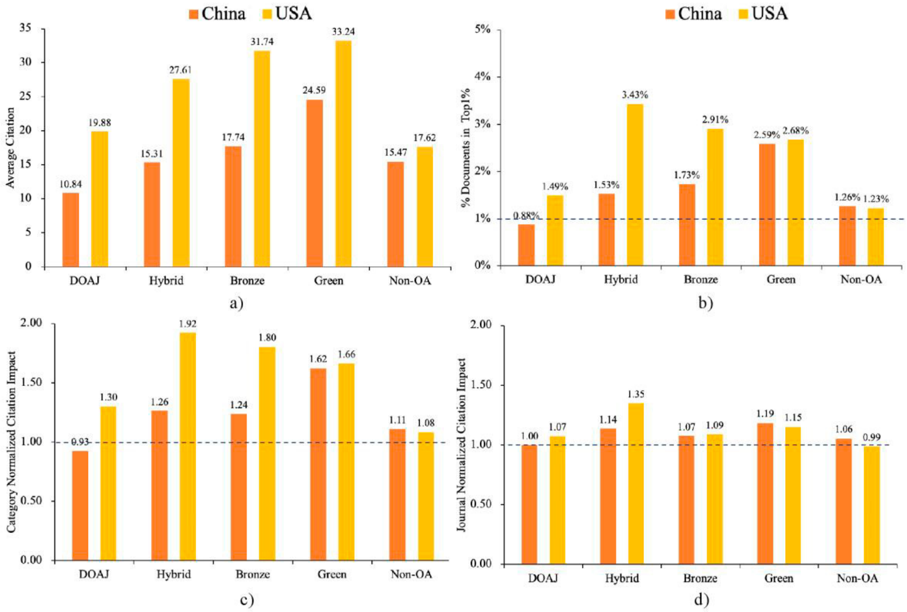


Figure 7. Impact indicators of the five types of OA research articles.

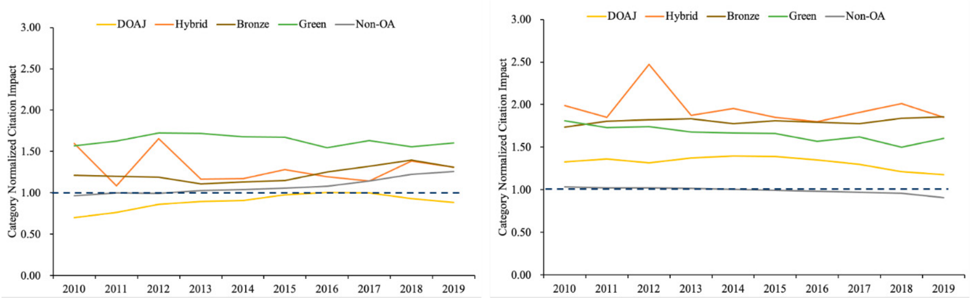
The CNCI indicator is frequently used in comparisons of countries with different research profiles. We chose this indicator as representative in a further analysis of trends during the period studied. Figure 8 displays the CNCI of the five types of OA research articles from both countries in the period from 2010 to 2019. The general differences between the two countries according to this indicator were already observed above. Here, we observe some interesting similarities and differences in the trends. The major difference is that the CNCI of Non-OA research articles increases for China while being stable or decreasing for the USA. China is even surpassing the impact of USA in these traditional journals. There is also an increase for China in the Bronze type of articles, which also may appear in traditional journals. This might indicate that China is not gaining from the so-called ‘citation advantage’ of OA. However, the impact of China in the Green type is high for China and stable over time while decreasing for the USA. The explanation these differences might that different journals are chosen within each type (as seen in Figure 7d). It might be that American articles are published in less influential journals whenever the Non-OA alternative is chosen. There is nonetheless one clear similarity. The impact of DOAJ OA research articles is low for both countries and falling towards the end of the period, probably because of the rapid growth of new DOAJ journals.

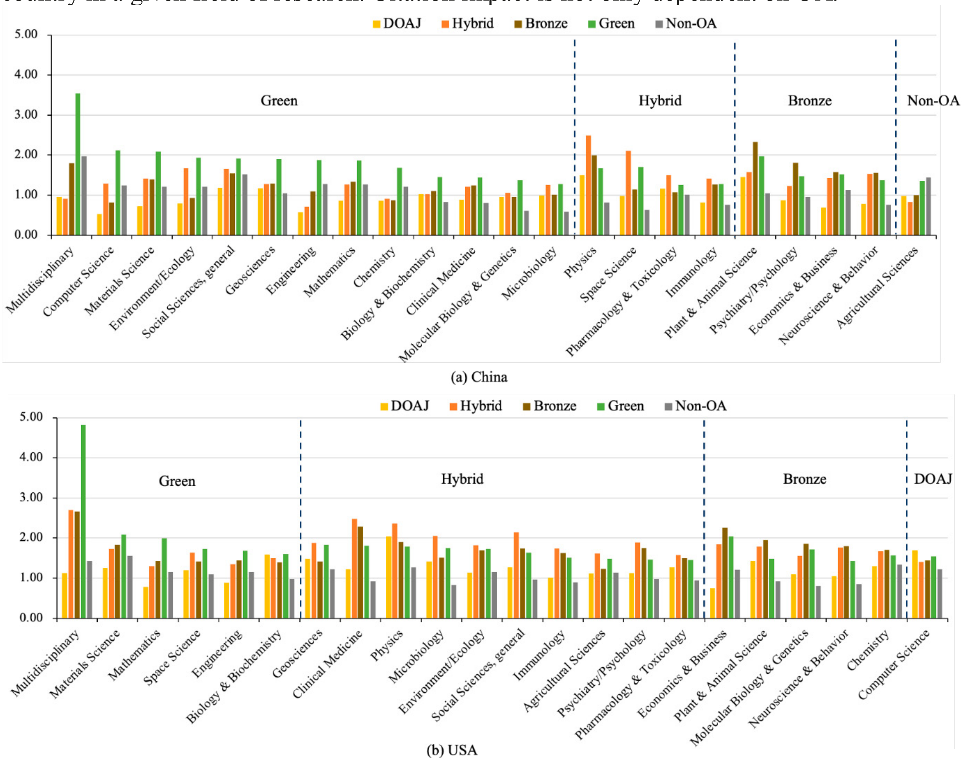


(a) China

(b) USA

Figure 8. The field-normalized citation impact (CNCI) of articles with different types of OA from 2010 to 2019.

The impact of different types of OA research articles in different disciplines is also worthy of attention. Figure 9 shows the CNCI of different types of OA research articles in the ESI 22 disciplines. To aid the interpretation of the results, we divide the 22 disciplines into four categories according to the most prevailing OA type both in China and the USA. The specific subject classification can be viewed from Figure 9. The most interesting observation here is that as many as half of the disciplines occur in different OA types by country when measured according to the citation impact of the country. The results indicate that citation impact from OA is not only contingent on the type of OA practice, but also on the relative impact of the country in a given field of research. Citation impact is not only dependent on OA.



(a) China

(b) USA

Figure 9. The CNCI of different types of OA research articles in 22 disciplines.

Discussion and conclusion

Our results show that policy intervention has an important impact on the development of OA. Firstly, we find that the percentage of OA research articles in the USA is higher than in China. The explanation may be that China's OA policies are mostly advisory, not mandatory. Some studies have showed that most Chinese researchers approve of OA in principle (Ren, 2015; Wang, 2013), but in practice, they are reluctant to submit papers to OA journals or to institutional repositories (Yuan & Zhang, 2016). As stated by Xu et al. (2016), many Chinese researchers are also sceptical and confused about OA publishing. However, we know from our finding in Figure 2 that this situation must be changing. A more recent questionnaire-based survey from the Chinese Academy of Science and Technology for Development (CASTED) （2020) showed that 65% of the Chinese researchers expressed their willingness to publish papers in OA journals.

Both of the governments of China and the USA promote Green OA, but the relative prevalence of the types of OA in the two countries is different. Green is the most prevalent OA type in the USA, while DOAJ is the most prevalent OA type in China. Zhang Xiaolin, chairman of the Strategic Planning Committee of the Chinese National Science and Technology Library, has said that the impression that OA has little influence in China is misleading.[5] Since 2014, funders and research institutions in China have encouraged and funded scientists to publish their papers in open-access formats and archive manuscripts openly online (Schiermeier, 2018). In practice, all research funders in China allow researchers to use research grants for publishing expenses, including article processing charges (APCs) for OA journals (Zhang, 2014). This may have led to an increase in the number of DOAJ articles in China. For example, our recent research found that one of the fastest expanding publishers of DOAJ journals, the Multidisciplinary Digital Publishing Institute (MDPI), publishes the more Chinese DOAJ articles than any other publisher within DOAJ. Since 2010, the proportion of Chinese papers in DOAJ published by MDPI has increased almost exponentially. The MDPI journal *Sustainability* has published more than 30,000 articles since 2016 among which Chinese mainland institutions contributed with about 17,000 articles. However, the expansion of Chinese articles within DOAJ has also created concern in China. As an example, the DOAJ journal *Tumor Biology* retracted 107 papers in one single notice, and most of them were from China (Watch, 2017). Tang (2019) found that China has published 8% of the world's scientific articles, but by 2017 was responsible for 24% of all retractions.

Concerned about these ethical issues, at the beginning of 2020, China issued a policy stipulated that "*For a single paper whose publication expenditure exceeds RMB 20,000, the academic committee of the corresponding author or first author's institutions must review the necessity of the publishing the paper*" and "*Papers published in academic journals on the 'blacklist' and early warning list shall not be included in the special funds for national science and technology plan projects*". This policy shows that China is not only concerned about the costs of article processing charges in Gold OA journals, but also of their consequences for research ethics and quality. Nevertheless, costs may be a concern *per se*: 79.2% of Chinese researchers selected "high publishing cost" as the reason for reluctance to publish papers in OA Journals, according to CASTED's survey (Chinese Academy of Science and Technology for Development, 2020). Recently, the National Science Library of the Chinese Academy of Sciences released the "International Journal Early Warning List (Trial)", which contains 65 journals indexed by Web of Science. Among them, 41 are OA journals and only 7 journals are Non-OA journals[6]. The 65 journals on the list published more than 50,000 Chinese researchers' articles in 2020, accounting for half of articles in the same journals[7]. Among others, *Sustainability* appears on

the journal list. And according to the China Publish Ecological Report (2020), the number and proportion of articles published by Chinese researchers in *Sustainability* declined for the first time in 2020. Similar lists of journals with warnings are created by and widespread among Chinese institutions. Even the two largest and most famous OA journals in the world, *PLOS ONE* and *Scientific Reports*, are frequently on the Chinese lists of controversial journals.

Our study shows that OA research articles in general have clearly more impact than Non-OA research articles. These results are consistent with previous findings (Wang et al., 2015; Zhang, & Watson, 2017). An explaining factor can be the 'citation advantage' of OA, namely that scholars are much more likely to read and cite easily accessible articles that those that are behind paywalls (Piwowar, 2018). Nevertheless, our study has shown the picture is more complex when comparing different OA types and two countries. Citation impact is not only contingent on OA.

The relatively high impact of Hybrid OA research articles, particularly for the USA, may be related to the characteristics of hybrid journals, which allow the authors to choose whether to make their articles OA to public. A phenomenon called "selection bias postulate" suggests that authors choose to pay APC for only their most potentially impactful work (Craig et al., 2007).

We also found that Green OA research articles published by Chinese researchers have the highest impact, while their DOAJ OA research articles have the lowest impact. There are several possible explanations for this observation. Firstly, the institutional repository is one of the most widely used forms of Green OA. Among the 33 registered repositories in Open DOAR in China, twenty-six of them are from the internationally influential institutes of the Chinese Academy of Sciences (CAS) (Zhong & Jiang, 2017). In our data, 19.2% of the Green OA research articles come from the CAS institutes. The average number of citations and the CNCI of Green OA research articles published by CAS are higher than the average of all research articles in China (CNCI: 1.85 versus 1.1) The influence of the CAS institutes on the indicator may affect the general impact of Green OA articles from China. Secondly, according to the results of the above-mentioned questionnaire survey conducted by the CASTED (2020), 81.8% of the Chinese respondents published OA articles due to "recognition by the evaluation system." It seems that some researchers have published low-quality articles for the needs of evaluation, which may affect the generally low impact of DOAJ OA articles.

However, we observed the relatively lower impact of the DOAJ type OA for both countries, but at clearly different levels. From a Chinese perspective, it is important to know DOAJ OA journals indexed by WoS have been given much weight in the evaluation systems in China until recently (Zhang & Sivertsen, 2020). Hence high quantities of articles with low impact could be expected. The result has been that publishing in DOAJ Gold journals has lost prestige in China although the quantity has risen (Archambault et al., 2013). For USA on the other side, it seems from our results, that by incentivizing or mandating the OA Green alternative, the researchers have been able to remain publishing in the traditionally most impactful journals offering the Hybrid or Bronze alternatives.

Abstract

Problematic publications and scientific misconduct have raised global concern, in which the authors have played a key role. Since research misconduct occurs more frequently in the clinical medicine field, we took this field as an example to explore productivity patterns, collaboration and scientific careers of authors at the individual level. The application of Lotka's law (C=0.886, n=3.854) showed a loose collaboration network and a predominant aggregation of multi-retracted authors. Most authors were retracted only once while a small group of authors produced most retracted publications. Authors with most retractions appeared to have stable collaboration with certain individuals. Two typical publication patterns of retractions in different stages of scientific career have been found: (1) committing scientific misconduct in the early career, mainly for promotion, and (2) participating in scientific misconduct when mature in the career, most due to neglecting the duty as a supervisor. The team culture, regulations, publication policies, and joint efforts by the scientific community have a direct influence on the occurrences of scientific misconduct. Conclusions are made with a focus on the need for more actions to prevent scientific misconduct and to strengthen scientific norms and integrity.

Introduction

Scientific research relies on its integrity and scientific misconduct has raised global concerns (Zhang & Grieneisen, 2012). Retracted publications refer to publications that are retracted by the scientific or publication community in concerns of errors, fraud, or other problems in the original publications. Evidence has shown that most of the retracted publications in health, life, and medical sciences were retracted due to research misconduct (Stavale et al., 2019). The rise of retracted publications has raised increasing discussions on scientific misconduct (Mongeon & Larivière, 2016), especially in the medical field (Zhang & Grieneisen, 2012). Repeating fraudulent aspect of funds caused the waste of public resources, but also harmed public trust in scientific research (Sabir, Kumbhare, Parate, Kumar, & Das, 2015). In the field of clinical medicine, flawed and fraudulent researches could lead to inappropriate clinical practice that harmed the safety and health of research participants, ineffective or even harmful treatment to the patients (Gupta, Sahani, Mohan, & Wander, 2013), posing a threat to the public health. What's worse, it may take a great deal of time and effort to discover and retract erroneous or fraudulent publications, while negative impacts of those work could continue by citation in subsequent works without alarming the problems (Budd, Sievert, Schultz, & Scoville, 1999; Hamilton, 2019; Steen, 2011). Therefore, analysis of the nature and dynamics of retracted publications in clinical medicine could contribute to the governance of scientific misconduct and provide profound meaning to the general public.

Previous studies have noticed the recidivism of authors and the unbalanced distribution of retracted publications and in medical field, namely a relatively small number of authors that were observed to have a higher repeating probability of retractions and have contributed to a larger portion of retractions (Kuroki & Ukawa, 2018). Authors with multiple retracted publications are also recognized as “authors with multiple retractions” (Foo, 2011), or “repeat offenders” (Lei & Zhang, 2018). In surgery journals, a quarter of the authors had more than one retraction and it usually happened for the same reasons and even in the same journal (Cassao, Herbella, Schlottmann, & Patti, 2018). Since most authors with multiple retractions were closely associated with scientific misconduct (Mistry, Grey, & Bolland, 2019), it is worth further exploration to analyze their motivation and pattern of producing retracted publications.

Previous studies have mainly revealed the publication and collaboration characteristics of authors with multiple retractions. It has been found that the majority of authors with multiple retractions tended to increase their publications until the first retraction (Mistry, Grey, & Bolland, 2019), and they were also collaboration prone (Tang, Hu, Sui, Yang, & Cao, 2020). Case studies focused on top multi-retracted authors, like Scott Reuben, Joachim Boldt, and Yoshitaka Fujii with the most retractions in clinical medicine, have analyzed the journal responses of their retracted publications (Elia, Wager, & Tramer, 2014; McHugh & Yentis, 2019; Saikia & Thakuria, 2019). Nevertheless, the motivations and factors explaining for individual performance in the problematic publications are remained to be discussed. Furthermore, while co-authors were believed to have a major role in ensuring the integrity of the research and tackling the misconduct (Luther, 2010; Sabir et al., 2015), the impact of collaboration between authors with multiple retractions are also lefted to be explored based on the observed collaboration characteristics.

To give insight of the patterns and motivation of individual scientific misconduct, our study was designed to explored the productivity pattern and collaboration characteristics of authors with multiple retractions, in particular analyzed the pattern and factors explaining for producing multiple retracted publications from the perspective of collaboration.

Meanwhile, although there were surveys and interviews conducted to explore the factors of scientific misconduct among scholars from several countries, such as the need for publications, attitudes of scientific misconduct and institutional policies (Davis, Riske-Morris, & Diaz, 2007; Hofmann, Helgesson, Juth, & Holm, 2015; Mabou Tagne et al., 2020; Mardani, Nakhoda, & Shamsi Gooshki, 2020; Were, Kaguiri, & Kiplagat, 2020; Yi, Nemery, & Dierickx, 2019), these self-report surveys might solely provide a conservative estimation of the emergences of scientific misconduct, considering the concealing to answering sensitive questions among interviewees and other limitations (Fanelli, 2009). Our analysis on the retracted publications will contributed with empirical evidence objectively demonstrating the impact of individual and collaborative factors on scientific misconduct.

The objective of this study is to reveal productivity patterns, collaboration, and reasons explaining why the authors published retracted publications in clinical medicine with empirical evidence, especially the influence of individual scientific careers and collaboration factors on their scientific misconduct. Specifically, the research questions are:

1. Whether the productivity pattern of authors with retracted publications in clinical medicine fit classic Lotka’s law?
2. What are the collaboration characteristics of multi-retracted authors and one-retracted authors?
3. In which stage of scientific careers are researchers more likely to take risks in scientific misconduct?

4. What are the potential motivations and factors which influence the misbehavior of multi-retracted authors?

To further explore the pattern and motivation of producing retracted publications, we selected the top 12 authors in three groups with the most retractions as a case study. The characteristics of group collaboration, and causal factors for misconduct have been discussed. Corresponding policy implications could put forward the governance of scientific misconduct and the improvement of constructions in scientific integrity.

Data and methodology

Searching strategy and data collection

In this study, raw data were retrieved from Science Citation Index Expanded (SCI-EXPANDED) database of Web of Science Core Collection from Clarivate Analytics. We collected retracted publications in clinical medicine from 1978 to 2017 by initially creating a general dataset of retracted publications and then picking out the publications categorized to clinical medicine. The general dataset of retracted publications was obtained using a mixed searching strategy in data retrieval based on the method in our previous study (Zhang, Abraham, & Fu, 2020), namely combing records of retracted publications and retraction notices by the three steps. To generate a sub dataset of clinical medicine from the general dataset, we categorized retracted publications by matching the journal and research fields of each records with Clarivate Analytics Essential Science Indicators (ESI) journal-category list. Clinical medicine with 1309 retracted publications took the largest proportion (27%) of retracted publications among 22 ESI fields.

Authors of retracted publications

All authors referred in retracted publications from the field of clinical medicine were identified according to their corresponding addresses, respectively. Different formats of their names had been unified manually. Except for four anonymous articles, there were 6,161 authors contributing to 1,305 retracted articles in clinical medicine. The "multi-retracted authors" in this article refer to authors who have more than one retracted publication, "one-retracted authors" refer to authors who only published one retracted publication, and the most-retracted authors refer to authors with the most retractions in clinical medicine.

The number of years for one's scientific career in this research count since the year of the author's first scientific publication. To retrieve the first year of the author's publication, we searched the author's name in the official website of the institution for personal curriculum vitae, and databases including PubMed, Google Scholar for the earliest record of the author's publication.

Collaboration indicators of authors

Collaboration was measured as co-authorship between two and more authors. Given different roles of positions of author, first author and corresponding author were discussed. The rate of the first authorship (or corresponding authorship) by the author equals the number of retracted publications first authored (or corresponding authorship) divided by the total number of retracted publications authored by the author.

The analysis of Lotka's law

It is widely acknowledged that most scientific publications are contributed by a few highly productive authors (Holliday, Fuller, Wilson, & Thomas, 2013; Rajgoli &

Laxminarsaiah, 2015). The Lotka's law originally gave a mathematical model measuring scientists' productivity distribution, and has been proved to fit diverse areas including LIS, computer science, medicine, biochemistry, etc. (Holliday et al., 2013; Kawamura, 2009; Pao, 1985; Pinto, Escalona-Fernández, & Pulgarín, 2012; Pulgarín, 2012; Zhang et al., 2018). The application of Lotka's law here is designed to explore the distribution and publication characteristics of multi-retracted authors in comparison to ordinary authors. After using full counting of authors of each paper, this study employed non-linear regression of the power model by SPSS v.22 to calculate the two parameters of Lotka's law. The R-square analysis and K-S statistical test were applied to verify the applicability of Lotka's law in this approach.

Network analysis of the co-authorship

To illustrate the collaboration characteristics of multi-retracted authors and one-retracted authors, an oriented co-authorship network was generated by Gephi 0.9.2. The closeness centrality of the nodes was calculated to quantify the degree of collaboration. The higher closeness centrality an author has, the more influential the author is over the entire network (Yin, Kretschmer, Hanneman, & Liu, 2006).

Results and discussion

Productivity patterns of authors by Lotka's law

Figure 1a reveals the application of Lotka's law of retracted articles in the field of clinical medicine. Figure 1b is the graph on a semi-logarithmic scale to explicit demonstrate the fitness of the model. The non-linear regression model was examined as validly fitted, as the maximum distance between each actual accumulated percentage of authors and expectation was 0.00997, smaller than the K-S test critical value = ${1.63}/{\sqrt{6161}} = 0.02077$. According to the non-linear model, the retracted articles (R^2 = 1.000) matched with Lotka's law model, with exponent n = 3.584, constant C = 0.886.

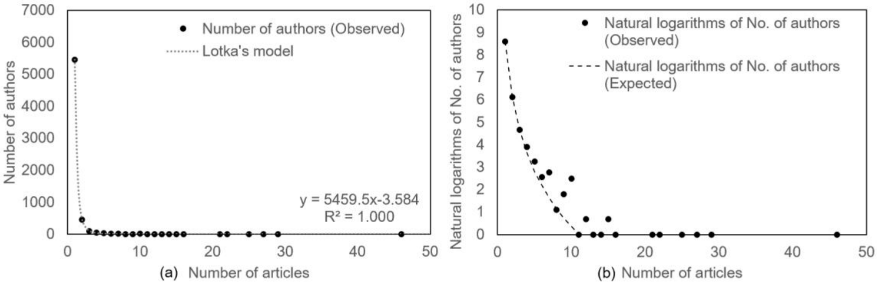

Figure 1. Application of Lotka's law in retractions in the field of clinical medicine

The theoretical Lotka's law has n = 2 and C = 0.6, and parameters varied among different disciplines empirically. In general, as the average level of co-authorship gets lower, such as in social sciences and humanities, parameter n tends to be generally higher; and the larger the C, the lower the author concentration (Kawamura, 2009; Pinto et al., 2012; Rajgoli & Laxminarsaiah, 2015). Previous empirical results in research fields related to clinical medicine varied, such as n = 2.8 and C = 0.52 in critical care medicine (Zhang et al., 2018), n 1.97 ~ 2.52 and C 0.61 ~ 0.77 in radiation oncology, n 2.17 ~ 2.39 and C 0.6622 ~ 0.7205 in dental sciences (Pulgarín, 2012). Notably, both parameters of $n = 3.584$ and $C = 0.886$ of retracted articles in clinical medicine were higher than the theoretical Lotka's law distribution and ordinary medical articles. As high as estimated by $C = 0.886$, most authors, namely 88.6% of all, were retracted only once. Despite a loose collaboration network generally in retracted articles, a small-scaled group of multi-retracted authors was responsible for a disproportionally large number of publications retracted (Holliday et al., 2013).

It is not rare to see such unbalanced or skewed distribution in the scientific community. Considering the potential problems such as errors and scientific misconduct in retracted publications, a predominant aggregation among multi-retracted authors and unbalanced distribution might bring more negative impacts in the scientific community. The following analysis focused on the characteristics of these multi-retracted authors to identify their collaboration patterns and potential motivations for scientific misconduct.

Collaboration at the individual level

Figure 2 revealed the co-authorship network of authors with more than one retracted publication and collaboration characteristics of top 12 authors in three groups. Authors with more than ten retracted articles are presented with name labels in the network. Thick lines indicate the frequency of collaboration. The clockwise bending direction represents the relationship from the first author to the partner.

	Author	*TP*	*RP%*	*FP%*	*CC*

TP: Proportion of retractions worldwide
RP%: Percentage of corresponding authorship
FP%: Percentage of first authorship
CC: Closeness centrality

● Multi-retracted authors
● One-retracted authors

Figure 2. Co-authorship network and collaboration indicators of authors

There were stronger links among multi-retracted authors in the network. It seems that multi-retracted authors closely collaborated with each other and some were acting as leading authors. The authors who published more retracted publications as first author appeared to have higher closeness centrality than the less published, indicating higher connectivity and more influential control over the retraction fields (Uddin, Hossain, & Rasmussen, 2013). Fujii, Boldt, Sarkar, and Wang in Fig. 2 were known for their high productivity of researches, projects, and quantities of publications (Marcus & Oransky, 2015), once described as leading or incredible example of researchers in the field (Cancer and Metastasis Reviews, 2010; O'Connor, 2008; Oransky, 2010), and accordingly a leading role in the collaborative teams.

Given collaborative occasions, dishonest people usually seek a partner who would also lie, usually called a “partner in crime”, while honest people, who normally didn’t lie but intended to take advantage of their partners’ lies (Gross, Leib, Offerman, & Shalvi, 2018). Consequently, the first offenders were more likely to find acquaintances to commit scientific misconduct (Wray & Andersen, 2018), while co-authors might be willing to take risks or indulge the problematic research practice in consideration of expected benefits. Moreover, mutual confidence and a set of shared norms of behavior between the partners can be constructed by stable co-authorship (Bordons, Aparicio, González-Albo, & Díaz-Faes, 2015).

Scientific careers of multi-retracted authors

To further discover the motivation of most retracted authors, we reviewed their scientific performances during the career and the investigation report on their scientific misconduct by groups, and explored potential motivations for multi-retracted authors’ recidivism of producing retracted publications.

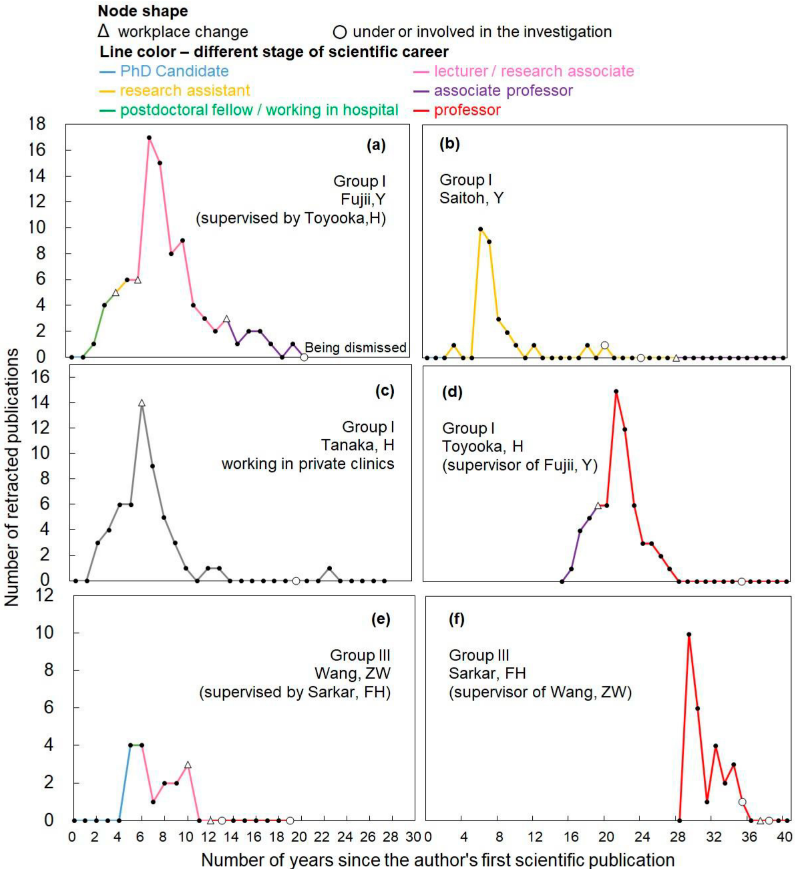

Figure 3. The number of retractions in scientific careers of multi-retracted authors

Figure 3 demonstrated the retraction publication path of retracted articles by top 12 most retracted authors in three groups during their scientific careers. Due to the unavailability of access to some researchers’ resumes on the internet, retractions of six authors during different stages of scientific careers were identified. Distinguishingly two different types of multi-retracted authors were observed: (1) committing scientific misconduct early in their career with a decrease after the peak, and (2) participating in scientific misconduct when mature in their career, namely qualified as senior professor. It is observed that the occurrences of retracted publications are related with individual promotion and mentorship. Firstly, junior researchers appear to have the first retraction quite early in their career, and the rise of retractions is closely associated with getting promoted. For example, Fujii (Fig. 3a) joined the faculty as a research associate from a research assistant, and successfully became a lecturer in the peak year with the most retractions, along with an eight-year decrease of retractions after being named as an associate professor. Wang (Fig. 3e) published four retracted articles in the fifth year as a doctoral undergraduate, which was also the most annual production of retracted articles in his scientific career.

Besides, the rise of the retractions by supervisors also showed consistency with collaborative junior researchers mentored in the same group. Senior researchers could also benefit from publications in pursuit of the promotion as a professor. For instance, Toyooka (Fig. 3d) became the professor in the 19th year near the peak of retractions, similar to Fujii. Moreover, the mutual influence of scientific misconduct though the mentorship seems to be constant in individual career. Apart from the investigation for falsification together with his supervisor Sarkar in the 13th year, Wang (Fig. 3f) was involved in another investigation after becoming a professor elsewhere in the 19th year, according to the latest investigation in 2020.

An in-depth investigation of multi-retracted authors by groups

To give an insight into motivations and factors accounting for scientific misconduct of multi-retracted authors, namely the influences of the mentorship and collaboration, Table 1 summarized the investigation results of most retracted authors based on the related reports (Japanese Society of Anesthesiology, 2012; Justus Liebig University Giessen [JLU], 2011; JLU, 2012; Kuroda, 2012; McCook, 2016; U.S. Office of Research Integrity, 2020). There were three groups under investigation due to scientific misconduct by principal offenders in each group, i.e., Fujii, Boldt, and Sarkar, as well as his postdoctoral fellow, Wang.

Table 1. The in-depth investigation of top 12 multi-retracted authors in three groups

Group	*Author*	*1st publication year*	*1st retraction year*	*Gap*	*Institution*
Group I	Fujii, Y	1991	1993	2	Toho University
	Toyooka, H	1977	1993	16	Teikyo University
	Tanaka, H	1992	1994	2	Toride Kyodo General Hospital
	Saitoh, Y	1992	1995	3	
Group II	Boldt, J	1984	1986	2	Klinikum Stadt Ludwigshafen; Justus Liebig University Giessen (JLU)
	Piper, SN	1997	1999	2	
	Suttner, SW	1998	1999	1	
	Maleck, W	1994	1999	5	
Group III	Sarkar, FH	1977	2006	29	Wayne State University (WSU)
	Banerjee, S	2005	2006	1	
	Wang, ZW	2001	2006	5	
Who calls for investigation & authors' involvement in the investigation? **Group I** Concerns raised by letters from a reader (Christian Apuferu) and request from Joint Editors-in-Chief. Investigated by Japanese Society of Anesthesiology and Toho University. All the authors above were interviewed in 2011. Saitoh was interviewed specifically in 2017.					

Group II Requested by Joint Editors-in-Chief and the State Medical Association of Rheinland-Pfalz, Germany (LÄK-RLP). Investigated by Klinikum Ludwigshafen (2010), LÄK-RLP and JLU (2011). Boldt and Suttner was investigated in 2011. Lack of information about others.

Group III Concerns raised by anonymous letters and from Pubpeer. Investigated by WSU and U.S. Office of Research Integrity (ORI). All were interviewed in 2014. Additionally, Wang was investigated individually in 2020.

Mentorship

Group I Toyooka, H: supervisor of Fujii, Y.

Group II (lack of information)

Group III Sarkar, FH: the head of the lab, Ph. D advisor and postdoctoral supervisor of Wang, ZW.

Results of the investigation & Motivation for the misconduct

Group I

Fujii, Y: falsification of data; lack of ethical approval; authorship falsification. In the pursuit of performance evaluation, obtaining university faculty positions, candidate selection, obtaining public research funding, and applying for social awards.

Toyooka, H: neglected the duty as a supervisor.

Tanaka, H: didn't participate in the falsification and wasn't informed of these publications.

Saitoh, Y: didn't participate in the falsification but agreed to be listed as a co-author.

co-authors above aware of the existence of the publication but left it was in consideration of their scientific output.

Group II:

Boldt, J: lack of ethical approval and patient consent; falsification in publications.

Group III

Sarkar, FH: falsification in grant applications.

Wang, ZW: falsification in the Ph.D. dissertation, publications, and grant applications. Mainly in pursuit of federal grant applications & scientific output. (Although Sarkar himself didn't admit he was motivated.)

Authors' response & punishment

Group I

Fujii, Y: admitted the allegation of scientific misconduct and was finally dismissed by Toho University.

Group II

Boldt, J: was stripped of his title of professor at the JLU for failing to teach. He had been dismissed as a chief physician from Ludwigshafen Hospital in 2010 due to scientific misconduct before. His co-author, Piper once rejected the retraction against the editor with a legal threat.

Group III

Wang, ZW: faced with the withdrawal of Ph.D. degree and a 10-year ban on any federally funded research.

Sarkar, FH: disagreed with the allegation of falsification firstly and sued PubPeer commenters. His employment was rejected by the University of Mississippi due to the event but then he was re-appointed by WSU.

Resulting retractions (in the case report)

Group I *Anesthesia & Analgesia:* 22 are retracted, 24 are suspected of fraud; *Canadian Journal of Anesthesia:* 9 are retracted because of lack of ethical approval.

Group II 88 articles that LAK-RLP was unable to find evidence of IRB approval (Miller, 2011); three including falsification, and were retracted by journals.

Group III 42 publications authored by Sarkar are identified as involved in misconduct and should be retracted; 14 publications authored by Wang should be retracted.

Others

Group I Saitoh was found to have ethical issues in research after being specially investigated by the Japanese Society of Anesthesiologists and quitted the society in 2017.

Group II JLU withdrew the doctoral degree in two cases of former Boldt's doctoral student P. and the doctor T. on account of their misconduct in previous publications and Ph.D. dissertations.

Generally, a common motivation for multi-retracted authors to take risks in scientific misconduct is obtaining research funds and seeking for promotion, which is also reflected in the trend of retracted publications in their scientific careers in Fig. 3. Interestingly, apart from the first authors who should take the main responsibility for misconduct in the investigation, some coauthors would take advantages of the problematic publications considering potential benefits in scientific output. For example, despite the fact that Saitoh didn't participate in the falsification, he also agreed to be listed as a co-author in the retracted publications with Fujii simply in pursuit of scientific output.

Moreover, negative team culture where the duty as supervisor and well-training in research practice is neglected, could facilitate inappropriate research practice and misconduct in the labs. It should be noted that both senior and junior researchers could be influenced by the team culture, especially through mentorship. In both the cases of Group I and II, Toyooka and Sarkar were blamed for neglecting the duty as senior supervisor or PI in the lab. Namely, being reckless and failed to review the data as the supervisor substantially lead to inappropriate preservation or manipulation of data, and miscommunication between laboratory members. The cases here were just a tip of the iceberg, as it was reported that 3/4 of PI in universities don't directly review data (Wright, Titus, & Cornelison, 2008).

Meanwhile, loose regulations and publication policies made it easier for multi-retracted authors to break the rule of scientific norms, namely forged authorship and the lack of ethical approval. Since not all journals require signatures from all authors, it is convenient for authors to fabricate the authorship without others' consent. Fujii, who forged authorship in tens of retracted publications, once confessed that he even didn't need to ask the authorship permission from all the co-authors when submitting the manuscript. Furthermore, irresponsive actions taken by scientific community in respond to the concerns of problematic research would lead to postpone in examination, corresponding investigation and disposal of scientific misconduct. Specifically, journals would fail to respond to the concerns about the problematic research due to the lack of supportive evidence or fear of legal threat from authors (Palus, 2015). On the other hand, corresponding investigation will also be more complex or even intervened under the circumstances where the original data were usually damaged or lost and resistance from the authors. In the case of Sarkar, it took more than 26 months for the investigation committee to find original evidence, under the circumstances where Sarkar and his team have already confused the real data and fabricated data in the lab (McCook, 2016).

Therefore, our results suggest a complete and proactive mechanism that coordinates institutions, journals, and other agencies, to improve transparency and responsibility between collaboration and mentorship, practice on the scientific norms and ethics, responsive actions toward scientific misconduct, and to protect the integrity of future science. More specific and effective examination on publication or research ethics in journal policies are necessary. According to an Editor-in-Chief from *European Journal of Anaesthesiology*, who once commented about the lessons learned from the case of Boldt, after adopting a new rule that requires all articles to provide detailed information about ethics approval, the practice turns out to help editors identify those authors who failed to provide details and never came back to the journal (Tramer, 2011).

On the other hand, corresponding investigation, report, and punishment are vital for building an efficient mechanism to restrain scientific misconduct. As is shown in Fig. 3, there appeared to be a decrease and even termination of publishing retracted articles after being investigated and punished. According to WSU, Sarkar was found to have changed his practice in his lab including reviewing raw data and checking figures ever since the investigation. Since formal sanction and losing jobs are proved to be severe negative results of scientific misconduct perceived by many scholars (Cyranoski, 2014; Pratt, Reisig, Holtfreter, & Golladay, 2019), researchers may reconsider and restrain individual scientific misconduct where the scientific community will respond to misconduct in time.

Abstract

Author Bibliographic Coupling Analysis (ABCA) is the extension of Bibliographic Coupling theory at the author level, widely used in mapping intellectual structure and scholar communities. However, the assumption of equal citations and the complete dependence on explicit counts may affect its effectiveness in today's complex context of the discipline development. This research proposes a new approach that uses multiple full-text data to improve ABCA called Enhanced Author Bibliographic Coupling Analysis (EABCA). By mining the syntactic and semantic information of citations, the new approach considers more diverse and in-depth dimensions as the basis of author bibliographic coupling strength. Comparative empirical research was then conducted in the field of oncology. Results show that the new approach can more accurately reveal the relevance between authors and map a more detailed domain intellectual structure.

Introduction

The Bibliographic Coupling (BC) concept originated from Kessler's (1963) discovery: When two documents are more similar in topic, they share more common references. Zhao & Strotmann (2008a) extended BC and proposed Author Bibliographic Coupling Analysis (ABCA), which is now used to characterize the research interest of communities of current active authors and reveal a field's intellectual structure. It has been proven that ABCA is a supplement to Author Co-citation Analysis (ACA), especially in finding active authors and research fronts (Ma, 2012; Zhao & Strotmann, 2014).

However, ABCA, like most bibliometric methods based on Citation Analysis (CA), has inherent flaws. CA relies on the assumption that all citations are equivalent, which ignores the different deep meanings represented by citations (Bornmann & Daniel, 2008), and only uses simple count as the basis for relevance strength. The count-based strength may affect the quality of utility of these methods, including ABCA, in the complex background where interdisciplinary research is increasing and rapidly progressing.

Fortunately, the accessibility of full-text scientific articles in databases such as PubMed Central (PMC), Citeseer, and arXiv, promotes the emergence of Content-based Citation Analysis (CCA). CCA extends the scope of CA from metadata to information inside scientific articles, and studies the motivations, sentiments, and topics of citation, which further provides strong support for scientific evaluation, retrieval, recommendation, automatic summarization, etc. CCA has been regarded as the next generation of CA (Ding et al., 2014). The current research of CCA can be summarized on the syntactic and semantic level. The syntactic level focuses on external characteristics of citations such as mention frequency in one paper (Count-X) (Ding et al., 2013), position (Gipp & Beel, 2009; Liu & Chen, 2012; Habib & Afzal, 2019). The semantic level focuses on the internal content of citation (Liu, Zhang, & Guo, 2013; Kumar et al., 2017). At present, researchers have engaged in content-based improvement for ACA using co-citation position (An et al., 2017) and co-citation sentence (Jeong & Song, 2014; Kim et al., 2016). These studies have achieved encouraging results. However, the research on ABCA is still almost blank.

Can CCA also take effect in ABCA? This investigation proposes a new model that uses full-text information to improve ABCA, named Enhanced Author Bibliographic Coupling Analysis (EABCA), to explore the feasibility and effectiveness of expanding the depth of data in the commonly used author-based bibliometric methods. Unlike ABCA, EABCA focuses on the similarities of citing behaviors between authors in multiple dimensions (Figure 1), comparing contents, locations, and mention frequency of citations, to obtain comprehensive relevance strength and then assign each coupling a different weight.

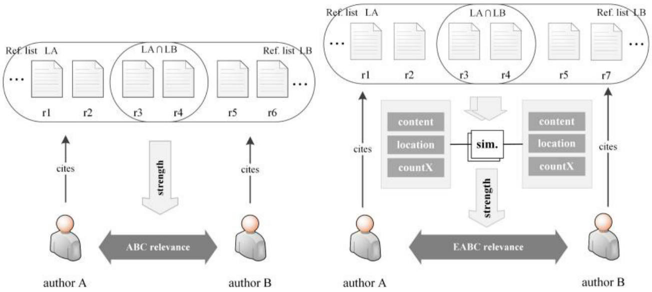

Figure 1. Difference between ABCA (left) and EABCA (right)

EABCA Model Design

In this section, we give an introduction to EABCA's three essential parts.

Location	[0.050, 0.856]
Count-X	2

Extraction of full-text data is essential preliminary work for our algorithm. Take the XML format data provided by PMC as an example (Figure 2). For each paper, the tag '<xref>' is used to locate the citations for each reference. Subsequently, citations' data of content, location, and Count-X, as well as other metadata, will be parsed. Finally, for each paper' reference, the data structure shown in Table 1 will be formed for each collaborator. Note that the citation contents include the citation sentences and their adjacent sentences separated from other ones by full stops (not dot etc.), and the locations are obtained by dividing the sequential index of each citation's first word by the length of the paper.

Language Model Pre-trainning

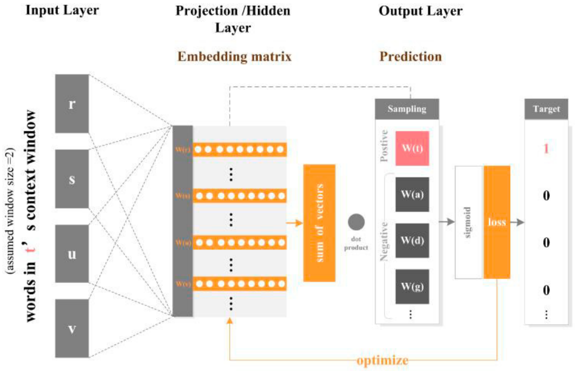

Figure 3. The mechanism of Continuous Bag of Words (CBOW)

Since EABCA involves calculating the content similarity between citations, Natural Language Processing techniques are required to provide word representation support. To overcome the disconnected relationship between word form and semantic using TF-IDF as previous studies (Kim et al., 2016), considering the efficiency and scalability, word2vec was chosen for pre-training distributional representation of words based on the field corpus. The word2vec algorithm uses a neural network to learn semantic and contextual associations of words from a large corpus in an unsupervised way (Mikolov et al., 2013). Continuous Bag of Words (CBOW) is one of its two modes, which has weaker sensitivity to rare words and is more suitable for our large-scale scientific literature corpus modeling than the other. As shown in Figure 3, CBOW predicts the central word t by inputting the sum of embedding vectors of words from t's context window and then backpropagates the loss to optimize the parameters in the embedding matrix. After training multiple iterations on the entire corpus dataset, those words with similar contexts tend to have similar embedding vectors.

Table 2. Example of the most similar words of 'glioma' in the trained language model

word	*similarity*	*word*	*similarity*
GBM	0.7782	astrocytomas	0.5494
glioblastoma	0.7727	GSCS	0.5428
astrocytoma	0.6234	GC	0.5425
osteosarcoma	0.5787	PDAC	0.5407
HCC	0.5721	CCRCC	0.5225

To fit the word2vec model to the terminology features and relations of the specific domain in advance, we pre-processed all full-text articles in our dataset and then utilized them as a corpus in pre-training. Table 2 shows an example of the most similar ten words of 'glioma' in the trained model. The close correlations between glioma and these words, such as GBM (glioblastoma), are correctly represented. In other words, even if two sentences on the same topic use completely different term forms, we can still compute the sentences' similarity.

Calculation

Consider two authors A and B. P_A and P_B denote the sets of articles of A and B, while L_A and L_B denote the reference sets of A and B. Suppose an intersection $L_{AB} = L_A \cap L_B$ exists, where we have eliminated those references included in A and B's co-author articles. For each reference $r \in L_{AB}$, We aggregate all the citation contents and locations of r in P_A and P_B, generating the total contents list donated by CON_A and CON_B, and the total location list donated by LOC_A and LOC_B. We then sum all the Count-X of r in P_A and P_B, generating the total Count-X donated by COX_A and COX_B.

Based on the above, the similarity between A and B when citing r is defined as (1).

$$Similarity_r(A,B) = cos\begin{pmatrix} w_1 \cdot \arccos(CON\_sim) + \\ w_2 \cdot \arccos\,(LOC\_sim) + \\ w_3 \cdot \arccos\,(COX\_sim) \end{pmatrix} \quad (1)$$

$$(w_1 + w_2 + w_3 = 1, w_1 \in [0,1], w_2 \in [0,1], w_3 \in [0,1])$$

A linear combination of the similarities' angles is adopted in (1) considering different nature of combined data suggested by Glänzel & Thijs (2011). The parameters, w_1, w_2 and w_3, are given to CON_sim, LOC_sim, and COX_sim, which denote the similarities of CON, LOC, and COX, respectively. After every $r \in L_{AB}$ has been traversed and calculated by (1), we added all the $Similarity_{rn}(A,B)$ to obtain the EABC relevance strength between author A and B as

$$EABC\_Relevance(A,B) = \textstyle\sum_1^n Similarity_{rn}(A,B) \quad (2)$$

The three sub-formulas in (1) are defined as follows:

- CON_sim

The items in $CON_A[con_{A1}, con_{A2}, \dots, con_{Am}]$ and $CON_B[con_{B1}, con_{B2}, \dots, con_{Bn}]$ are enumerated paired. For each pair $p(con_{Am}, con_{Bn})$, i dimension term vectors are extracted from the trained word2vec model and summed to generate sentence vectors V_A and V_B . We then apply the cosine to measure their similarity (3):

$$sim_{mn}(con_{Am}, con_{Bn}) = \cos\,(V_A,\ V_B) = \frac{\sum_i V_{Ai} V_{Bi}}{\sqrt{\sum_i V_{Ai}^2}\sqrt{\sum_i V_{Bi}^2}} \quad (3)$$

After obtaining all $sim_{mn}(p)$, we average their value as the content semantic similarity denoted by CON_sim. Note that the CON_sim value is also used to support identifying content-irrelevant relations. If A and B's CON_sim ranks in the lowest 20% of all CON_sim values in the dataset, their relation will be ignored.

- LOC_sim

The items in $LOC_A[loc_{A1}, loc_{A2}, \dots, loc_{Am}]$ and $LOC_B[loc_{B1}, loc_{B2}, \dots, loc_{Bn}]$are enumerated paired. We refer to the generalized alternative of the Jaccard Index (Ružička, 1958), for each pair $p(loc_{Am}, loc_{Bn})$, the smaller value is divided by the larger one as $\min(p)$ / $\max\,(p)$ into a similarity ratio sim_{mn} represented how similar this pair of locations are. The set $sim = \{sim_1, sim_2, \dots, sim_{mn}\}$ is then averaged as the location similarity LOC_sim.

- COX_sim

COX_A and COX_B are first normalized by the number of A's and B's total references, respectively. We then use the larger value to divide the smaller one to obtain COX_sim, which represents how similar the importance of r is for author A and B. Note that if both COX_A and COX_B are only 1, the calculation will not be performed because in this case COX_sim will incorrectly be high, and theoretically, we cannot further deduce the two authors are similar from the fact that r is unimportant to them.

Research Design and Methods

Returning to the research question, we conduct the empirical research as shown in Figure 4 to verify the effect of EABCA. We first collect and process the full-text data from PMC in a specific field, then carry out a comparative analysis on the two models, and present the results through factor analysis and network analysis.

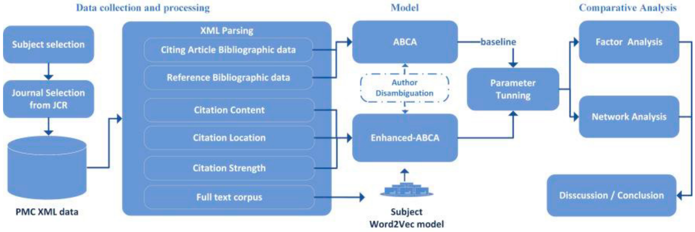

Figure 4. Framework of the research process

Data collection

The field of Oncology was chosen for our empirical study, in which the top 15% (36 items) journals ranking by Impact Factor in the Journal Citation Reports 2019 were selected, and the full-text XML data of these journals during 2016-2020 was downloaded from PMC. Considering the unavailability of open access in some journals and the difference in citation pattern of Review with Research articles, 7,056 full-text research articles from 33 journals were finally retained. Table 3 shows the details of a part that provides more than 400 full-text research articles of these selected source journals.

Table 3. List of source journals providing full-text research paper (part)

Journal title	*IF*	*Full-text research papers*	*% of all published*
Journal of Experimental & Clinical Cancer Research	32.956	1235	84.01%
Oncogene	7.971	990	90.49%
Journal for Immunotherapy of Cancer	11.577	772	63.96%
Molecular Oncology	6.574	541	85.06%
Oncoimmunology	5.869	538	81.64%
Leukemia	13.357	470	70.15%
Molecular Cancer	15.302	411	51.89%

After processing these data in a full-authors pattern, we have 36,532 authors, who totally have 1,741,626 reference entries. Using the full-author pattern in such a field with dense collaboration, which has an average of more than 12 authors and a maximum value of up to 507, generates large-scale redundant data. Therefore, to focus more on the active authors and significant intellectual structure during 2016-2020, and apply quality control well i.e. author disambiguation, thresholds on the number of publications were adopted.

Methodology

Author Bibliographic Coupling Analysis (ABCA)

ABCA is used as the theoretical basis and the comparison in this study. Currently, there are three methods for its strength calculation (Ma, 2012), including the simple method (Rousseau, 2010), minimum method (Zhao & Strotmann, 2008a), and combined method (Leydesdorff, 2011). We chose the minimum method as the comparison: for each reference r in author A and B's reference intersection set, it records the frequency w of A and B respectively citing r in the weighted reference sets W_A and W_B, and sum all the minimum w to obtain the strength.

Author Name Disambiguation (AND)

Author name ambiguity is a crucial problem in author-based bibliometric studies. We adopted a procedure of balancing efficiency and quality to solve the prominent cases as follows:

- Multiple author entities share a single name. We checked each name in the filtered list to confirm whether its owner belongs to multiple affiliations and whether its owner's affiliation repeatedly changes within a period of 2 years. If so, and no entity owned more than 90% of this name's articles, we removed the name (i.e., Wang, Wei).

• Single author entity with multiple name forms. Based on the above, we performed similar name pattern matching for authors and then verify whether these names belong to the same entity by affiliations and research topics. If so, we respectively merge their reference sets and publication sets. Some author entities with multiple forms identified are shown in Table 4.

Table 4. Example of author entities with different name forms

Author entity	*Different name forms*
Munshi,Nikhil C.	['Munshi,Nikhil C.', 'Munshi,Nikhil', 'Munshi,N C', 'Munshi,Nikhil C', 'Munshi,NC']
Anderson,Kenneth C.	['Anderson,Kenneth C.', 'Anderson,K C', 'Anderson,Kenneth C', 'Anderson,Kenneth']
Kaufman,Howard L.	['Kaufman,Howard L.', 'Kaufman,Howard L', 'Kaufman,H. L.', 'Kaufman,H.']

Parameter Tuning

To fit the EABCA model to the characteristics of citation in Oncology, we conducted a parameter tuning toward w_1,w_2 & w_3 in (1) on 66 different weight configurations. The tuning was based on 218 top authors who published more than five papers for better control.

To evaluate the clustering solutions, we applied the method using Medical Subject Headings (MeSH) introduced by Zhang, Xu & Zhang (2019) toward the author level. MeSH is a controlled vocabulary of terms annotated by specialists in life sciences. For each author, we associate his papers with MeSH descriptors in PubMed. After eliminating general and low-frequency terms, we aggregated descriptors and their frequency weights to form the author's MeSH Pool. Subsequently, we used the Jaccard Index, defined as

$$J(A,B) = \frac{|A \cap B|}{|A|+|B|-|A \cap B|} = \frac{|\sum \min(w_{cA}, w_{cB})|}{|Pool_A|+|Pool_B|-|\sum \min(w_{cA}, w_{cB})|} \quad (4)$$

where $Pool_A$ and $Pool_B$ denote author A's and B's MeSH Pools, w_{cA} and w_{cB} denote the weights of descriptor c ∈ $Pool_A \cap Pool_B$ in frequency-weighted sets of A and B, respectively. If $J(A,B)$ exceeds a certain threshold, A and B were considered to belong to the same category. After experimentation and expert judgment, the threshold was set to 0.1.

The matrix generated by EABCA and ABCA was clustered using K-means after converting into the Pearson correlation matrix. Based on (4) and the process shown in Table 5, the Precision, Recall and F1-score is calculated as (5), (6) and (7). We set the number of clusters for K-means to 10 because both EABCA ($w_1 = 0.33$,$w_2 = 0.33$,$w_3 = 0.33$) and ABCA have relatively good performance.

Table 5. Process to evaluate the result of each pair of authors

Two authors belong to the same cluster?	***Two authors belong to the same category based on their MeSH Pool?***	
	Yes	*No*
Yes	True Positive (TP)	False Positive (FP)
No	False Negative (FN)	True Negative (TN)

$$Precision = \frac{TP}{TP+FP} \quad (5)$$

$$Recall = \frac{TP}{TP+FN} \quad (6)$$

$$F1 - score = \frac{2Precision \cdot Recall}{Precision+Recall} \quad (7)$$

Factor Analysis

Factor analysis is a dimension reduction technique commonly applied in author-based bibliographic analysis for exploring the implied relevance between domain representative authors (White & McCain, 1998). In this study, the analysis was implemented following the steps: (a) Selecting and disambiguating 218 top authors who published more than five papers. (b) Building matrixes with mean as the diagonal, including one based on the BC frequency for

ABCA and one on the EABC relevance for EABCA, which were both then converted to correlation matrixes. (c) Extracting factors based on observations of eigenvalues, scree plot, and percentage of variance. (Hair et al., 2009) (d) Applying oblimin rotation for better interpreting. (e) Labelling the factors and comparing the results.

Network Analysis

To study on a larger scale and intuitively map the relevance between authors and research interest groups, we conducted a further network analysis using Gephi on 723 authors who published more than three papers. The edge weight depended on BC frequency and EABC relevance for ABCA and EABCA, respectively. Louvain algorithm (Blondel et al., 2008) was utilized for community discovery, which is highly efficient facing large networks.

Result

Parameter Tuning Result

Figure 5 shows the performances of models with different parameter values. By comparing the values, we notice that the parameter w_1 has a strong positive correlation with Precision (0.798 with significance at 0.01), and w_2 has a weak positive correlation with Recall (0.251). On the contrary, there exists a negative correlation between w3 and Precision (-0.709) and Recall (-0.647). The above indicates that the content and location similarity switched by w_1 and w_2 play roles in improving the performance, while a too high proportion of Count-X similarity may not lead to an outstanding result because the w_1 and w_2 are therefore reduced.

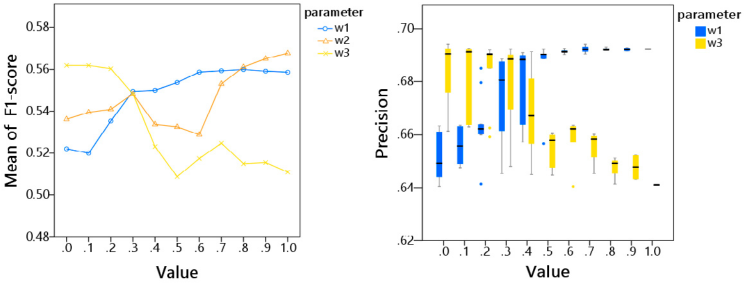

Figure 5. F1-score Mean Plot of three parameters (left) and Precision Box-plot of parameter w_1 and w_3(right)

Table 6 shows the performance of the top 5 models ranked by F1-score, the model with the highest Precision and Recall, and ABCA in parameter tuning. These scores are all average values generated by 30 rounds of reproducible initialized centroids to ensure the stability of the results. The Recall of the top model significantly exceeds ABCA by 10.961%, while the Precision increases by 6.148% and the F1-score by 9.887%. To a certain extent, the above indicates the advantage of EABCA over ABCA from a quantitative perspective. Hence, the EABCA ($w_1 = 0.4$, $w_2 = 0.4$, $w_3 = 0.2$) was chosen.

Table 6. Performance of models on K-means clustering

Rank	*Model*	*Precision*	*Recall*	*F1-score*
1	EABCA(w1=0.4,w2=0.4,w3=0.2)	69.033%	48.971%	**57.268%**
2	EABCA(w1=0.3,w2=0.4,w3=0.3)	68.788%	48.814%	57.064%
3	EABCA(w1=0.3,w2=0.6,w3=0.1)	68.738%	48.722%	56.993%
4	EABCA(w1=0.3,w2=0.5,w3=0.2)	68.761%	48.539%	56.877%
5	EABCA(w1=0.4,w2=0.5,w3=0.1)	69.089%	48.244%	56.796%
7	EABCA(w1=0.0,w2=1.0,w3=0.0)	66.336%	**49.624%**	56.774%
15	EABCA(w1=0.7,w2=0.3,w3=0.0)	**69.417%**	47.301%	56.250%
66	Baseline - ABCA	62.885%	38.010%	47.381%

Factor Analysis Result

After name disambiguation, 218 authors published more than five papers were retained for factor analysis. Ten factors were extracted, explaining 70.300% of the total variance for ABCA, while 13 factors were extracted, explaining 70.389% of the total variance for EABCA. Details are shown in Table 7. Note that an author variable may have loadings on many factors here; therefore, our factor analysis aims at comparing the differences between the two models in mining latent topics rather than giving each author a one-to-one category.

The topic labels in Table 7 come from our keyword extraction procedure for each factor. For the coupling authors of every factor, the titles and MeSH descriptors were extracted from their BC articles to support topic identification based on TF-IDF. We then surveyed the representative authors online to label factors with the assistance of domain experts.

Table 7. Factor Analysis results of ABCA and EABCA

Topic Label	*ABCA (10 Factors,70.300 %)*			*EABCA (13 Factors, 70.389%)*		
	Factor	*Size*	*Highest loading*	*Factor*	*Size*	*Highest loading*
RNA Interference	F1, F7, F8	114	0.951	F1	30	0.933
Multiple Myeloma and Therapy	F4	28	1.008	F2	28	1.016
Immunotherapy	F3	26	0.917	F3	24	0.929
Multiple Myeloma and Genomics	F2	27	0.692	F4	25	1.006
Stem cell Transplantation	F5, F9	35	0.896	F5, F10	36	0.931
Acute Myeloid Leukemia	F6	25	0.753	F6	18	0.839
Gene Expression Regulation in Esophagogastric & Stomach Neoplasms				F7	24	0.729
Gastric & Colorectal Neoplasms and Carcinogenesis Target Research				F8	15	0.774
Myeloproliferative Disorders	F10	20	0.825	F9	14	0.904
Lymphoma				F11	11	0.680
Signaling Pathways / Computational Biology / Head and Neck Neoplasms				F12	9	0.539
Gene Expression Regulation in Liver Neoplasms				F13	33	0.761

Table 8. Factors exclusively identified by EABCA

Factor	*keywords from MeSH and Title(by Tf-idf)*	*Representative author (with loading in structure matrix)*
F7	Stomach Neoplasms / Gene Expression Regulation, Neoplastic / Esophagogastric Junction / Signal Transduction / MicroRNAs	Shen, Lin (0.716) Xu, Zekuan (0.545)
F8	HCT116 Cells / Colorectal Neoplasms / Caco-2 Cells / HT29 Cells / E1A-Associated p300 Protein / rela / last2yap1/ p300-mediated	To,Ka Fai (0.828) Wong,Chi Chun (0.757)
F11	Lymphoma, Large B-Cell, Diffuse / DNA Copy Number Variations / Lymphoma / Rituximab / Doxorubicin / dlbcl	Nowakowski,Grzegorz S. (0.654) Witzig,Thomas E. (0.628)
F12	ErbB Receptors / Computational Biology / Gene Expression Regulation, Neoplastic / Head and Neck Neoplasms / Epidermal Growth Factor / histone / tmem16a / six3	Teng, Yong (0.519) Liu, Changhong (0.516)
F13	Gene Expression Regulation, Neoplastic / Carcinoma, Hepatocellular / Liver Neoplasms / MicroRNAs / Epithelial-Mesenchymal Transition / m6a	Tu, Kangsheng (0.849) Zhou, Lin (0.705)

From the results, we find that ABCA and EABCA are similar in some of the identified factors, including F2, F3, and F4. The main difference occurs in F7, F8, F11, F12, and F13, which are only identified in EABCA. These factors' highest loadings are not high, and some of them closely associate with others, i.e., F7, F8, F13, and F1, while F11 and F12 are relatively independent. However, the author groups under these new factors have their own common characteristics in research content or scenarios, as shown in Table 8. Factor F7 & F13 both involve the studies of RNA interference, but F7 focuses on esophagogastric & stomach neoplasms while F13 on liver-related neoplasms. F8 involves gastric & colorectal neoplasms, and it focuses on carcinogenesis targets. F11 involves lymphoma, including its clinical therapy as well as related basic genomic research. F12 mainly involves researches on signaling pathways, of which most use head and neck neoplasms as specific objects.

Network Analysis Result

After name disambiguation, 723 authors who published more than three papers were retained for network analysis. For these authors, ABCA generated 73,984 edges, EABCA generated 40,878 edges. The overview of networks is shown in Table 9, where we find that EABCA's network is sparser and has weaker connectivity.

Table 9. Overview of network of ABCA and EABCA

	Num. of edges	*Average Degree*	*Average Weighted Degree*	*Density*	*Average Path length*	*Connected Components*
ABCA	73984	204.658	570.866	0.283	1.723	2
EABCA	40878	113.079	144.191	0.157	1.944	3

To show a distinctive network structure, we adopted edge filtering for both ABCA and EABCA. ABCA retained 21,677 edges with a weight of 3 or more, while EABCA retained 9,304 edges with a weight of 1.5 or more because of its relatively lower edge weight. The community discovery algorithm found five modules for ABCA with modularity of 0.619, while ten modules for EABCA with modularity of 0.621. ForceAtlas2 was applied in the layouts as shown in Figure 8 & Figure 9. The modules' details are shown in Table 10.

Table 10. Modules identified by ABCA and EABCA in Network Analysis

Module	*ABCA*	*EABCA*	*MeSH*	*Keywords*
A	Multiple Myeloma		Multiple Myeloma / Lenalidomide / Gene Rearrangement	lenalidomide / relapsedrefractory / ixazomib
A-1		Multiple Myeloma and Therapy	Multiple Myeloma / Lenalidomide / Combined Modality Therapy	myeloma / relapsedrefractory / bortezomib
A-2		Multiple Myeloma and Genomics	Multiple Myeloma / DNA Copy Number Variations / Genomics	myeloma / genomic / genetic
B	Immunotherapy in Melanoma and Esophageal Cancer		Melanoma / Nivolumab / Stomach Neoplasms / Esophagogastric Junction / Programmed Cell Death 1 Receptor	melanoma / gastric / checkpoint
B-1		Melanoma and Immunotherapy	Antineoplastic Agents, Immunological / Melanoma / Immunotherapy / CTLA-4 Antigen	melanoma / checkpoint / immunotherapy
B-2		Esophageal & Gastric Cancer	Stomach Neoplasms / Esophagogastric Junction / Esophageal Neoplasms	gastric / junction / attraction-2
C	Myeloid Sarcoma		Hematopoietic Stem Cell Transplantation / Leukemia, Myeloid, Acute / Myeloproliferative Disorders / Primary Myelofibrosis	myeloid / myelofibrosis / aml
C-1		Stem Cell Transplantation	Graft vs Host Disease / Hematopoietic Stem Cell Transplantation / Transplantation, Homologous	transplantation / ebmt / allogeneic
C-2		Acute Myeloid Leukemia and Therapy	Leukemia, Myeloid, Acute / Myelodysplastic Syndromes / Remission Induction	myeloid / myelodysplastic / aml
C-3		Myeloproliferative Disorders and Therapy	Primary Myelofibrosis / Myeloproliferative Disorders / Thrombocythemia, Essential	myelofibrosis / myeloid / ruxolitinib
D	RNA Interference	RNA Interference	MicroRNAs / RNA, Circular / RNA Interference	rna / pathway / lncrna
E	Lymphoma and therapy	Lymphoma and therapy	Lymphoma, Large B-Cell, Diffuse / Lymphoma / Lymphoma, Non-Hodgkin	lymphoma / b-cell / dlbcl
F		Colorectal Neoplasms and Proteomics	Colorectal Neoplasms / Protein Kinase Inhibitors / Proteomics	colorectal / muc1-c / mastl

From the macro perspective of the layout, the division among EABCA's modules is clearer, and there are also more subdivided modules, which appear more compact. In ABCA, the modules C, A & D are in a triangular relationship that closes to each other. While in EABCA, there exists a gap from C-1, C-2 & C-3 to A-1 & A-2, and even a far distance to D.

From the meso perspective of the module, some large modules are subdivided in EABCA. Figure 10 shows how these nodes migrated from ABCA to EABCA. Module C# Myeloid Sarcoma is subdivided into three closely related modules C-1, C-2, and C-3. Module B is divided into B-1 that focuses on immunotherapy in melanoma, and B-2 on esophageal & gastric cancer. Module A# Multiple Myeloma is divided into A-1 that focuses on therapy and

A-2 on genomics. We also find that B-2 includes authors transferred from D and engaged in gastric cancer research, represented by To, Ka Fai. Besides, a small immature module F in EABCA involving colorectal neoplasms is composed of nodes moved from B, C, and D.

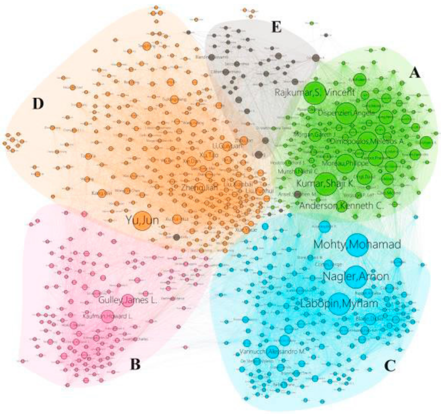

Figure 8. Network layout of ABCA

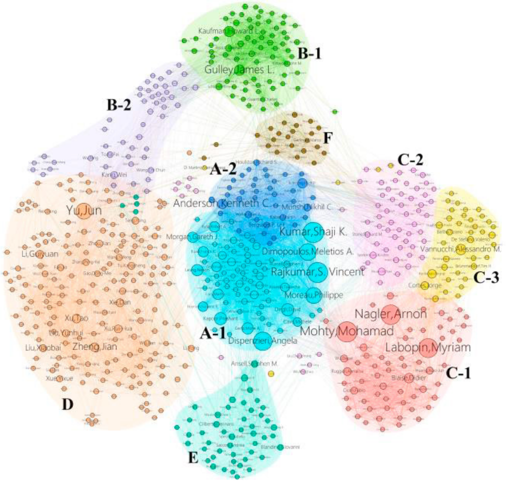

Figure 9. Network layout of EABCA

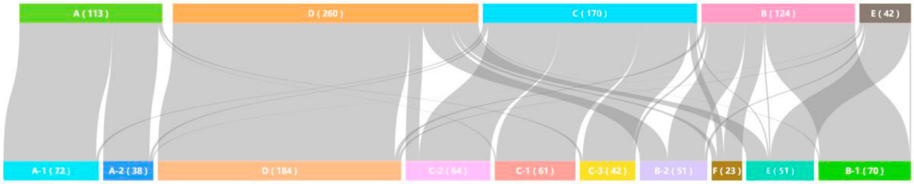

Figure 10. How do the nodes in modules of ABCA migrate to modules of EABCA

Table 11. Example of the different citation context of single reference

Reference PMID	*CON_SIM*	*BC Authors*	*Citation Context in Citing Articles*	*Citing Title*
24836762	0.289	Mohty, Mohamad	['... Several studies have demonstrated feasibility of azacytidine during the post-transplant period, and the correlation of the expansion determined cytotoxic T cell subsets against tumour antigens with a lower relapse incidence [37]…']	['Allogeneic stem cell transplantation in adult patients with acute myeloid leukaemia and 17p abnormalities in first complete remission...']
		Anderson, Kenneth C.	['...These need not be myeloma-specific panels, as many vendors provide kits or services for TP53[25]...']	['A high-risk, Double-Hit, group of newly diagnosed myeloma identified by genomic analysis']

From the micro perspective, the above phenomenon, including the gap, subdivision, and migration, could be explained from key nodes. For example, in EABCA, the edge weight between the representative author Mohty, Mohamad of C-1 and Anderson, Kenneth of A-2, shrinks from 15 in ABCA to 1.7407; hence, the distance between them is greatly extended. Indeed, there are apparent differences in their research interests, whose BC is limited to transplantation therapy in Myeloma, or some commonly involved substance, genes, etc. As shown in Table 11, although they both cite one paper, the contexts greatly vary. The strength correction also occurs between other key nodes, such as Mohty, Mohamad and Kumar, Shaji

K. of A-1 (drops from 10 to 2.816); Dispenzieri, Angela of A-1 and Li, Guiyuan of D (from 2 to 0.527); Li, Guiyuan and Kang, Wei of B-2 (from 5 to 0.699); Kaufman, Howard L. of B-1 and Doi, Toshihiko of B-2 (from 10 to 2.179); Gulley, James L. of B-2 and Yu, Jun of D (from 4 to 1.017); Mohty, Mohamad and Stone, Richard M. of C-2 (from 10 to 3.163), and Cortes, Jorge of C-3 (from 19 to 5.019); Li, Guiyuan and Blandino, Giovanni of E (from 5 to 0.558), Cerham, James R. of E and Dimopoulos, Meletios A. of A-1 (from 6 to 0.387), etc..

Discussion and Conclusion

In summary, the results show EABCA has the following advantages over ABCA:

(1) EABCA can more accurately reveal the association between authors, which is manifested as follows: The matrix generated by it obtain clustering results with higher performance, the edge weight between key nodes is verified to be in line with reality better. That is mainly because EABC relevance is calculated based on the full-text level data source and comprehensively considers multiple dimensions instead of solely relying on explicit counts. This kind of richer scale may also help us reason what happened in the black box of BC.

(2) EABCA can find a more detailed intellectual structure, especially among some research interest groups that are not clearly distinguished, as shown in factor and network analysis. It is known that scientific literature usually needs to intensively cite relevant works, which leads to rather dense BC relations. The fact makes it difficult to subdivide emerging sub-fields from other close or parent fields when the strength solely relies on the count, while EABCA's particular strength is competent. This is because there exist differences in terms, contexts, etc., among research topics; hence the citations may appear with different syntactic and semantic characteristics when researchers cite literature with various degrees of relevance. On this basis, detailed research topics and communities are easier to distinguish in EABCA.

This study shows that expanding the depth of data in ABCA can improve its analysis effect, revealing that it is feasible and meaningful to apply CCA further in promoting precision bibliometrics. Also, this effect improvement may positively impact a broader range of high-level applications, i.e., academic cooperation prediction and recommendation.

The study's main limitation is the incompleteness of full-text resources available; therefore, our empirical output results only have practical value in a specific range. Besides, we believe EABCA still has room for further refinement. For example, due to the inconsistent section titles in BC articles, we applied an alternative location tagging method to overcome large-scale missing location data; the better solution is to map a standardized structure. Moreover, the implications of the full-author pattern and the discipline specificity on EABCA are still not explicit, requiring further exploration and a wider range of empirical studies.

Acknowledgments

We thank Prof. Ronald Rousseau for his valuable suggestions, Dr. Yining Zhang of The First Hospital of China Medical University, Dr. Xiaoxue Zhang of Liaoning Cancer Hospital & Institute for their help in identifying and labeling topics. Abstract

Bibliometrics is effective in studying scholarly communication patterns and mapping domains of knowledge published in scholarly documents. The present study explores what we may learn from applying bibliometric methods to studying domains of knowledge represented in Wikipedia, a gigantic encyclopaedia created and maintained collectively by volunteers world-wide. In particular, we adapted and applied author bibliographic coupling analysis to examine one of the many topic areas on Wikipedia: Traditional Chinese Medicine (TCM). We found that seven dimensions of TCM are represented on WP: Acupuncture and related practices, Falun Gong, Herbal Medicine, TCM and its common concepts, Qigong, Chinese Martial Arts, and non-herbal medicine. The first three dimensions attracted the most Wikipedia contributors to TCM. Acupuncture and Qigong have the most connections to the TCM field, and also serve as bridges for other topics to connect to the TCM filed. Herbal medicine is linked to the field through the generalists who made low contributions to many TCM topic areas. Non-herbal Medicine is isolated from the rest of the field. It appears that specific topics are represented well on WP but their conceptual connections are not, especially between a general topic (e.g., TCM and its common concepts) and its sub-topics (e.g., Qigong, Taichi).

Introduction, background and related studies

Wikipedia (WP) is a system unique in the history of civilization (Simonite, 2013). Both benefits and challenges of the WP system have been widely debated in academia, law, business, and other sectors of society.

WP started in 2001 with the lofty goal of compiling all human knowledge. It grew quickly into the largest encyclopaedia in the world (Burke & Kraut, 2008). As of January 2021, WP has over 40.7 million registered and uncounted unregistered volunteer editors and over 6.2 million articles in the English version alone (WP:Statistics). Many WP articles were of a quality comparable with corresponding ones in Encyclopaedia Britannica (Giles, 2005). WP's success also made it play a symbolic role in highlighting the potential for voluntary peer-production to generate valuable collections of information. Hansen, et al., (2009) even contend that WP "approximates features of the ideal speech situation articulated by Habermas" in his Theory of Communicative Actions (Habermas, 1984). WP has now become a one-stop shop for information on pretty much any topic. As WP articles often intentionally show up at the top of Google search result lists and are now promoted as fact check sources on Facebook, to name just two prominent examples, WP is clearly a primary information source that people see, and in many cases even the only source that people use.

However, WP's success was to many a surprise. Among the fundamental problems of the WP system that have been criticized are unpredictable motivations (and competences) of editors and an emphasis on consensus rather than authority (Denning et al., 2005). WP evolves without supervision by certified subject experts or authorities, and its largely anonymous volunteer editors are left both to select, write about and organize the topics it includes and to define, interpret and implement its policies and resolve conflicts on their own. WP editors may be knowledge domain experts or an elementary school student, and "may be altruists, political or commercial opportunists, practical jokers, or even vandals" (Denning et al., 2005, p. 152). Inaccuracy or errors may exist due to lack of supervision by certified subject experts. Bias can be introduced and maintained as long as a group of editors with that bias manage to dominate the discussion and force it to a "consensus." Mechanisms used in traditional systems to ensure quality and avoid abuse of power are normally based on true identity along with social expectations, norms, and status positions, and thus cannot work for WP (Arazy et al., 2011; Ransbotham and Kane, 2011).

The incident when WP rejected an entry about Donna Strickland, a Canadian female winner of the 2018 Nobel Prize in Physics, half year before the announcement of the prize is just one of the many examples of problems in WP's topic selection policy and practices (The Guardian, 2018). WP categories have been found to be "very loosely structured" (Perez, 2021) and therefore there have been many studies on automatic categorization of WP articles (e.g., Refaei et al, 2018; Perez, 2021; Simone Paolo Ponzetto and Strube, 2007; Strube, and Simone Paolo Ponzetto, 2006; Gantner & Schmidt-Thieme, 2009). Despite these problems, as the largest open encyclopaedia, the WP's content (articles and categories) "has been used extensively for tasks like entity disambiguation or semantic similarity estimation" to enhance AI-based knowledge representation and organization (Heist and Paulheim, 2019).

Given the prominent position WP has for both information users and for researchers on knowledge organization and information retrieval, it is important to study how well knowledge is represented and structured on WP. The present study applies one of the effective bibliometric methods for mapping knowledge domains represented in published scholarly documents, i.e., author bibliographic coupling analysis (Zhao and strotmann, 2008), to examine one of the many topic areas on Wikipedia: Traditional Chinese Medicine (TCM). We chose the TCM topic area for this study because it has been reported to be one of the most controversial topic areas on WP in which WP's problems in topic selection and treatment may be more pronounced (Koppelman, 2017; McLuhan, 2013).

Methodology

Author bibliographic coupling analysis (ABCA)

Verifiability is one of the two fundamental principles among all the detailed policies and guidelines for contributing and for resolving conflicts that WP has developed, the other being Neutral Point of View (NPOV). These principles intend to ensure all important viewpoints are represented fairly and supported by trustworthy published resources (cited references).

Bibliographic coupling method uses the number of cited references shared by two publications to measure how closely these two articles are related in terms of topics or methodological approaches. The degree to which they share references has also been used to measure topic similarity between WP articles (Das et al., 2016).

Author bibliographic coupling analysis (ABCA) uses author instead of article as the unit for analysis. ABCA has been found to have a number of advantages compared to article-based analysis (Zhao and Strotmann, 2008). One of these advantages is the wider granularity and more data an author represents that can smooth out impact of outliers on the analysis. Authors represent schools of thought whereas articles represent individual pieces of evidence for or findings about concepts, theories or methods. Individuals tend to develop a set of information sources that they prefer to consult when they contribute to knowledge production (e.g., writing scholarly or WP articles) or deal with work or life problems (White, 2001). The more information sources are shared by two individuals the more closely their interests and beliefs may be related.

Data collection and analysis

We adapted and followed the well-established procedures and techniques for ABCA. Instead of using a citation database, we used the English version of WP as data source, and developed computer programs to collect and analyze data from WP.

We identified articles on Traditional Chinese Medicine (TCM) from WP by starting with the articles on TCM proper and with articles under the sub-categories and sub-sub-categories of TCM. We downloaded all these articles from WP in late 2019, including the entire editing and discussion history of each article.

Following ABCA techniques, we chose the top 500 editors who have contributed the most to the downloaded articles to represent this topic area. A matrix of shared reference scores was produced for all these editors. Specifically, if editors A and B have contributed substantially to article sets S1 and S2 respectively, and n different information sources were cited in both S1 and S2, n would be the shared reference score for A and B. We deleted those editors whose vectors contain only zeros, i.e., those who do not share cited references with any other editors in the set, which resulted in a 380x380 matrix. We left the diagonal cells empty in this matrix as in previous studies. They were treated as missing data and replaced with the mean in the Factor Analysis routine in SPSS that we used to explore the underlying structure of the interrelationships between these editors.

Factors were extracted by Principal Component Analysis (PCA). The number of factors extracted was determined based on an examination of the Scree plot, total variance explained, and correlation residuals – the differences between observed correlations and correlations implied by the factor model (Hair, et al., 1998). This resulted in an 18-factor model that explains 57.5% of the total variance, and the differences between observed and implied correlations are smaller than 0.05 for the most part (92%).

An oblique rotation was applied resulting in a pattern matrix and a structure matrix. We use the highest loading of a factor in the pattern matrix to indicate its distinctiveness. The size or prominence of a factor is indicated by the number of editors who load primarily on this factor in the pattern matrix. A Component Correlation Matrix showing how closely factors are related to each other was also produced by the Factor Analysis routine.

Factors are labeled upon manual examination of articles that authors who load primarily in each factor have significantly contributed references to. A factor is labeled as undefined (UD) if all loadings in this factor are lower than 0.7, although an attempt may still be made at interpreting it.

Results and discussion

Table 1 shows the topics identified and their distinctiveness and prominence indicated by the highest loading and the number of editors loading primarily and significantly on a factor respectively. Table 2 is the Component Correlation Matrix showing how closely these topics are related to each other. Correlations that are higher than 0.2 are highlighted and are considered as indicating a close connection in the discussions below.

Table 1. Topics and their prominence (Size) and distinctiveness (Highest loading)

Factor	*Topical Label*	*Size*	*Highest_loading*

Structure of the TCM field on WP

Identified topics in Table 1 can be grouped into seven dimensions: TCM and its common concepts (F6), Acupuncture and related practices (F1, F9), Qigong (F8), Falun Gong (F2, F3), Herbal Medicine (F7, F10, F13, F15, F16, F17), Chinese Martial Arts (F5, F12), and non-herbal medicine (F18).

Acupuncture and related practices, Falun Gong, and Herbal Medicine are the most prominent topic areas as indicated by the large numbers of WP editors associated with them primarily. Among the identified topics, Acupuncture and Qigong have the most connections to the TCM field, with 5 and 6 highlighted correlations in Table 2 respectively. They also serve as bridges for other topics to connect to the field: "TCM and its common concepts" connects with Acupuncture which connects to the rest of the field; Falun Gong and Chinese Martial Arts only connect to the rest of the filed through Qigong. The strongest connections (i.e., correlation above 3) are between Acupuncture and TCM concepts, and between Qigong and Chinese martial arts. It is somewhat surprising to see that TCM concepts are perceived on WP as only closely related to a single topic area: Acupuncture, which suggests that TCM concepts have not been applied to the discussions of the other conceptually related TCM topics such as Qigong and Taichi.

Herbal medicine has many different types such as those that are also used as spices (e.g., Cinnamomum cassia) and those used as psychoactive drugs (e.g., Cannabis). This topic area is linked to the TCM field through the generalists who made low contributions to all TCM topics except for Falun Gong and Tiger Bone Wine. In contrast, only one non-herbal medicine topic (Tiger bone wine) stands out as a separate factor, and this very small area is largely isolated from the rest of the TCM field indicated by the very low correlations with all other factors.

Topics of the TCM field on WP

The most prominent topic is Acupuncture (F1), which aligns well with the fact that among TCM theories, techniques and practices, acupuncture is the most recognized, accepted and practiced in the Western world. In many western countries, acupuncture therapists are trained and certified, and acupuncture treatments are covered by most health insurance plans while other TCM practices such as herbal medicine are not. Qigong (F8) and Chinese massages (F9; cupping therapy, Guasha, etc.) are practices closely related to acupuncture (Table 2), but are much less recognized as seen from their much smaller sizes (Table 1).

The second most prominent topic is Falun Gong, which has a size only slightly smaller than Acupuncture when considering both constructive (F3) and destructive (F2) contributions to the topic. Falun Gong has been highly controversial and attracted attention from many. Editors who belong to the constructive group tend to have broad interest in TCM beyond Falun Gong and added or modified significantly more references than they removed on Falun Gong. In contrast, editors who belong to the destructive group tend to be highly focused on Falun Gong and removed significantly more references than they added or modified.

Falun Gong is largely separated from the rest of the TCM field as indicated by the mostly very low correlations with all the other topics. The only relatively high correlation the two Falun Gong factors have is with Qigong, which recognizes their conceptual connection. We can speculate on reasons for this separation. Although there are controversies over several TCM topics, such as acupuncture and Chinese herbal medicine, those are mostly about whether they are scientific and effective. Controversies around Falun Gong, however, are highly political. Essentially, editors who contributed to Falun Gong related WP articles may not be interested in TCM per say but in politics whereas editors who contributed to other TCM topics were drawn to the medicine aspects of the topics.

It is interesting to see that sub-areas of herbal medicine are not interrelated to each other but form a weak partial linear chain of links: Fungi used in TCM (F7) is related to Plants used as both spice and medicine (F17) and to the topic that appears to be flowering plants such as rose and magnolia (F16) which is then related to psychoactive plants (F15). Goji (F10) and the generic topic area on medicinal plants (F13) are not related to any other sub-areas of herbal medicine. Similar to the earlier observation that TCM concepts are perceived on WP as only closely related to a single topic area: Acupuncture, it is somewhat surprising to see that the general topic on medicinal plants is not closely related to any of the specific types of medical plants.

Several sub-areas of herbal medicine, including the generic topic area on medicinal plants (F13), Plants used as both spices and medicine (F15), and Psychoactive plants (F17), have a relatively high correlation with only one of the other TCM topics. The topic "Plants used as both spice and medicine" (F17) is largely separated from the rest of the TCM field, with mostly very low correlations with all the other topics. Contributors to this area who are only interested in the plants as spice may have separated this area out from the rest of TCM.

Taichi (F12) is correctly recognized on WP as a form of Chinese martial arts as indicated by its relatively strong correlation with Chinese martial arts (F5). It is interesting to see that Qigong (F8) is perceived on WP as more closely related to Chinese massages (F9) than to Chinese martial arts although it is often mentioned together with both in the literature and movies.

Conclusions

The present study applied one of the effective bibliometric methods for mapping knowledge domains represented in published scholarly documents, i.e., author bibliographic coupling analysis, to examine one of the many topic areas on Wikipedia: Traditional Chinese Medicine (TCM). It is interesting to explore what we may learn from bibliometric studies of domains of knowledge represented in Wikipedia, a gigantic encyclopaedia created and maintained collectively by volunteers world-wide.

We found that seven TCM topic areas are represented on Wikipedia, among which Acupuncture related practices, Falun Gong, and Herbal Medicine attracted the most of significant contributors to TCM. Acupuncture and Qigong have the most connections to the TCM knowledge domain, and also serve as bridges for other topics to connect to the domain. Herbal medicine is weakly linked to and non-herbal medicine is isolated from the rest of the TCM knowledge domain.

It appears that specific topics are represented well on WP but their conceptual connections are not, especially those between a general topic (e.g., TCM and its common concepts) and its sub-topics (e.g., Qigong, Taichi).

The present study shows that ABCA is effective for mapping knowledge domains represented on Wikipedia.

Acknowledgments

This study was supported by an Insight Development Grant from the Social Sciences and Humanities Research Council of Canada (SSHRC). We would like to thank our research assistant Xinru Zhang for writing some of the data collection and analysis programs for this study.

Abstract

Germany has become a major country of immigration, as well as a research powerhouse in Europe. As Germany spends a higher fraction of its GDP on research and development than most countries with advanced economies, there is an expectation that Germany should be able to attract and retain international scholars who have high citation performance. Using an exhaustive set of over eight million Scopus publications, we analyze the trends in international migration to and from Germany among published researchers over the past 24 years. We assess changes in institutional affiliations for over one million researchers who have published with a German affiliation address at some point during the 1996-2020 period. We show that while Germany has been highly integrated into the global movement of researchers, with particularly strong ties to the US, the UK, and Switzerland, the country has been sending more published researchers abroad than it has attracted. While the balance has been largely negative over time, analyses disaggregated by gender, citation performance, and field of research show that compositional differences in migrant flows may help to alleviate persistent gender inequalities in selected fields.

Introduction

In the current era of knowledge-based economies, highly skilled people are the most mobile population group worldwide (Schiller & Cordes, 2016). In OECD countries, highly qualified individuals, including researchers, make up one-third of the immigrant population (Docquier & Marfouk, 2004; Schiller & Cordes, 2016). The international mobility of researchers facilitates the exchange of knowledge, ideas, and skills, and thus contributes to the dynamic development of the global knowledge production system (Bauder, 2015; Franzoni et al., 2015; Netz & Jaksztat, 2017). Countries see researchers as prized groups because of their high levels of human capital and potential for fueling innovation and economic growth. Gaining a better understanding of this kind of mobility is crucial for evaluating scientific research at the national level, and for informing policy on science and mobility in academia (Netz et al., 2020). As Germany is a science powerhouse that hosts more non-EU researchers than any other EU country (Jöns, 2009; IDEA Consult, 2013; Lörz et al., 2016; Guthrie et al., 2017; Aman, 2018), Germany is expected to be able to attract and retain international researchers with high citation performance. A lack of fine-grained data on the international migration of German-affiliated researchers and their citation performance makes it difficult to understand the in- and out-flow patterns and costs associated with this kind of mobility. This study develops individual-level migration data in order to analyze the mobility of researchers to and from Germany, while taking into account the citation performance of internationally mobile scholars across disciplines and genders.

Germany's relatively liberal immigration laws and its powerful position as the world's fourth-largest economy (Schiller & Cordes, 2016) are key factors in explaining why about one-fifth of the top-level researchers in Germany in 2004 were foreign-born (Ioannidis, 2004). Over the past three decades, German universities and research institutions have attracted large numbers of researchers from other countries, especially from other European countries (Giousmpasoglou

& Koniordos, 2017). In addition, Germany spends over 3.1% of its gross domestic product (GDP) on research and development (R&D), which is more than the R&D spending by GDP in most OECD countries, including the United States (US) (2.8%) and the United Kingdom (UK) (1.7%). It has been suggested that highly cited researchers tend to migrate to countries with higher R&D spending (Hunter et al., 2009). However, when the two migration directions are considered, Germany appears to have suffered a net loss of 28% due to the global migration of researchers (Schiller & Cordes, 2016; OECD, 2008). More specifically, Germany is experiencing a "brain drain" in certain specializations, including medical research (Giousmpasoglou & Koniordos, 2017). Although existing studies on the German science system have explored some aspects of academic migration (Netz & Finger, 2016; Aman, 2016; Parey et al., 2017; Netz & Jaksztat, 2017; Netz & Grüttner, 2020), there has been no systematic analysis of international academic migration for Germany that has taken the citation performance of researchers into account, and that has covered all fields of scholarship. This study provides a much-needed baseline for the development of future policies that can help Germany succeed in attracting and retaining qualified researchers from overseas, facilitating the circulation of brainpower, and advancing the performance of the German science system.

It is generally recognized that international academic mobility has a positive influence on the global scientific system. By promoting knowledge production and diffusion between countries, migration among researchers enhances the performance of global science production (Giousmpasoglou & Koniordos, 2017; Guthrie et al., 2017; Netz et al., 2020). From a micro perspective, there is strong evidence that mobile researchers outperform non-mobile researchers (Dubois et al., 2014; Franzoni et al., 2014; Moed & Halevi, 2014; Guthrie et al., 2017). Findings from the MORE survey have shown that mobility leads to increased outputs for researchers in both academia and industry. Notably, there is evidence that the output effects are higher among researchers moving from the EU to the US than among those moving in the opposite direction (Børing et al., 2015). Gibson and McKenzie found that emigrant researchers have much greater research outputs and impacts, as measured by total citation and *h*-index, than researchers who stay in their respective origin countries (Gibson & McKenzie, 2014). A comprehensive evaluation of the interplay between migration and citation performance that takes individual all disciplines into account can deepen our understanding of this crucial topic.

Qualitative interviews, surveys, bibliometric data, and data from curricula vitae are among the most common data sources for studying the migration of researchers (Netz & Jaksztat, 2017; Netz & Grüttner, 2020). The idea of using the historical records of researchers to follow their geographical movements can be traced back to a study by Rosenfeld & Jones (1987) on the movements of psychologists in the US that used a sample from the biographies of members of the American Psychology Association. The digital revolution and the advent of digitized sources of bibliometric information enables us to expand this simple idea to cover a large number of data points with a flexible level of granularity that is suitable to our research objectives. Previous studies that utilized similar applications of bibliometric data have mapped academic mobility among countries, and have shed light on the causes and consequences of academic mobility (Moed & Halevi, 2014). Recent methodological innovations for re-purposing bibliometric data to study internal migration within country boundaries have made the process of inferring migration events from affiliation addresses more reliable (Miranda-González et al., 2020).

This paper relies on large-scale digitized bibliometric data from *Scopus* to document and analyze international migration to and from Germany among researchers over the past 24 years. The cleaned and pre-processed bibliometric data provide a unique perspective on the international migration patterns and geographical trajectories of mobile researchers. The results help to clarify the position of Germany in the global science system. In addition, the analysis evaluates the interplay between migration and citation performance across different disciplines.

Thus, this analysis adds a demographic dimension to the science of science literature by providing several in-depth statistics related to academic mobility.

Materials and methods

Scopus publications of all German-affiliated authors

This paper relies on a complete enumeration of the Scopus-indexed publications of researchers who have published with an affiliation address in Germany at some point during the 1996-2020 period (over eight million publications from more than one million researchers). Note that these data do not provide information about researchers who have not published in Scopus-indexed sources during the temporal window. The unit of the data is an *authorship record,* which we define as the linkage between an author affiliation and a publication.

The raw data are pre-processed to ensure that we are performing a reliable analysis of mobility events based on the changes in affiliation addresses. The pre-processing steps involve the adoption of an unsupervised machine learning algorithm for disambiguating authors and a neural network algorithm for handling missing values (Miranda- González et al., 2020; Subbotin & Aref, 2020). In our dataset, a large majority of authorship records have a country variable. However, there are 96,465 authorship records with missing country information. The missing values are systematically inferred using a neural network algorithm inspired by Miranda-González et al. (2020), which takes an affiliation address as the input and predicts the country as the output. We use a random set of one million authorship records from our dataset that have country information, and use them as training data (80%) and testing data (20%). The technical details of the development of the neural network have been explained elsewhere (Miranda-González et al. 2020). It has been demonstrated that the neural network can correctly predict the country for 98.4% of records, which is a level of accuracy we consider acceptable for predicting missing country information.

The second step of our data pre-processing helps us overcome the problems associated with using Scopus author IDs to identify unique authors. It has been shown that Scopus author IDs have high levels of *precision* and *completeness*. Precision measures the percentage of author IDs that are associated with the publications of a single individual only. Completeness measures the percentage of author IDs that are associated with all of the Scopus publications of an individual. The results of the latest evaluation of the accuracy of Scopus author IDs conducted in August 2020 showed that the precision and the completeness of Scopus author profiles are 98.3% and 90.6%, respectively (Paturi & Loktev, 2020). However, while it appears that the quality of individual-level Scopus data is sufficiently high to enable us to study the migration of researchers (Kawashima & Tomizawa, 2015; Aman, 2018), there are several notable limitations to keep in mind when using Scopus data for migration research. The precision limits in Scopus author IDs imply that 1.7% of Scopus author IDs may be associated with the publications of more than one person, which could affect the accuracy of the migration events detected through changes of affiliation countries per author ID. We overcome this problem by using an unsupervised machine learning algorithm that was inspired by a recently developed author name disambiguation method (D'Angelo and van Eck, 2020). The conservative adaptation of this method (Miranda-González et al., 2020) assumes that every two authorship records are from distinct individuals unless sufficient evidence is found to the contrary using a rule-based scoring approach and a clustering method. We first calculate the similarity score of each pair of two authorship records belonging to the same author ID. The similarity is measured based on author names, co-author names, subjects, funding information, and grant numbers. The author disambiguation algorithm makes all pairwise comparisons between authorship records with the same author ID, and creates a distance matrix based on similarities and dissimilarities in the aforementioned features for each pair of records. A clustering algorithm is then used to process the distance matrices, and to cluster similar authorship records. We then issue revised author IDs based on the resulting clusters. We use the *agglomerative clustering* algorithm from the scikit-learn Python library (Pedregosa et al., 2011) to cluster authorship records. This algorithm belongs to the family of hierarchical clustering methods. Supporting our conservative approach, it first places each record in its own cluster, and then merges pairs of clusters successively if doing so minimally increases a given linkage distance (Pedregosa et al., 2011). As well as being compatible with our conservative approach, agglomerative clustering has the advantage of offering us the flexibility to process any pairwise distance matrix.

Our author disambiguation procedures are based on the extraction of a subset of *suspicious* author IDs that are especially likely to be affected by the precision flaws of Scopus author IDs. An author ID is considered suspicious if it is associated with more than six countries or more than 292 publications (an average of more than one publication per month across a period of 24 years and four months). Based on these criteria, only 25,000 out of a total of 1.4 million author IDs are classified as suspicious. These author IDs are associated with 2,242,797 publications. After disambiguation, revised author IDs are issued for these records according to their clusters, and then they are merged with the rest of the data for the purpose of inferring migration events.

The international mobility of researchers is determined by identifying the changes in the affiliation addresses of authors across different publications over time. To detect migration events more reliably, the most frequent (mode) country(ies) of affiliation is extracted for each researcher in each year. A migration event is considered to have happened only if the mode country of affiliation changes for the researcher across different years such that the previous mode country disappears. By aggregating the movements for each pair of origin and destination countries, we can estimate the international scholarly migration flows. Accordingly, the country of academic origin is defined as the mode country during the first year of publishing. Similarly, the country of destination is defined as the mode country of the most recent year of publishing.

Based on their migration events or lack thereof, and on their academic origins and destinations, researchers are assigned to one of the following six categories (mobility types) from the perspective of the German science system:

(1) Single-paper author (having only one publication);
(2) Non-mover (having multiple publications and Germany as the only mode country);
(3) Immigrant (origin: not Germany; destination: Germany);
(4) Emigrant (origin: Germany; destination: not Germany);
(5) Return migrant (origin: Germany; destination: Germany, with international migration); and
(6) Transient (origin: not Germany; destination: not Germany, but with Germany being among the researcher's mode countries at some point).

The annual net migration rate (NMR) is calculated based on the difference between incoming and outgoing flows in a year divided by the population of research-active scholars in that year, and then expressed as a per-thousand rate. The size of the population of research-active scholars in a given year is based on the number of researchers who have listed Germany as their country of affiliation on publications within a two-year vicinity of that year. A positive NMR value can be interpreted as indicating that more researchers are entering than leaving the country under analysis.

We define the *academic age* of researchers as the number of years since their first publication (as of 2020). We calculate the average annual citation rate for each researcher by dividing their total number of citations (as of April 2020) by their academic age. This measure allows us to compare the citation performance of researchers who have different levels of experience, but are in the same field. When comparing the citations of migrant researchers from different fields, we apply a second normalization by dividing the annual citation rate by the average annual citation rate of migrant researchers in that field.

We use the *All Science Journal Classification* (ASJC) codes to incorporate the fields and disciplines (subfields) of scholarship in our analysis. The ASJC codes are based on four fields (*Heath Sciences*, *Life Sciences*, *Physical Sciences*, and *Social Sciences*). These codes are further divided into 26 academic disciplines that provide a more granular level of information about the scholarship. The field and the discipline of each researcher are determined based on the frequencies of the ASJC codes in the individual's publications. We first compute the frequencies of each field and discipline in the authorship records of an individual, and then compare them using a Z-test (Subbotin & Aref, 2020) with the mean and the standard deviation of frequencies for that field or discipline among all researchers in our dataset. The main field and discipline of each researcher are determined based on the largest Z-score that exceeds a threshold of one. If neither of the Z-scores exceeds one, we categorize the researcher as *Multidisciplinary*.

The first names of researchers can be used to infer their gender (Larivière et al., 2013; Goldstein & Stecklov, 2016b, a; Dworkin et al., 2020). This study utilizes the *Genderize* library, a simple application programming interface (API) that provides the gender most commonly associated with a given first name from a dataset of over 114 million names. After performing basic text operations (like removing middle initials from the first name field), we obtained the gender for 1,046,873 author profiles in our dataset. For the remaining profiles, we manually searched for public author information to determine the gender by checking the individual's personal homepages, curricula vitae, online profiles, biographies in publications, and other online sources. Accordingly, the genders for 6,767 additional author profiles were determined manually. Finally, the gender of 1,053,640 author profiles (75.96%) were reliably determined by either algorithmic or manual gender detection. For our analyses that involve gender (e.g., measuring gender ratios), we set aside the 24.04% of author profiles whose gender cannot be determined either algorithmically or manually. The binary genders inferred and used in our analysis do not refer directly to the sex of the researchers, assigned at birth or self-chosen; nor do they refer to the socially assigned or self-chosen genders of the authors.

Results

We look at citation-based performance by discipline across different mobility types. We also provide descriptive results on common countries of origin and destination, and calculate the annual net migration rates of researchers for Germany. Furthermore, the discipline-normalized citation performance of the researchers is evaluated and compared for the common origin and destination countries. Finally, we provide detailed results on the gender ratios of researchers by discipline, and compare the gender ratios among mobile researchers and all researchers.

Mobility types and annual citation rates by discipline

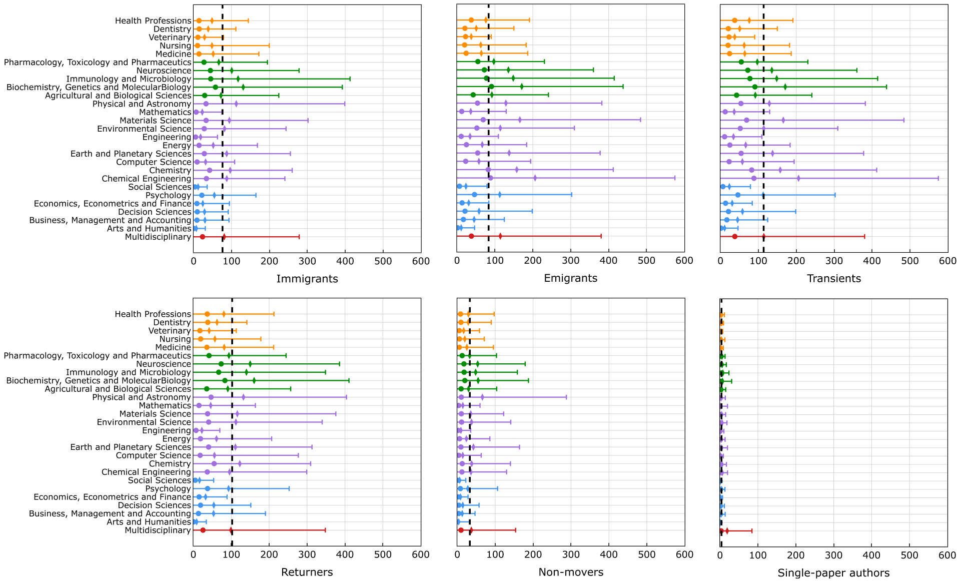
Among the researchers who have Germany as a mode country for at least one year, 44.01% are single-paper authors, 42.08% are non-movers, and only 13.91% are internationally mobile. More details are provided in Table 1.

Table 1. Number and proportion of researchers by mobility type.

	Single-paper author	*Non-mover*	*Immigrant*	*Emigrant*	*Return migrant*	*Transient*
Count	610,449	583,679	51,135	63,003	37,078	41,722
%	44.01%	42.08%	3.69%	4.54%	2.67%	3.01%

Figure 1 shows the average, median, and standard deviations of annual citation rates by discipline for researchers of each mobility type. There are substantial disparities in the annual citation rates of these researchers, as the large standard deviations indicate. As expected, we find that there are notable differences in the annual citation rates of researchers across different disciplines (Marmolejo-Leyva et al., 2015; Bedenlier, 2017; Horta et al., 2019). On average, researchers in the social sciences (colored in blue) receive fewer citations and researchers in the life sciences (green) have more citations than their counterparts in other fields.

When we look at differences in citation rates by mobility type, we can see that mobile researchers markedly outperform non-movers, even after separating single-paper authors. Compared to non-movers, mobile researchers have much higher annual citation rates for almost all disciplines. Thus, even though they represent a minority of the researchers in Germany, mobile researchers make substantial scientific contributions in terms of receiving citations. Among the internationally mobile researchers, transients and return migrants have higher annual citation rates than immigrants and emigrants. This pattern may be explained in part by the more complex mobility trajectories of transients and return migrants.



Immigrants

Emigrants

Transients

Returners

Non-movers

Single-paper authors

Flows, origins, and destinations

Figure 2 illustrates the total migration flows of researchers from and to Germany during the 1996-2020 period. By far, the largest academic migration inflows and outflows are with the US, as various studies have documented (Maier et al., 2007; Weinberg, 2009; Hunter et al., 2009; Franzoni et al., 2012; Guthrie et al., 2017). For Germany, the US is also the most common resource hub of highly skilled individuals, due to the large number of researchers in the US and their high mobility potential (Schiller & Cordes, 2016). After the US, the common academic origins and destinations for Germany-affiliated migrant researchers are the UK in a distant second, followed by Switzerland. Most of the other common origin and destination countries are in Europe, which indicates that geographical proximity is also relevant. Moreover, EU policies might have played a role in facilitating large migration flows of scholars within Europe. For example, the *Bologna Process,* which was introduced in the 2000s, was designed to ensure comparability in the standards and the quality of higher education qualifications in Europe (Teichler, 2015). A more recent example is the *IPID4all* program, which was launched in 2014 with the aim of creating an attractive environment in Germany for young international researchers (IDEA Consult et al., 2017). Such polices are helping to drive and facilitate academic mobility by providing researchers with more opportunities for academic exchange and communication. In addition, there are a number of countries that are exporting substantial numbers of published researchers to Germany, but that are not equally attractive destinations for researchers from Germany, including Russia and India.

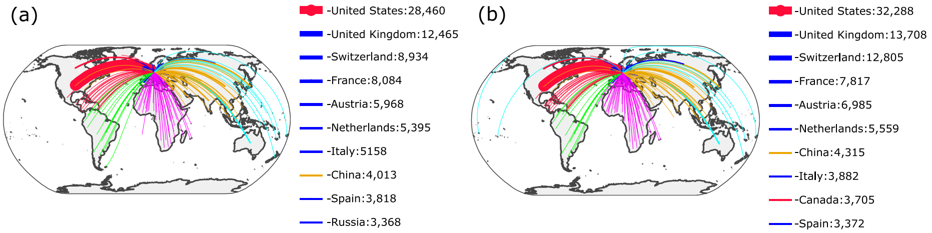

Figure 2. Migration flows of researchers to Germany (a) and from Germany (b) over the 1996-2020 period.

Net migration rates

Figure 3 illustrates the shifting annual net migration rates of researchers in Germany over the 1998-2017 period (other years are not reported due to boundary effects). The data suggest that for nearly the entire two decades of our analysis, the outgoing flow of published researchers exceeded the incoming flow. The lowest NMR value is for 2008, at -10.52 per 1,000 researchers. Note that the NMR in the general population also reached its lowest value in 2008, which was during the global economic crisis. However, in contrast to migration among researchers, the net migration rate for the general population as a whole was consistently positive throughout these years. After 2008, the NMR for researchers displayed a generally increasing trend until 2014, when it reached a peak of +1.56. In the most recent years, the NMR for researchers followed a generally decreasing trend. Our finding of a generally negative NMR for scholars is consistent with the results of studies by Schiller et al., which compared the birthplaces and workplaces of researchers, and reported that Germany has suffered a net loss of 28% of researchers due to international mobility (Schiller & Revilla Diez, 2008; Schiller & Cordes, 2016). The recent trends in migration among scholars contrasts with the NMR in the general population, which indicates that since 2008, Germany has increasingly become an immigrant destination. Indeed, since 2012, Germany has admitted large numbers of asylum-seekers.

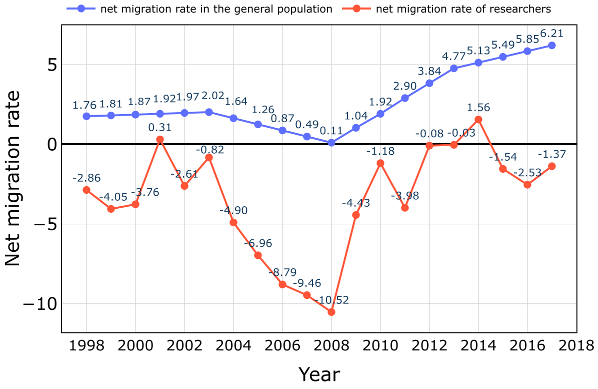

Figure 3. Net migration rates for researchers (in red) and for the general population (in blue).

Citation-based performance by geography

We previously examined the disparities in the citation-based performance of researchers of different mobility types (Fig. 1). In this subsection, we analyze the citation performance of immigrant and emigrant researchers by country. First, we divide the annual citation rate of each migrant researcher by the average of all migrant researchers in the respective discipline to obtain a discipline-normalized annual citation measure. Based on the three quantiles of the resulting distribution for all migrant researchers, we have distinguished three equally sized citation groups: low, medium, and high. Accordingly, the discipline-normalized annual citation rate is between 0.18 and 0.73 for migrant researchers in the medium group, it is below 0.18 for those in the low group, and it is above 0.73 for those in the high group.

Figure 4 shows the composition of the citation groups among the emigrants and immigrants for 30 countries.

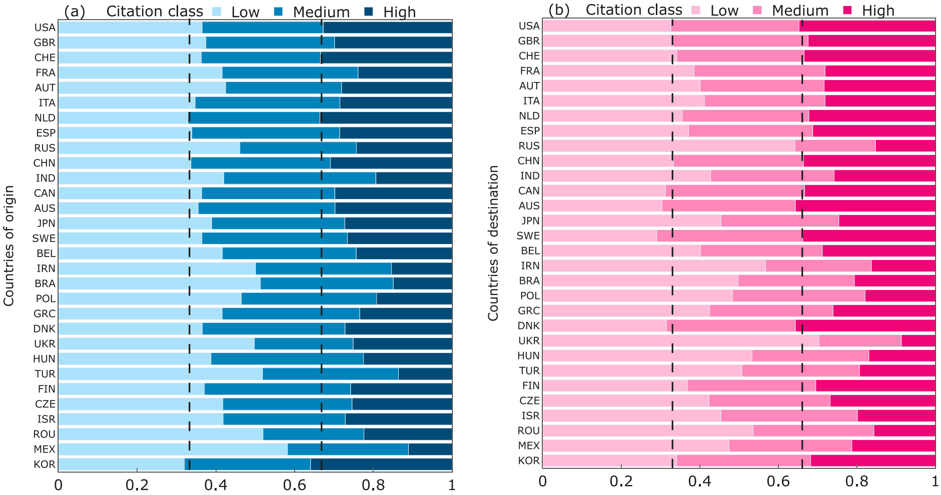

Figure 4. Citation class composition of immigrants by origin (a) and emigrants by destination (b). Vertical gridlines are shown to enable a comparison to the average migrant researcher, who is equally likely to belong to any of the three citation classes.

Among emigrants, scholars moving to Denmark, Austria, and Sweden are more likely than other emigrants to belong to the high citation group. Among the common destinations for emigrants, Sweden, Austria, and Denmark rank ninth, 10th, and 13th, respectively. Among immigrants, those who come from South Korea and the Netherlands are more likely than those who come from other countries to belong to the high citation group.

When we look at the numbers of immigrant and emigrants from the 10 countries with the largest flows, we observe that for most citation groups and country combinations, there are more emigrants than immigrants. This finding is also consistent with the overall negative net migration rate that we observed in Figure 3. For the US, the UK, and Switzerland (which have the three largest flows), the number of emigrants is considerably higher than the number of immigrants. Conversely, while Russia, Italy, and Spain, have comparable migration flows with Germany, they send more published researchers to Germany than they receive from Germany.

Gender disparities among migrant researchers by discipline

Figure 5 shows on the X-axis that almost all disciplines in Germany are dominated by male researchers. Especially for the disciplines in the physical sciences, like engineering, physics, and astronomy, the male-to-female ratio exceeds eight. The only disciplines for which the gender ratio is close to unity are veterinary sciences, psychology, and immunology and microbiology.

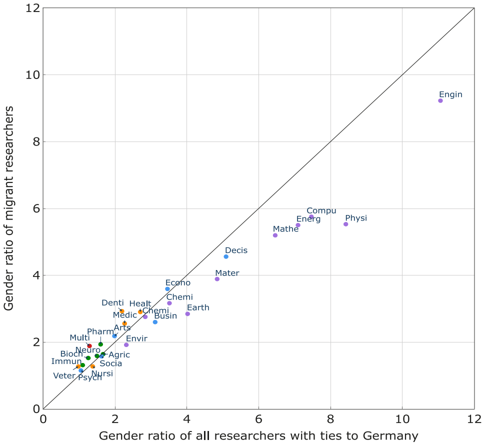

Figure 5. Male-to-female gender ratios of migrants and all researchers by discipline

Given these observations, we examine the gender ratios among the migrant researchers of each discipline, and then compare them to the corresponding ratios among all German-affiliated researchers in Figure 5. The most striking finding is that in disciplines that have a gender ratio above four among all researchers, the gender disparity is less severe among the migrant researchers (see the data points under the 45° line, and especially all of the disciplines with ratios above four). In contrast, for most disciplines in the life sciences (green dots), the male-to-female ratio is more balanced than it is in the physical sciences, and it is slightly higher among migrant researchers.

Discussion and future directions

As researchers play a unique role in innovation and economic growth, and are among the most mobile members of the occupational structure, most countries impose few, if any, limits on their mobility. Thus, it is crucial that we understand whether and, if so, how countries like Germany are situated in the global migration flows of published researchers (Docquier & Marfouk, 2004; Schiller & Cordes, 2016; Aref et al., 2019). We used Scopus bibliometric data (Falagas et al., 2008; Mongeon & Paul-Hus, 2016) to extrapolate the key variables and to infer the geographic locations of researchers. In addition, we drew from these data information on individual researchers, including on their scientific discipline, gender, and citation performance. Based on this information, we created five distinct mobility categories for researchers who had multiple publications and were exposed to mobility. These categories accounted for 55.99% of the 1.4 million author profiles identified in the Scopus data.

Algorithmically pre-processed and author-disambiguated Scopus data enabled us to provide uniquely rich, albeit preliminary, insights into Germany's role in the global system of migration among published researchers. Examining the 24-year period from 1996 to 2020, we demonstrated that internationally mobile researchers accounted for nearly 14% of the population of published researchers with ties to Germany. This group of internationally mobile researchers made disproportionately large contributions, as their differences in citation-based performance compared very favorably to those of non-movers in Germany.

The sheer size of our census of German-affiliated researcher data allowed us to differentiate the population of internationally mobile researchers according to their countries of origin and destination. Thus, these data provided us with a unique and detailed mapping of the key countries associated with academic mobility to and from Germany. We found that the US, the UK, and Switzerland were the three largest origin countries of published researchers immigrating to Germany. Our findings also showed that Germany has gone beyond reciprocating these levels of migration, with higher numbers of researchers emigrating from Germany to these countries. While these three countries were the primary destinations and accounted for 58% of all scholarly migration in this period, they were not necessarily the most significant in terms of their citation performance. Researchers who emigrated to Denmark, Sweden, and Austria and researchers who immigrated from South Korea and the Netherlands were more likely to be highly cited than other German-affiliated immigrants and emigrants.

Our data also allowed us to explore levels of gender disparities in the German science system, to investigate how these inequalities varied between migrant and *stationary researchers* (non-movers and single-paper authors), and to explore the heterogeneity in levels of gender inequality across scientific fields. We observed that the gender ratios (males to females) were nearly equal in disciplines such as veterinary sciences and psychology, whereas in fields such as engineering and physics and astronomy, there were six to eight times more men than women. While some of these patterns have been well-documented in the literature (Larivière et al., 2013; Macaluso et al., 2016; Sugimoto et al., 2015; IDEA Consult et al., 2017), our results highlight the key role that international mobility may play in helping to moderate some of the most extreme gender disparities. We found that female researchers were better represented among migrants than among stationary researchers in the most gender-imbalanced disciplines. This observation allows us to speculate that migration could further counterbalance the extremely gendered nature of certain disciplines in Germany. The results also highlight that more can be done to support female scholars wishing to remain in Germany, and to encourage the immigration of female scholars in fields that are heavily unequal, such as engineering, physics and astronomy, computer science, energy, and mathematics.

The analysis enabled us to uncover – within the quality limitations of the bibliometric data and our pre-processing approach for handling missing values and disambiguating authors – new aspects of the academic life course, and to show how it is connected to scholarly migration. Ultimately, our analysis helps to shed light on Germany as both a hub and a through station on the international map of academic mobility. The preliminary questions explored here offer some initial insights for policymakers, as they improve our understanding of the role of migrant researchers in the German science system, and their demographic composition. Our analysis contributes to the science of science by providing relevant evaluation measurements of the mobility of researchers from all disciplines based on their geography, gender, and citation performance.

Our study opens a number of new directions for further research. Building on this work, we intend to move from using an aggregate perspective to applying a micro-level perspective in order to gain further insights into the relationship between migration and scientific performance. This approach will be particularly useful for studying how women are affected, especially in fields where they are severely under-represented, and for examining the impact of specific national policies in Germany that aim to improve the gender balance in academic fields. Ultimately, by understanding the role of migration both into and out of Germany in each field and discipline, we can provide additional insights into researchers' characteristics, mobility behavior, and performance. Thus, our study represents a key step toward gaining a better understanding of migration among scholars.

Acknowledgments

The authors highly appreciate the technical support from Tom Theile and the comments from Aliakbar Akbaritabar. This study has been funded by the German Academic Exchange Service with funds from the Federal Ministry of Education and Research. This study has received access to the bibliometric data through the project "Kompetenzzentrum Bibliometrie," and the authors acknowledge their funder BMBF (funding identification number 01PQ17001).

Abstract

It is generally believed that the tide of interdisciplinarity is rising and becomes increasingly prevalent among various disciplines in natural and biomedical sciences. However, for the social sciences and humanities (SSH) limited evidence supports such a statement from bibliometric perspectives. Also, it has seldom been quantified how interdisciplinarity and its various aspects evolve over time. This paper analyzes the evolution of interdisciplinarity focusing on two aspects, namely process and outcomes, to draw a comprehensive trajectory of interdisciplinarity for five SSH disciplines over 50 years. We find that research in each of these five SSH disciplines is broadening its knowledge base by involving more disciplines yet is at the same time shifting towards further specialization. Interdisciplinarity is found to be positively correlated with citation impact and visibility and becomes stronger as the citation window widens up. The disruptiveness of publications, however, is negatively correlated with the level of interdisciplinarity and increasingly so over time.

Introduction

Interdisciplinary research (IDR) emerges to tackle the complex and societal-pressing problems that cannot be truly resolved by a single discipline (Carayol & Thi, 2005; Frodeman & Mitcham, 2016). To closely monitor and evaluate the supporting initiatives and understanding the status and mechanisms behind IDR, several recent studies are devoted to examining its different aspects (Rousseau et al., 2019), such as input (e.g. disciplinary diversity in team assembly; Schummer, 2004; Zhang et al., 2018), process (e.g. disciplinary diversity in references; Mugabushaka et al., 2016; Porter et al., 2007), outputs (e.g. topic diversity in abstracts; Bu et al., 2020), and outcomes (e.g. research impact; Larivière et al., 2015; Larivière & Gingras, 2010; Szell et al., 2018; J. Wang et al., 2015). Among all, quantitative measurements and indicators to evaluate the intensity of IDR processes, i.e., how interdisciplinary one's research is, is one of the most discussed focal research topics (Wagner et al., 2011). Although criticized as confusing and unsatisfying to achieve universally convergent assessment for precise decision-making (Q. Wang & Schneider, 2019), these indicators can still assist us to get a glimpse of IDR as a social phenomenon and to interpret it from a macro perspective.

One of the frequently referenced macroscopic statements by researchers, policy-makers, and the media is that "science is becoming more interdisciplinary". A consensus seems to have formed that scientists inhabiting dissimilar knowledge bases or mastering different skills have been crossing disciplinary borders and collaborating more frequently and with unconventional partners; this leads to more interdisciplinary and scientifically significant outcomes. Empirical evidence, however, is still limited to disciplines from STEM and biomedical sciences. Temporal change in IDR in the social sciences and humanities has not been studied so far.

In this study, we analyse the evolution of interdisciplinarity in five SSH disciplines over half a century and examine the possible impact such change in IDR, if any, might produce on the outcome of scientific research. The rest of the paper is organized as follows: we first introduce the dataset and methodology we adopt. The next section presents the results and discussion and the last section concludes.

Data

The Microsoft Academic Graph (MAG) dataset is adopted in our empirical study; previous studies have shown that MAG is a viable source for scholarly communication research in terms of coverage (Paszcza, 2016) and the completeness of citation and metadata (Thelwall, 2017). As Microsoft continues to improve the coverage, design, and accessibility of MAG, it has become one of the most promising bibliographic datasets and is more frequently employed by those who study research dynamics quantitatively (Kong et al., 2020; Ma et al., 2020).

MAG distinguish from other bibliographic databases in that it adopts a bottom-up approach for the field categorization process (K. Wang et al., 2020), as opposed to, for instance, Web of Science, which uses existing journal categories to classify publications (called a top-down or classification-based approach, see Wagner et al., 2011). Different from previous bottom-up classification methods that tend to adopt co-citations, co-words, and/or bibliographic couplings (Wagner et al., 2011), MAG quantifies the semantic distance between two textual paragraphs representing two certain publications and then clusters the retrieved semantic representations to form the basis of concepts, which are de facto fields, domains, or disciplines in practice. Six levels of concepts are clustered automatically on different granularities. The top two levels of concepts (L0 and L1) are manually defined into a unique hierarchical structure to be consistent with most of the categorization systems (K. Wang et al., 2020), where L0 is comprised of 19 fields (e.g., physics, chemistry, and economics) and L1 consists of 294 subfields (e.g., theoretical physics, biochemistry, and macroeconomics).

The disciplines we use as case studies in this paper, i.e. Anthropology, Applied Psychology, Linguistics, Library Science, and Macroeconomics, are situated in the L1 level of MAG's category setting. Therefore, L1 is also used in the categorization of individual publications and their corresponding references to achieve consistency.

We recognized 300,559 journal or conference publications between 1960 and 2009 under the field category Anthropology (62,619), Applied Psychology (116,868), Linguistics (65,557), Library Science (17,678) and Macroeconomics (39,481). Publications labeled for more than one category were assigned to each category.

Method

We investigate the evolution of IDR focusing on two aspects, namely IDR process, and IDR outcome.

IDR Process

Stirling (2007) pointed out that diversity consists of three basic concepts, namely variety, balance, and disparity, each of which is a necessary but insufficient property of diversity as a whole. This notion and their generic indicator of diversity were then introduced and modified by Rafols and Meyer (2010) to Information Science as a quantitative measurement of knowledge integration to infer interdisciplinarity. A significant proportion of research is devoted to devising indicators that integrate two or three factors (dimensions) of diversity to achieve a reliable metric and assess or compare interdisciplinarity for different entities. In this study, we try to work as comprehensively and detailed as possible so that information loss caused by dimension reduction or integration can be minimized. Therefore, to quantify the intensity and evolution of IDR processes, we employed both single-factor (variety, balance, and disparity themselves; Stirling, 2007) and multi-factor measurements: Rao-Stirling (RS) diversity (Rafols & Meyer, 2010; Stirling, 2007), DIV (Leydesdorff et al., 2019), and $^2D^s$ (Zhang, Rousseau, & Glänzel, 2016) that involve two or all three single factors. We believe that the involvement of single-factor measurements may provide more implications that directly point to practical aspects of IDR, for instance, the number of disciplines referenced, and that the multi-factor measurements shed insight into the evolution of IDR from a more comprehensive perspective.

Table 1 provides notations and mathematical definitions of each indicator we employed in this study. Variety (n_c) is operationalized as the number of disciplines referenced for each publication, which reveals information regarding the **broadness of the knowledge base** in this study. Its variant, relative variety (n_c/N), is used in DIV representing variety in a relative scale; this variant is defined as variety divided by the number of categories in total. Balance (B), representing the **evenness of the knowledge base**, is set to be $1 - Gini_c$ where B = 1 indicates maximum evenness and B = 0 shows extreme imbalance. Here, $Gini_c$ represents the Gini coefficient of the distribution of disciplines in references. Disparity captures the average dissimilarity (or distance, explained further on) between every two disciplines referenced for each publication, which can be utilized to examine the cognitive distance and **heterogeneity of the knowledge base**.

Table 1. Selected measures of IDR.

Notation			
n_c	number of disciplines referenced	d_{ij}	dissimilarity between categories *i* and *j*
p_i	proportion of elements in category *i*	N	number of categories in total
x_i	number of references to the i-the category in an ascending order		
Indices			
Variety	n_c	Rao-Stirling (RS)	$\sum_{i,j} d_{ij}(p_i p_j)$
Balance (B)	$1 - Gini_c = \quad 1 - \frac{\sum(2i - n_c - 1)x_i}{\sum_{n_c} x_i}$	DIV	$(n_c/N) * B * D$
Disparity (D)	$\frac{\sum_{i \neq j} d_{ij}}{[n_c * (n_c - 1)]}$	$^2D^s$	$1/(1 - RS)$

Three indicators integrating a part of or all the above-mentioned three factors are also employed (i.e., multi-factor indicators as aforementioned). DIV is the multiplication of relative variety, balance, and disparity ranging from zero to one. In terms of RS, this indicator calculates the sum of distances between every two disciplines referenced multiplied by the product of proportions each discipline accounts for in reference. $^2D^s$can be regarded as a variant of RS that possesses greater discriminatory power, satisfying the properties proposed in Leinster and Cobbold (2012). Like RS, this indicator employs similarity among categories instead of disparity directly.

Four out of six measures (i.e. disparity, RS, DIV, and ${}^{2}D^{s}$) employ the dissimilarity between two categories d_{ij} in their calculation, which is operationalized as (1 - similarity) in practice, as shown to be valid and efficient in Zhang, Rousseau, and Glänzel (2016). The temporal perspective of this paper makes a few modifications to the cosine similarity necessary, that is, the application of a time window on similarity calculation. As the distance or reference strength among disciplines may be changing over time (Frank et al., 2019), potential structural changes to the similarity matrix itself cannot be ignored when performing temporal analysis. To account for this, we construct ten similarity matrices with a five-year time window each. This yields the following equation:

$$d_{ij} = 1 - \frac{R_{ij}+R_{ji}}{\sqrt{\left(TC_i^t + TR_i\right)\left(TC_j^t + TR_j\right)}} \tag{1}$$

where i and j refer to two sets of publications from two different categories published during the period t, R_{ij} denotes the number of times set i publications cite set j publications, TC_i^t denotes the total number of citations set i publications received during the period t, and TR_i denotes the total number of references initiated by papers from set i.

The handling of multi-labeling in the categorization of publications is also a tricky issue when calculating balance, disparity, and RS as counting frequencies of categories for references is required. Upon our examination, more than 50% of the publications in our dataset are labeled with more than one category. To address this issue, we used fractional counting to quantify the relative frequencies. For each multi-labeled reference, we set the frequency of each category labeled to $1/m$ where m equals the number of unique categories associated with this reference and then sum all the category frequencies for each reference to form the category frequency for the publication. For example, a publication with two references A and B, where A is labeled with both "Linguistics" and "Literature", and B is labeled with "Linguistics" and "Natural Language Processing (NLP)", will have an overall category frequency distribution as follows: Linguistics 1; Literature 0.5; and NLP 0.5.

IDR outcome

Furthermore, the evolution of IDR outcome is investigated focusing on two aspects, namely **citation impact** and **disruptiveness**. 2-year, 5-year, and 10-year citations are calculated to reflect the academic significance and visibility over time. Disruptiveness, proposed in Funk & Owen-Smith (2017) and applied in Wu, Wang, and Evans (2019), captures the level of disruption a publication contributes by calculating the percentage of the net increase of citing papers it invites to an existing local citation network. As shown in equation (2), for a certain paper P, n_i denotes the number of its forward citations received during time t that did not cite any of P's backward citations, n_j represents publications published during time t citing both P and its backward citations, and n_k captures publications that only cited P's backward citations instead of P itself.

$$D_t = \left(n_i - n_j\right)/\left(n_i + n_j + n_k\right) \tag{2}$$

Results and discussion

The evolution of IDR process

Broadness of knowledge base

Figure 2a illustrates the evolution of variety for five disciplines in 50 years (1960-2009). Each subplot represents a discipline and each solid curve shows the probability distribution of variety for all publications in that discipline in the corresponding period. The vertical dashed lines denote the mean of variety for each period. The same color for a solid curve and a dashed line means that they are describing the same period.

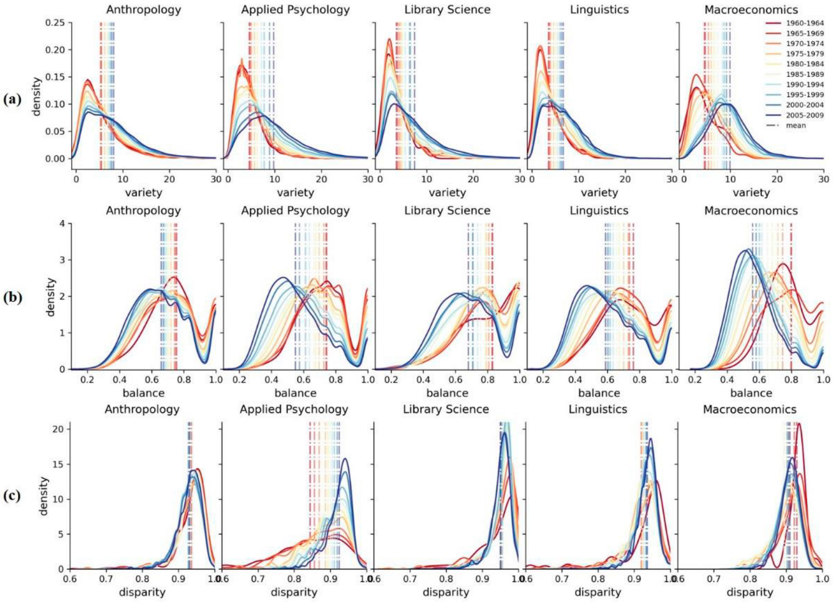

Figure 2. Evolution of variety, balance, and disparity in Anthropology, Applied Psychology, Library Science, Linguistics and Macroeconomics.

The dashed curves show sustained growth in terms of the central tendency, i.e. mean values, of variety for all five disciplines, but also illustrate a few discipline-wise differences. Applied Psychology and Macroeconomics, for instance, possess the biggest rise (from 5 to 10), which makes them the most interdisciplinary fields in terms of the broadness of the knowledge base. A rather moderate increase is associated with Linguistics and Anthropology. On the other hand, the growth of mean variety in Applied Psychology and Library Science seems to be accelerating as the gap between adjacent mean values (i.e., the distance between two adjacent vertical, dashed lines) keeps widening up over time. Such a phenomenon is missing or nebulous in the other disciplines.

The dominance of low variety publications has weakened over time as opposed to the rise of high variety publications. The rise of right tails is significant in all five disciplines which indicates an increasing percentage of high variety publications in each year. On the other hand, the right-shifted peak (mode) can also be spotted in Applied Psychology and Macroeconomics and illustrates that an obvious shift towards a diverse knowledge base for research in recent years.

The aforementioned findings capture the ever-increasing broadness of the knowledge base for research in SSH, more significantly in application-oriented disciplines. Furthermore, such multi-discipline-sourced studies have become the main force of science production. Clearly, researchers in SSH are more eager and proactive to absorb external knowledge or skills to advance their own study.

Evenness of knowledge base

In this paper, balance (B) is operationalized as $1 - Gini_c$ where B = 1 indicates the maximum evenness (e.g., an array [2,2,2,2] that has the same value for all elements has a value of balance equal to one) and B = 0 indicates the maximum imbalance. If the allocation of references to each category is evenly distributed, the authors have absorbed knowledge equally from various disciplines and treat each discipline as an equally significant part of the knowledge base to their study, hence indicating diversity and interdisciplinarity. On the contrary, if references are primarily devoted to one or a few disciplines, we can assume that certain specializations or sets of specializations take place in the study, yielding a low level of balance and less interdisciplinarity. A special and contradictory case occurs for papers that only have one category (discipline) in their references. This type of publications show a high specialization and low balance; yet, based on the formula of calculating B, its balance equals one which indicates maximum diversity. To handle this issue, in this paper, we exclude all papers with variety equal to one when examining balance. As such, 9.09% of publications for Linguistics, 4.08% for Applied Psychology, 6.84% for Anthropology, 9.62% for Library Science, and 1.57% for Macroeconomics are excluded.

As shown in Figure 2b, the distribution of balance exhibits multiple peaks and skewness in distribution. Publications with B =1 account for the right-most peak in all curves. The other peaks are associated with publications having a high balance in the earlier period and a low balance in recent years. It is also worth noticing that the skewness of the distribution also changes over time: In Linguistics, Applied Psychology, and Macroeconomics, the distribution is left-skewed in earlier years and shifted to right-skewed in recent years.

Contrary to variety, the mean of balance, as shown in vertical dashed lines, exhibits a decreasing trend for all disciplines. Macroeconomics achieved the largest drop of around 30.1% for 50 years, followed by Applied Psychology with a 26.0% decrease. The smallest drop can be found in Anthropology whose values for mean balance are reduced only by 12.6% during the same period. If we recall the results from the last section, we can see that disciplines which decreased the most in balance also achieved the biggest increase in terms of variety. One interpretation is that disciplines that tend to acquire knowledge from more peer disciplines do not always treat them as equally significant or relevant partners. Even though more disciplines are invited to their knowledge base, researchers from Applied Psychology and Macroeconomics are still heavily and unevenly reliant on a few disciplines.

The decreasing trend of balance is tightly related to the specialization of research (Foster et al., 2015). The formation of sub-disciplines or research topics might result in clusters of disciplines that are always regarded as the most significant knowledge base and more frequently and intensely referenced together thus yielding a dominant knowledge combination. Such tendency indicates that SSH researchers tend to have a clearer and more strategic agenda in terms of how to situate their research and how to learn from their peer scientists. Furthermore, we suppose that the increasing richness in knowledge base (i.e., variety) might as well be associated with the decrease in evenness (i.e., balance) to some extent. The occurrences of new disciplines (an increase of the value of variety) in the knowledge base might be naturally weak in intensity and proportions, which leads to an imbalanced knowledge base.

Heterogeneity of knowledge base

Disparity is operationalized as the mean distance among each pair of disciplines referenced. If only one discipline is referenced in a certain publication, its value of disparity is undefined as no "distance" can be defined or calculated. Therefore, we intentionally exclude this set of publications since there is no added information other than the decrease of the share of mono-source publications, which was already discussed in previous sub-sections

Figure 2c shows the evolution of disparity for our three selected disciplines, where one can see that the range of disparity looks similar, from ~0.60 to 1.00. Yet, the change of mean disparity varies fundamentally among all five. We observe an increase in Applied Psychology and Linguistics (9.6%, and 1.5%, respectively). Macroeconomics, on the other hand, has experienced a minor decrease in terms of mean disparity over the selected period. The other two disciplines, namely Anthropology and Library Science, fluctuate and remain at a similar level of disparity throughout the 50-year time window.

Besides changes in the mean values, we would also like to discuss the change in overall distributions of disparity, for which Applied Psychology exhibited more dramatic changes than the others. In the case of Applied Psychology, two clear and significant changes can be spotted, namely the formation of high peaks and the weakening in the left tail. Both indicate that researchers in Applied Psychology are referencing more "remote" or previously less connected disciplines to constitute their knowledge bases.

The decrease regarding the proportion of low variety publications illustrates a general tendency in Applied Psychology that researchers from this domain are aiming to voluntarily absorb and borrow knowledge or skills from more "remote" disciplines and the cognitive distance within their knowledge base continues to widen.

Integrated IDR trends

We calculated the evolution of integrated IDR using three indicators, namely DIV, ${}^{2}D^{s}$, and Rao-Stirling (RS) to investigate how the diversity of references as a whole evolves over time. The distribution over time for ${}^{2}D^{s}$ and five disciplines are shown in Figure 3, where dots represent mean values and bars indicate their 99% confidence intervals. Different periods are denoted as various colors in which darker colors represent more recent periods. Similar temporal trends are also found for RS and DIV.

It is obvious that publications from all studied disciplines in Social Sciences and Humanities are, at the aggregate level, becoming increasingly interdisciplinary over time, with a few distinctions for each. Linguistics was and continues to be the least interdisciplinary one among all five. Applied Psychology experienced the largest increase in the last 50 years. Although failing to gain as much growth as the others, Anthropology retains its leading position in interdisciplinarity. For the most recent 5 year period 2005–2009, Library Science is found to be the most interdisciplinary among all five.

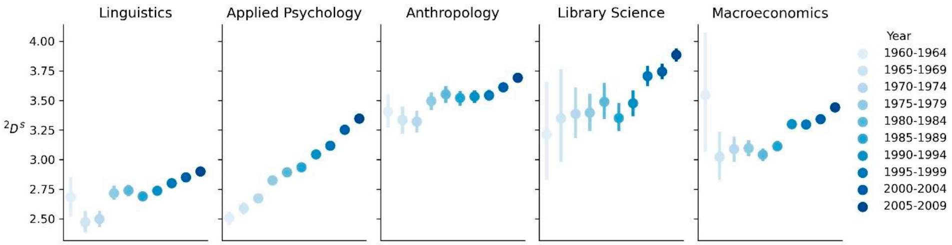

Figure 3. The evolution of integrated IDR measurements.

What should be additionally pointed out is that interdisciplinarity is not ever-increasing for all disciplines and all periods. In the mid-1960s, Linguistics and Anthropology exhibit a temporary drop in the level of interdisciplinarity on average, same for linguistics, Anthropology, and Library Science in 1985-1989. On the other hand, we can also observe certain synchronicity in change for certain periods, which suggests that although the developments in interdisciplinarity are realized by each individual discipline itself with their own pace or characteristics, they might be synchronously facilitated or hindered by a certain historical factor which could be academically related or otherwise.

The evolution of IDR outcome

Academic significance and visibility

To examine the potential impact of interdisciplinarity on academic significance and visibility, we determined citation impact with a 2- (C_2), 5- (C_5), and 10-year-long (C_{10}) citation window. The Spearman coefficient is calculated for each citation indicator and IDR indicator pair, as shown in Table 2. All correlations are statistically significant at the 0.1% level.

Table 2. Correlation between IDR measures, citation impact, and disruptiveness.

	Variety	***Balance***	***Disparity***	***RS***	***DIV***	$^2D^s$
C_2	.317	-.323	.094	.165	.229	.165
C_5	.395	-.406	.110	.209	.286	.209
C_{10}	.423	-.438	.117	.223	.306	.223
D_2	-.232	.277	-.048	-.092	-.147	-.092
D_5	-.276	.338	-.054	-.106	-.172	-.106
D_{10}	-.293	.363	-.055	-.109	-.180	-.109

Five out of six indicators turned out to be positively correlated with all three citation indicators, which indicates IDR's potential positive effect in terms of alleviating publications' academic significance and visibility. Balance, on the other hand, which measures the level of specialization in knowledge base, is negatively correlated with citation impact. This suggests that research may benefit from a more specialized perspective or knowledge base than focus-lacking ones. Variety is most positively correlated with citations among all.

Furthermore, the correlation becomes stronger as the citation window widens up which holds for all six IDR measurements. A possible interpretation of this observation is that the benefit interdisciplinarity might produce on citations requires time to form and may not be achieved overnight.

Disruption or consolidation

As explained in the “Methodology” section, the disruptiveness index (Wu et al., 2019) captures the proportion of net increase of new citing papers a publication invites to the local citation network. For instance, the publication will be regarded as disruptive with $D_t > 0$, if the number of its citing papers that also cite its references triumphs the number of citing papers that do not. In this case, the citing papers only acknowledge this paper’s contribution rather than its intellectual forebears which can be a sign of disruption. The counter case would be publications with $D_t < 0$, which means more of their citing papers also acknowledge their forebears, yielding consolidation.

This index has many advantages. Firstly, it possesses the potential capacity of recognizing scientific works that are commonly regarded as innovative and break-through in the field. A large-scale empirical study devised by Wu et al. (2019) found that papers that directly contribute to Nobel prizes tend to show high levels of disruptiveness while review articles are normally associated with low disruptiveness. What’s more, it can be more robust in resisting malicious citing behavior that is initiated by strategic considerations in one’s career rather than the quality of the work.

The correlations between disruptiveness and all of the IDR measurements are shown in Table 2. D_2, D_5, and D_{10} denote disruptiveness within a 2-year, 5-year, and 10-year time window, respectively. All correlations are significant at the 0.1% level. It seems that all IDR indicators except balance are negatively correlated with disruptiveness, which suggests interdisciplinary publications tend to consolidate fields or knowledge rather than disrupt them. Another interpretation is that research whose knowledge base is more diverse might eventually lead to scientific outcomes that are more likely to back up or build on prior knowledge. On the other hand, as captured by the correlation between balance and disruptiveness, a more specialized knowledge base could be beneficial in the production of disruptive research.

Similar to correlation with citation, IDR also seems to be more correlated with disruptiveness in a longer citation window. This suggests that disruption or consolidation one might produce in certain research domains will become more evident as time passes by.

An interesting question about the relationship between disruptiveness and interdisciplinarity is why the out-of-the-box thinking that interdisciplinary research strives for leads to consolidation while the more specialized publications turn out to be more capable of disrupting. A possible interpretation is that interdisciplinary publications tend to investigate emerging topics that are possibly heading towards the formation of a newborn field. The exploratory work these IDR research conducted can be conceived as creative or unorthodox in their creation but as consolidating when the topic emerges to discipline after a while. On the other hand, specialized scientific research is normally diving into specific topics that already have a solid foundation of previous knowledge and skill set. Limited room for consolidation can be found which yields more possibilities for disruptive outcomes.

Conclusions

This paper has examined the evolution of IDR in five fields from Social Sciences and Humanities (SSH), namely Anthropology, Applied Psychology, Linguistics, Library Science, and Macroeconomics over a 50-year-long time window. The IDR processes, embodied by disciplinary diversity in references, and outcomes, characterized by citation impact and disruptiveness, are studied and analyzed from a temporal perspective. We find that research from SSH is absorbing knowledge from an increasing number of increasingly “remote” disciplines, which leads to growth in the overall level of interdisciplinarity. Yet, the increasing level of specialization observed in the knowledge base is also significant which could be influenced by the formation or emergence of specific research topics. On the other hand, most of the IDR measurements and citations are found to exhibit positive correlations, which are strengthened as the citation window widens. Most of the IDR measurements and disruptiveness, however, are negatively correlated which becomes more evident with a longer time window.

There are many interesting implications based on our findings. The increasing trend of interdisciplinarity found in SSH further strengthens the evidence of the statement “science is becoming interdisciplinary”. This changing phenomenon calls for a necessity for us to reexamine the research paradigm in many disciplines and the evaluation system for various entities. Many research evaluations, for instance, peer review in journals, are conducted by specialized domain experts who might not have the relevant expertise for all interdisciplinary papers that integrates knowledge outside the discipline silos. The selection of a competent evaluation panel could be a somewhat challenging endeavor in the era of interdisciplinarity and should be handled seriously in a scientific way. Furthermore, we observe that the absolute value of the correlation between the number of citations and some interdisciplinarity indicators increases as the length of the citation time windows raises; and so does the degree of disruptiveness. This hints that interdisciplinary research needs time to show its potential, which is consistent with Wang et al., (2015). Previous studies have shown that interdisciplinary research is often encouraged by science policies, but they are insufficiently supported under current funding structures (Bromham et al., 2016). Thus, one implication for science policy decision-makers and funding providers is that assessing interdisciplinary research requires a longer time window.

Limitation and future work

This article has several limitations. For instance, only five disciplines in SSH are investigated which limits us to draw a comprehensive understanding for all SSH disciplines regarding the evolution of interdisciplinarity. In addition, the relationship between interdisciplinarity and research outcomes (citation and disruption) is analyzed in a simple way as a first step. A more sophisticated methodology that involves other confounding variables is required. In future studies, we will expand our current analysis to more disciplines in SSH and adopt advanced models to thoroughly uncover the interaction between interdisciplinarity and research outcomes.

Acknowledgments

This investigation has been made possible by the financial support of the Flemish Government to ECOOM, among others. The opinions in the paper are the authors’ and not necessarily those of the government.

Abstract

With the development of modern technology, the boundaries between different technical fields are gradually blurring, and technological convergence has become an important research topic. Patent data is rich in information about technology and the development in various technical fields. Understanding the development trends of technology in patents is incredibly beneficial for future research and industrial development of advanced technology. This research analyzes the co-occurrence of technical fields at a large scale based on the International Patent Classification (IPC) numbers issued by the World Intellectual Property Organization (WIPO) and the industrial matching relationships in the technical fields. Subsequently, according to entropy theory, we investigate the technological convergence in 35 technological fields. After that, complementary convergence and substitution convergence among several fields are analyzed. It is found that the technological convergence of the chemical industry has been the most persistent in the past 20 years. The information technology industry has also grown rapidly in technological convergence in recent years. The results could help guide the direction of in-depth research within the entire industry and other prominent industries.

Introduction

As technology advances, the accelerating industrial innovation process has significantly increased the complexity and diversity of various technologies. In this progress, various technologies continuously integrate and interact, which causes a fusion phenomenon regarded as "technology convergence” (Griliches, 1990). In technology convergence, multiple technologies belonging to two or much more fields merge with others to develop a new function or product that has not existed previously (Hacklin, Marxt, & Fahrni, 2009). The significance of technology convergence is that technological revolutions are sometimes promoted by technology integration or reorganization of the basic knowledge of existing technologies in different fields, not just by the development of new technologies (Hacklin, 2008). For example, the integration of emerging electronic technologies and traditional mechanical technologies has provided us with mechatronics systems (Kodama, 2010).

As one of the most effective carriers of technical information, patents have the fastest updates, the broadest coverage, and the most comprehensive documentation of technical developments. They are the most reliable and reasonable indicators for understanding technical information development (Acs, Anselin, & Varga, 2002). Thus, we reviewed the literature on technological convergence based on patent analysis and noted the following issues. First of all, the definitions of "technological convergence" are diverse. Different scholars have some differences in their cognition and understanding of technological convergence.

Secondly, there is no agreement on the matching between technological patents and industrial classification in the literature. Lastly, there are various methods for measuring the degree of technological convergence. Most of the measurement methods are based on the International Patent Classification (IPC) code, and analyses rarely consider the industrial classification. Thus, this study is designed to investigate the technological convergence in different industries by taking these issues into consideration.

The rest of the paper is structured as follows. The following section starts with the definition and theories of technological convergence. After that, we introduce data and measurements of technological convergence. The third section presents a descriptive statistical analysis based on the measurement results. Lastly, we discuss the research results and give suggestions for future research directions.

Theoretical background

Definition of technological convergence

The concept of technological convergence was first proposed in 1963. Rosenberg (1963) found that there is very high similarity in terms of technology between different products produced by the machinery manufacturing industry and the metal processing industry. He interpreted this phenomenon as "technological convergence." This definition is the result of technological association. The academic community widely regards Rosenberg's work as the beginning of research in industrial integration. Since then, many scholars have cited the definition of technology convergence to describe the phenomenon of industrial technology convergence.

Lei (2000) believes that the boundaries between technology industries continue to weaken with the continuous emergence of innovative product concepts across multiple markets. Technology that belongs to one industry can have a profound impact on other industries or even multiple industries. From the perspective of industry evolution, Hacklin (2007) defines technological convergence as the potential impact of knowledge fusion on technological innovation capabilities. Knowledge spillover between industries promotes technological convergence, which leads to the emergence of new technologies. Here, technological convergence is regarded as the combination of various technical fields in patents.

Theories of technological convergence

The current patent-based technological convergence research has two major streams: patent citation analyses and patent classification analyses. The patent citation analysis method analyzes the citation network formed by the citation relationship that patent documents have with other patent documents or non-patent documents. The patent classification analysis method mainly analyzes the co-occurrence of different technical fields in patents to estimate the level of technological convergence. Leydesdorff, Kushnir, and Rafols (2014) used US patent information as sample data and established a patent similarity measurement model based on IPC codes and patent citation information. Criscuolo (2006) conducted an empirical analysis based on patent information provided by the patent databases of the European Patent Office (EPO) and the United States Patent and Trademark Office (USPTO) and found related families of patents.

The patent classification analysis method covers the primary technical fields and considers the effects of patent aging over time and technological differences. Generally, patent classification analysis methods can be divided into static and dynamic aspects. Static analyses of technological convergence consider interdisciplinary industry convergence in different technical fields to be necessary to continually search for and absorb relevant knowledge, as well as for emerging technologies generated by technological convergence to infiltrate into other industries. Therefore, the development directions of existing technologies and existing industries' business content have been continuously supplemented and improved.

Different technical fields share the same knowledge platforms for research and development. Lei (2000) and Stieglitz (2003) defined the mutually integrated technology fusion process as "Complementary Technological Convergence (CTC)" and defined the phenomenon of technologies in other fields eliminating current technologies as "Substitutability Technological Convergence (STC)." The technological convergence process can be seen as a combination of complementary technologies in multiple fields and a substitution of existing technologies.

From the dynamic perspective, technological convergence is not only a static phenomenon but also an evolutionary process (Yayavaram & Chen, 2015). The degree of convergence includes both the depth and width of technological convergence (Song, Almeida, & Wu, 2003). We can analyze the changes in the breadth and depth of technological convergence through the diversity of technological convergence. The current mainstream methods are mainly the Shannon Wiener index, Simpson index, and N index for dynamic analysis of technological convergence. All of them are based on the measurement methods of biological diversity and are formed by blending to analyze technical and economic fields. Stirling (2007) was the first to introduce biodiversity index analysis to a technical field. Gambardella and Torrisi (1998) used the Simpson index to conduct an empirical analysis of the electronic information industry's internal technological convergence.

Data and methodology

Data

This study analyzes patent data from the PATSTAT database. The patent classification system in the database is mainly based on the International Patent Classification IPC code. The IPC system is an accurate, useful, and easy-to-use tool for classifying and searching patent applications, authorized patent descriptions, utility models, and similar technical documents. It divides technical fields into eight divisions (A-H) with about 75,000 subclasses. Every subclass is represented by a language-independent classification number, which is composed of letters and Arabic numerals. IPC consists of multiple levels, and several dots indicate the grouping level. The more dots, the lower the grouping level is.

Many scholars around the world have explored the consistency between the IPC system of patents and the classification of industrial technology. One famous example is the concordance table that records the relationship between IPC and International Standard Industrial Classification (ISIC). In this study, we use the IPC and technology concordance table from the World Intellectual Property Organization (WIPO) because the ISI-OST-INPI classification method proposed by Schmoch (2008) combines theoretical analysis and empirical research. Furthermore, it entirely takes into account the differences in industrial classifications in different countries. Therefore, the types of industrial technology designs can be applied to international comparisons with broad applicability and strong persuasiveness.

First of all, we selected patent data with filing years between 2000 and 2019 from the PATSTAT database. Next, we matched IPC codes and technical fields according to the ISI-OST-INPI classification. Finally, we performed de-duplication operations to ensure that the one patent and one technical field only match once. We collected 17,755,027 patents through this process, and there were 23,941,243 data records in total over the period of 2000-2019. By filtering the data, we found that the patent data for 2019 is somewhat incomplete, so we excluded the data for 2019 and only considered the filing years between 2000 and 2018, leaving a total of 23,770,593 data records.

Methodology

The current measurement method for patent technological convergence mainly uses patent indicators for evaluation. Based on the literature, we have compiled the results of various index measurement methods in academia, as shown in Table 1 (Li & Shu, 2017). Considering the large amount of information in our selected database, the patents involved are numerous and complex.

Table 1. Measurement indicators of technological convergence (Li & Shu, 2017).

	Definition	Formula
Macro-level	Technological convergence: The ratio of the number of cross-patents (multi-technology classification) to the total number of patents (full field)	$Technological\ convergence = \frac{Numbers\ of\ cross\ patents}{Numbers\ of\ total\ patents}$
	Technological coverage: Using Shannon Entropy to calculate the technological convergence breadth in a particular field, the F value changes with time. The greater the F value, the greater the convergence breadth of the technological field.	$Fi = -\sum_{k} P_{ik} lnP_{ik}$ Fi: The entropy of field i; P_{ik}: Percentage of field k in field i.
Meso-level	Technological cross-convergence coverage: The coverage of cross-technological convergence.	$W_i = \frac{Ui}{UA}(i \in A)$
	Technological cross-convergence intensity: The intensity of cross-technological convergence.	$Ii = \frac{Pi/Ui}{PA/UA}(i \in A)$, Cross technology i belongs to industry A, Ui and Pi represent the number of USPCs and patents included in cross technology i; UA and PA are the number of USPCs and patents included in industry A.
	Convergence intensity: The ratio of the number of cross patents to the minimum number of patents in the two different source technologies.	$CIA - B = N_{P_{A-B}}/Min\ (N_{PA}, N_{PB})$ $CIA - B$: The convergence intensity of field A and field B; $N_{P_{A-B}}$: Numbers of patents in field A and field B.
	Convergence coverage: The number of patented technologies involved in the same category is used to measure the degree of diffusion in the convergence process of a specific technical field.	$CC = \frac{C}{M \times N}$
Micro-level	Originality: Measure the originality of a technology by the presence of patents outside its classification.	$OI = 1 - \sum_{i=1}^{k} \left(\frac{N_i}{N}\right)^2$, k represents the number of different technical fields to which the patents cited in the observed patent citations belong; N_i represents the number of cited patents belonging to technical field I; N represents the total number of cited patents.
	Generality: Measure of the generality of the technology based on the citation volume and the classification distribution of the cited patents.	$GI = 1 - \sum_{i=1}^{k} \left(\frac{N_i}{N}\right)^2$, k represents the number of different technical fields to which the patent citing the observation (citing patent) belongs; N_i represents the number of citing patent belonging to technical field; N represents the total number of citing patents.

Therefore, according to the various index measurement methods mentioned above, this study firstly adopted Shannon entropy algorithm to measure the degree of convergence of technical fields and to find the fields that are more actively convergent for more in-depth research. We measured the complementary and substitutability technological convergence in four steps based on the measurement method by Dibiaggio, Nasiriyar, and Nesta (2014).

In step 1, we used four or five years as a time interval and divided the period of 2000-2018 into four stages. We then constructed a 35*35 co-occurrence matrix of technical fields according to the time interval. If two different technical field codes appeared once in the same patent, a technical co-occurrence was considered to have appeared in the two fields. We chose 5*5 technological fields to show in Table 2.

Table 2. Technology co-occurrence matrix (sample from 2000-2004).

	Analysis of biological materials	*Audio-visual technology*	*Basic communication processes*	*Basic materials chemistry*	*Biotechnology*
Analysis of biological materials	34401	256	22	1041	20649
Audio-visual technology	256	191490	8210	2634	228
Basic communication processes	22	8210	43205	7	29
Basic materials chemistry	1041	2634	7	94370	4607
Biotechnology	20649	228	29	4607	81089

In step 2, taking the technology co-occurrence matrix as a benchmark, we found the Shannon entropy based on the following equation:

$$Entropy_i = -\sum_j p_{\frac{j}{i}} \, log_2 p_{\frac{j}{i}} \tag{1}$$

where *p* represents the ratio of the number of patents in technical fields *i* and *j* to the number of patents in technical field *i*. In step 3, we chose the top-five technical fields with the highest entropy, counted the co-occurrence frequencies between different technical fields, and estimated the mean value and standard deviation based on equations (2) and (3).

$$\mu_{ij} = E(X_{ij} = x) = \frac{O_i O_j}{K} \tag{2}$$

$$\sigma_{ij}^2 = \mu_{ij}\left(\frac{K - O_i}{K}\right)\left(\frac{K - O_j}{K - 1}\right) \tag{3}$$

O_i represents the number of all patents involved in technical field *i*, and O_j represents the number of all patents involved in technical field *j*. *K* stands for a summary of all patent applications.

In step 4, according to the basic calculation equations above, the CTC index was calculated using equation (4):

$$CTC = \frac{C_{ij} - \mu_{ij}}{\sigma_{ij}} \tag{4}$$

where C_{ij} is the total number of patents involving patents *i* and *j* at the same time. In step 5, we use a cosine function to measure the convergence of substitutability technology using the STC index:

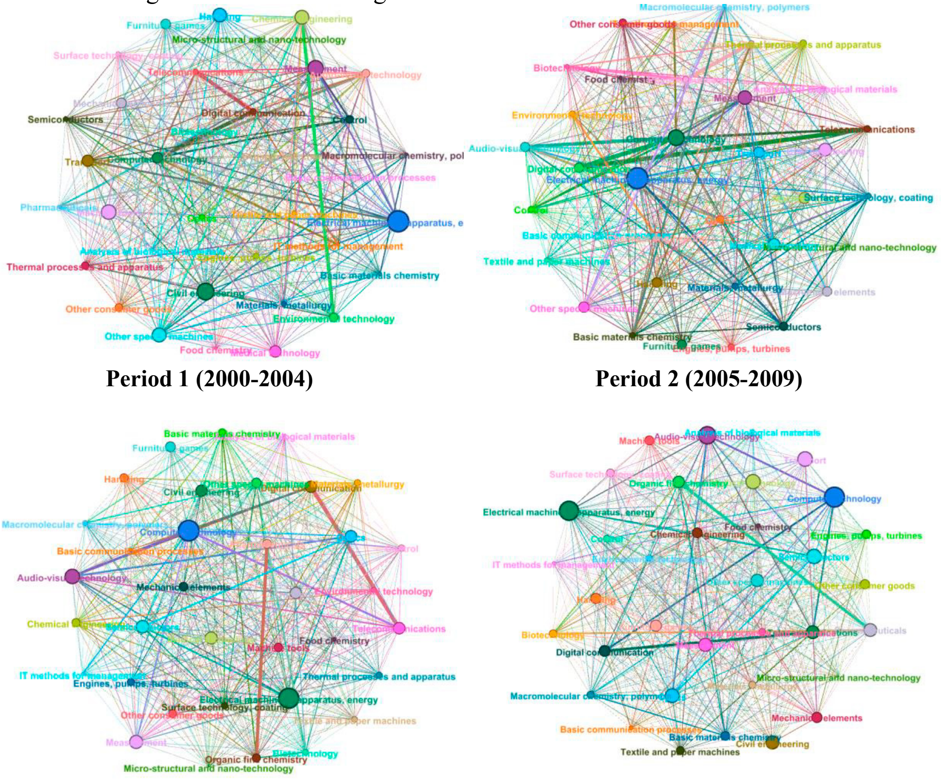
$$STC = \frac{\sum_{n=1}^{k} C_{in} C_{jn}}{\sqrt{\sum_{n=1}^{k} C_{in}^{2}} \sqrt{\sum_{n=1}^{k} C_{jn}^{2}}} \tag{5}$$

where *k* represents the total amount of patents applied for, C_{in} represents the frequency of the technical element with code *i* and *n* other technical fields appearing in the same patent, and C_{jn} represents how often the technical field with code *j* and *n* other technologies appears in the same patent.

Empirical analysis

Network visualization

Graphs can represent most scientometric data-based networks. They are applied to collaboration networks as well as to co-citation networks (Glanzel, 2012). Network visualization provides the most direct display of the cross mode in technological convergence in this study. We introduce a node analysis at the technical-field level. According to the co-occurrence matrix results of four five-year windows, the number of patents in each field is used as point data, and the number of co-occurrences between fields is used as side data. The node circle size and the thickness of the line connecting the two nodes respectively represent the strength of the domain attribute and the degree of co-occurrence. The four final network visualization diagrams are shown in Figure 1.



Period 1 (2000-2004)

Period 2 (2005-2009)

Period 3 (2010-2014)

Period 4 (2015-2018)

Figure 1. Network visualization of technical fields by periods.

Comparing the network visualization diagrams of technical fields in the four periods, we can find that the main fields involved in the patent applications have transformed from the *computer technology* field to the field *of electrical machinery, apparatuses, and energy* since around 2010. The largest node in Period 1 and Period 2 is *computer technology*, followed by *electrical machinery, apparatuses, and energy*, and the third one is *audio-visual technology*. In Period 3 and Period 4, the size of the *computer technology* field is gradually decreasing, while the node of *electrical machinery, apparatuses, and energy* becomes the largest one, followed by *audio-visual technology*.

The technical fields with more patents do not represent a higher impact on the other fields based on the visualization. Among the four periods, the two areas with the most co-occurrences are the *organic fine chemistry* field and *pharmaceuticals* field in Period 1, the *digital communication* field and *telecommunications* field in Period 2 and Period 3, and the *organic fine chemistry* field and *digital communication* field in Period 4. However, these technical fields with the most co-occurrences are not the fields with the largest nodes. Thus, the co-occurrence of technical fields is not necessarily related to the number of patents in the technical field.

STC and CTC

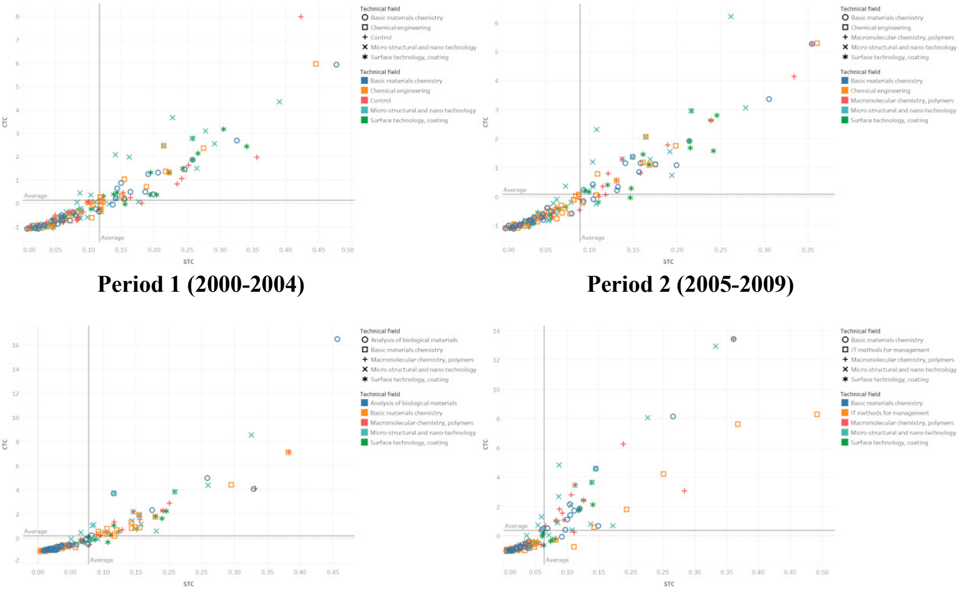
STC and CTC also show technological convergence. Table 3 shows the empirical results of Shannon entropy's estimation, in which there are five technical fields with enormous entropy values in each time window. Using this as a benchmark, we calculated the STC and CTC of each field with the other 34 fields.

Table 3. The highest entropy of technical fields (by period).

Period	*Technical field*	*Entropy*
2000-2004	Micro-structural and nano-technology	6.6356036710
	Surface technology, coating	5.7884236280
	Chemical engineering	5.6370176984
	Basic materials chemistry	5.4449187914
	Control	5.0690933392
2005-2009	Micro-structural and nano-technology	5.8079235452
	Surface technology, coating	5.0940984975
	Basic materials chemistry	4.7347813344
	Chemical engineering	4.5223951158
	Macromolecular chemistry polymers	4.5163670576
2010-2014	Micro-structural and nano-technology	5.6658510134
	Surface technology, coating	4.5690331727
	Macromolecular chemistry polymers	4.5425173526
	Basic materials chemistry	4.4230508371
	Analysis of biological materials	3.8200670523
2015-2018	Micro-structural and nano-technology	3.3441336768
	Macromolecular chemistry polymers	2.8603060175
	Basic materials chemistry	2.5983972381
	IT methods for management	2.3276341583
	Surface technology, coating	2.2365707230

To better understand the evolution of individual technical fields within the patent network, we constructed a two-dimensional quadrant with a substitutability technology convergence axis and complementary technology convergence. This matrix was depicted for the four periods with the STC indicating the compatibility between related technologies and the CTC for the differences. The first quadrant is defined as the convergence of high-substitution and high-complementarity technologies. This phenomenon is the mature stage of the convergence, where both substitution and complementarity have reached a certain level.

The second quadrant's technical fields have a higher CTC and a lower STC, which means that most of the two technologies in this quadrant are gradually integrated through reorganization and creation in the same environment. In the third quadrant, STC and CTC values between the two different technical fields are both low. It is indicated that the two technologies in this quadrant are relatively independent, and the degree of convergence of various technologies between industries is weak. Finally, in the fourth quadrant, the STC value is high, whereas the CTC value is low. This quadrant's technical fields mainly improve the reliability of new products and accelerate market acceptance through the compatible docking of similar technical elements.



Period 1 (2000-2004) **Period 2 (2005-2009)**

Period 3 (2010-2014) **Period 4 (2015-2019)**

Figure 2. Scatter plot of technical fields by periods.

Our study discovered that the values of STC and CTC have a certain degree of correlation. Figure 2 shows that scattered points are distributed in the third quadrant and are scattered around the diagonal with a slope of 1. This means that the process of technological convergence and industry evolution requires complementary convergence to promote industrial innovation and substitutability convergence to promote industrial evolution.

With subdivision into four periods for comparison, we can see that there has been a significant increase in both the abscissa and the ordinate, which confirms the increase in technological convergence between different industries. In addition, according to the distribution of the points in the first quadrant and the entropy ranking of the four periods in Table 1, we can see that although the entropy value of the *microstructure and nano-technology* field has always been the highest, the proportion of points of the field in the first quadrant is being pursued by other fields. The range is gradually shrinking from period 1 to period 4. This shows that technological convergence is no longer limited to several fields but is spreading to various industries, and industrial boundaries are constantly blurring. We list the top five industry combinations with the highest STC and CTC in the four periods in Table 4 for further analysis and comparison.

Table 4. The highest STC and CTC of technical fields from 2000 to 2004.

Period 1	*Technical field*	*Sub-field*
STC	Basic materials chemistry	Macromolecular chemistry, polymers
	Chemical engineering	Environmental technology
	Control	IT methods for management
	Micro-structural and nano-technology	Semiconductors
	Control	Computer technology
CTC	Micro-structural and nano-technology	IT methods for management
	Surface technology, coating	Environmental technology
	Basic material chemistry	Macromolecular chemistry, polymers
	Chemical engineering	Semiconductors
	Macromolecular chemistry, polymers	Materials, metallurgy

During the period of 2000-2004, the high STC values within the chemical industry and environmental industry are closely related to promoting the environmental industry as a "green industry" or "sunrise industry" in the early 21st century. Although the semiconductor industry has reached the end of its heyday, it still has strong technological convergence with the *micro-structural and nano-technology* field. The *IT industry* has gradually begun to rise and has closely converged with the *control* industry, which belongs to the instruments category.

Table 5. The highest STC and CTC of technical fields from 2005 to 2009.

Period 2	*Technical field*	*Sub-field*
STC	Chemical engineering	Environmental technology
	Basic materials chemistry	Macromolecular chemistry, polymers
	Macromolecular chemistry, polymers	Other special machines
	Basic materials chemistry	Organic fine chemistry
	Micro-structural and nano-technology	Semiconductors
CTC	Micro-structural and nano-technology	Materials, metallurgy
	Chemical engineering	Environmental technology
	Basic material chemistry	Macromolecular chemistry, polymers
	Macromolecular chemistry, polymers	Other special machines
	Basic materials chemistry	Organic fine chemistry

In the period of 2005-2009, regardless of STC and CTC values, the top five fields are almost all chemical-related technologies. It can be seen that the chemical industry in this period is in a stage of transition between old and new. Compared with the first period, *raw materials chemistry* fields are distributed less than *chemical engineering* fields within the first quadrant. This reflects the development trend of the chemical industry to a certain extent. Also, combined with the Shannon entropy in Table 2, *control* technologies are no longer a field of high technological convergence during this period. The changes in industry development trends can be predicted from this.

Table 6. The highest STC and CTC of technical fields from 2010 to 2014.

Period 3	*Technical field*	*Sub-field*
STC	Analysis of biological materials	Biotechnology
	Basic materials chemistry	Macromolecular chemistry, polymers
	Macromolecular chemistry, polymers	Other special machines
	Analysis of biological materials	Measurement
	Micro-structural and nano-technology	Materials, metallurgy
CTC	Analysis of biological materials	Biotechnology
	Micro-structural and nano-technology	Materials, metallurgy
	Basic material chemistry	Macromolecular chemistry, polymers
	Analysis of biological materials	Pharmaceuticals
	Basic materials chemistry	Organic fine chemistry

For the period of 2010-2014, an incredibly unique phenomenon is the distribution *of biological materials*, as shown in Figure 2 and Table 6. The convergence relationship between the *analysis of biological materials* and *biotechnology* is quite prominent. Both CTC and STC are much higher than for other technical fields. However, in the top-five technological fields in terms of entropy, there is less distribution of *analysis of biological materials* in the first quadrant than for the other four fields. However, CTC and STC values are higher than for other fields, such as the convergence with *measurement* and *pharmaceuticals*. The "Pareto principle" has been fully embodied in the *analysis of the biological materials* field.

Table 7. The highest STC and CTC of technical fields from 2015 to 2019.

Period 4	*Technical field*	*Sub-field*
STC	IT methods for management	Computer technology
	IT methods for management	Digital communication
	Basic materials chemistry	Macromolecular chemistry, polymers
	Micro-structural and nano-technology	Materials, metallurgy
	Macromolecular chemistry, polymers	Other special machines
CTC	Basic materials chemistry	Macromolecular chemistry, polymers
	Micro-structural and nano-technology	Materials, metallurgy
	IT methods for management	Computer technology
	Basic materials chemistry	Organic fine chemistry
	Micro-structural and nano-technology	Semiconductors

During the period of 2015-2018, the technology convergence in the *IT methods for management* dramatically increased. The value of STC for *computer technology* and *digital communication* shows that the ICT industry is developing at its peak. We believe that the development of miniaturization technology has led to the convergence of alternative products between handheld computers and mobile devices. While companies continue to use innovative opportunities advantages, they have also promoted this industry's continuous development. The internal technology convergence of the chemical industry and the electrical engineering industry are still strong.

Combined with Table 3, it is easy to see that the *micro-structural and nano-technology* field has always had the highest Shannon entropy during the past 20 years. Analysis of this domain alone reveals that although the entropy has been highest, the entropy of this field has been decreasing with time. We believe that this is related to the industry-wide diffusion of technology convergence, which is no longer concentrated in individual fields due to the expanding scope of technology convergence. At the same time, the values of STC and CTC in the *micro-structural and nano-technology* domain do not exhibit particularly high values, which we believe validates the theory of technology convergence diffusion.

Conclusion

This study has investigated technological convergence based on patent analysis by developing and applying concepts of Shannon entropy, complementary technological convergence, and substitutability technological convergence. We believe that the quadrants of STC and CTC indicate the unique patterns and technological convergence trends. Furthermore, we have found the evolutionary patterns of technological convergence and provided a valuable blueprint for future research.

Our study is limited in terms of its measure of technological convergence. Patent data is important for identifying the intersection of technical fields. We only used the IPC patent analysis method to measure the intersection of technical fields. Thus, future research could introduce a patent citation analysis method into the analysis framework, which could provide a more accurate measurement tool to comprehensively examine characteristics of cross-field technological convergence.

Acknowledgments

The authors thank Ruichun Peng for his wonderful figures. We also thank Chang Zhang for the help and advice provided. Funding was obtained from the National Natural Science Foundation of China under Grant 72072087, which is also gratefully acknowledged.

Impact of Model Settings on the Text-based Rao Diversity Index

Andrea Zielinski[1]

Fraunhofer Institute for Systems and Innovation Research ISI, Breslauer Strasse 48, 76139 Karlsruhe (Germany)

Abstract

Topic models such as Latent Dirichlet Allocation (LDA) have been proved to be effective tools to discover latent topics in text collections in a data-driven way. These topics can be further utilized to investigate academic disciplines in terms of *interdisciplinarity* by means of indicators that reflect the diversity of the scientific output. This study provides a systematic analysis of model parameters that affect the diversity scores which are computed directly from the output of the LDA model.

We present an empirical study on a real data set, upon which we quantify the diversity of the research within several departments of Fraunhofer (FH) and Max Planck Society (MPG) by means of scientific abstracts published in Scopus between 2008 and 2018. Our experiments show that parameter variations, i.e. the choice of the number of topics, hyper-parameters, and size and balance of the underlying data used for training the model, have a strong effect on the LDA-based Rao metrics. In particular, we could observe sharp fluctuations of the Rao index when varying over the number of topics. Due to its instability, it might not be a useful indicator of *interdisciplinary.*

Introduction

Interdisciplinary research (IDR) is a mode of research that integrates information, data, techniques, tools, perspectives, concepts, and theories from two or more scientific disciplines. According to innovation theory, research addressing social and economic needs is often beyond the scope of a single discipline and therefore policy-makers often promote IDR (see National Academies (2005)[1].

The most frequently used method to operationalize the concept of IDR is by means of the multi-dimensional Rao-Stirling indicator (Stirling, 2007) which contains three different dimensions: (1) variety: number of distinctive categories; (2) balance: evenness of distribution; and finally (3) disparity: degree to which the categories are different. In bibliometrics, the diversity score considers the number of publications in a scientific category and/or the percentage of references to documents into other scientific disciplines and relies on the metadata of scientific publications (Leydesdorff & Rafols, 2009).

According to Cassi et al. (2017), Rao is a relevant indicator at the scale of a research institution and can be adopted for comparing institutions' interdisciplinary practices but requires a proper delineation into research fields. Even though major publishers such as Elsevier provide a categorization scheme designed to define a scientific discipline, e.g. the ASJC codes in Scopus, the classification of articles is often too imprecise and course-grained for measuring interdisciplinarity, since articles are assigned to subject categories associated with the journal rather than the article (Zhang et al., 2016).

In contrast, clustering approaches based on machine learning allow to produce more fine-grained, faceted topics of the research literature. In addition, they are able to classify scientific knowledge into novel categories without the need to resort to human-defined subject categories that might be outdated (Suominen and Toivanen, 2016). In particular probabilistic topic models such as LDA (Blei et al., 2003, 2010) have been applied to the task of mapping research into fields of science (Yau et al., 2014).

Topic models have also been used to capture the notion of *interdisciplinarity* of research institutions, either based on scientific publications (Paul and Girju, 2009; Nanni et al., 2016) or research awards (Nichols, 2014; Talley et al., 2011).

When dealing with large datasets, employing ML algorithms that are able to calculate indicators in an unsupervised fashion are particularly attractive. An appealing work in this direction is provided by Bache et al. (2013) and Wang et al. (2014) who have re-interpreted the Rao Stirling indicator on the basis of topic modeling, relying exclusively on textual features. The authors conduct experiments on synthetic as well as real data sets (using abstracts, full papers, or grants) that suggest that also the text-based implementation of Rao's index correlates with human judgements.

Topic models are popular because of their data-driven nature that seeks to find emerging clusters of scientific disciplines automatically. Furthermore, they are multi-mixture models where a document may contain several topics. Yet, it is well known that purely unsupervised models such as LDA often result in topics that do not fit the needs of a specific application, i.e. they do not necessarily align with an established subject domain classification schema. Moreover, hyper-parameter setting is important to produce high quality topics (Syed and Spruit, 2018; Chang et al., 2009). According to Tang et al. (2014), LDA's performance depends mainly on the factors a) number of topics, b) the Dirichlet (hyper)parameters, c) number of documents, and d) the length of individual documents.

One of the most crucial factors is the number of topics: Standard LDA requires that a good estimate of the number is known to avoid over-/underfitting of the data. By design, LDA topic models often make use of the sparse Dirichlet priors such that each document contains only a small number of topics and each topic uses only a small set of words frequently. Yet, setting these hyper-parameters has an impact on the document-topic and topic-word distribution and leaves room for variation.

This paper seeks to investigate in a pilot study in how much the LDA-based Rao measure is sensitive to parameter settings and if it can be used as a reliable indicator to automatically calculate a diversity ranking according to an institute's research output, i.e. based on abstract and title as listed in Scopus.

The rest of this article is organized as follows. First, we briefly discuss related work. In the second section, we summarize the definition of the Rao-based disciplinarity indicator, and discuss the topic-specific calculation of the metrics on the basis of LDA. Then, we briefly introduce the data used for the empirical analyses. Subsequently, we present the experimental results on the publication output of two research institutes. Finally, we conclude the article and state future directions.

Related Work

Establishing methods for defining and measuring interdisciplinarity is central and intensively studied within bibliometrics (Wagner et al., 2011). The main goal of the task is to automatically define reliable indicators that are efficient to calculate, predictive, and robust regarding data errors (Guo et al., 2009).

A well established indicator has been set up by Rao (1982) and Stirling (2007), i.e. the Rao-Stirling diversity, which considers variety (number of distinct categories), balance (evenness of the distribution), and disparity (distances or similarities between categories). Accordingly, variety is defined as the number of subject categories assigned to the papers' references and takes values between one and the number of subject categories[ii], balance is a function of assignments across categories and ranges between zero and one[iii], and disparity is the complement of similarity and computed pairwise between the referenced subject categories. Its value also ranges between zero and one[iv]. Yet, the bibliometric operationalization of diversity is actively discussed in the research community (Leydesdorff, 2018; Leydesdorff, 2019). Based on a case study on Web of Science data, Wang and Schneider (2020) found that many measures are inconsistent. This also holds for the Rao-Stirling indicator which has recently been criticized for its low discriminatory power (Zhou et al., 2012).

Starting from the pioneering works by Hall et al. (2008), Paul and Girju (2009), Griffiths and Steyvers (2004), among others, models of diversity have also spread in the area of computational linguistics, especially in connection with topic modelling. These approaches all rely on accepted subject classifications from journals or conference proceedings. Paul and Girju (2009) assess the interdisciplinary nature of distinct research fields based on their topic overlap. Document collections featuring different research fields are compared via their mean topic vectors using cosine similarity. Nichols (2014) apply LDA topic modelling to analyze research awards issued at the National Science Foundation (NSF), inducing 1,000 latent topics from 170,000 project award descriptions. The institutional structure serves as a proxy for research disciplines and topics are assigned to the discipline in which they occur most frequently. The author observed a high variation in the topic frequency over years, while the aggregation of the topics into disciplines accounted for the temporal stability and resulted in a relatively constant score between 0.11 and 0.125.

In contrast, Bache et al. (2013) define the Rao measure entirely on the LDA output, without mapping topics to pre-defined classes that reflect specific scientific disciplines, and without verifying the nature of the topics. In their work, the Rao index is derived in a fully data-driven way and computed on the level of a document over the LDA document-topic and word-topic matrices. The authors conduct various experiments on PubMed Open Access, NSF Grant Awards, and the ACL Anthology and build a topic model for each corpus, varying over the number of topics (K = 10, 30, 100 and 300) and keeping the hyper-parameters fixed, in order to compute the Rao diversity scores. The authors state that the topic-based Rao diversity measure outperforms alternative approaches like entropy in a classification task on pseudo documents. The authors hypothesize that the method would be invariant to the number of topics in the model. Wang et al. (2014) use the same approach as Bache et al. (2013), however, their LDA model is induced from a corpus that considers a paper's references and citations. The authors propose a discounting weight on the balance attribute as part of the diversity score.

Furthermore, a variety of LDA models has been proposed to address certain limitations of LDA and give better performance, for instance, when it comes to detecting rare topics in an imbalanced collection (Jagarlamudi et al., 2012) or short text (Newman et al., 2011; Quan et al., 2015). Incorporating meta-information directly into the generative process of topic models can improve modelling accuracy and topic quality. Various authors have used document labels as a priori information to infer the underlying topic distributions, using training data with known labels in a semi-supervised setting (Ramage et al., 2010). Topic models have been often used in combination with partially supervised methods (Chuang et al., 2012). It has been shown that document regularization yields improved model performance, however requires reliable labeled data (Zhao et al., 2017).

Rao Stirling Diversity Measures based on LDA

The classic Rao Stirling diversity index has been widely used to measure diversity and interdisciplinarity (e.g. Porter & Rafols, 2009; Wang et al., 2015). In this section, we will discuss the three different dimensions of diversity i.e. variety, balance, and disparity.

Variety

Instead of subject categories, the thematic diversity can be related to the number of distinct topics K. A characteristic of latent topics generated by LDA, however, is that every topic is in principle present in every document, with a non-zero proportion. A rough estimate is that a large number of topics is needed to account for small scientific communities. Current approaches set the number of topics between K=300 (Griffiths et al., 2004) and K=1,000 (Nichols, 2014) to cover the whole scientific landscape. Griffiths et al. (2004) determine the number of topics based on the log-likelihood of the data, while Nichols (2014) set the number of topics according to the number of research divisions at NSF. In practice, a higher number of topics will necessarily result in a larger variety. This issue is crucial because the optimal number of topics in a corpus is unknown and based on a heuristic choice.

Balance

Generally, a more balanced document-topic distribution results in a higher thematic diversity estimate. The balance component as part of the Stirling Index can be calculated as follows:

$$\sum_{i=1}^{K}\sum_{j=1\,(i\neq j)}^{K} P(i|d)\,P(j|d) \qquad \forall\ \mathrm{d}: \min^{\mathrm{T}\,(\mathrm{T}-1)} \leq\ \mathrm{B} \leq \max^{\mathrm{K}\,(\mathrm{K}-1)}$$

where *P(i|d)* is the probability of topic i in a paper d and individual pair scores take small values in the range of *[min*: $\sim 10^{-6}$,*max*: $\sim$0.25]. Regarding the distribution of papers into scientific categories, it is likely that any database that seeks to monitor scientific research will consist of long-tailed, imbalanced data that is prevalent in any real-world setting. In order to deal with the issue of imbalanced data, it is necessary to have a good estimate of the scalar concentration parameter α that governs the shape of the document-topic distribution. Setting α to a value close to zero will result in a distribution where the probability mass is concentrated on a smaller set of topics. Moreover, an asymmetric learns a non-uniform prior, assuming that certain topics might be more prominent in the collection. Thus, some topics may be the majority topic in a larger share of documents in the corpus overall and make up more of the total corpus. As an alternative, proper sampling methods that re-balance the data can help to mitigate the problem.

Disparity

Topic similarity metrics can be applied to estimate the (dis)similarity $\delta(i,\ j)$ between topics i and j, and are generally computed from the topics' word probability distributions. A systematic evaluation of different topic similarity measures for pairs of topics generated by LDA has been conducted by Aletras et al. (2014) and Wang et al. (2019), comparing which measure aligns best with human judgements. Their experiments show that intrinsic coherence scores like Jensen-Shannon, Hellinger, Jaccard Distance and cosine similarity applied on the original dataset are generally inferior to extrinsic metrics that make use of external data. However, it is crucial that the external datasets fit well to the domain of the data used to build the topic model. In the setting of Aletras et al. (2014), co-occurrences of words were drawn from Wikipedia, while Wang et al. (2019) use word embeddings, which have been specifically trained on Twitter data. Since external data that covers the immense variety of scholarly topics is not readily available, we use intrinsic measures to compute topic similarity. An alternative approach proposed in Bache et al. (2013) is to make use of the document-topic matrix in order to calculate the probability or cosine distance of distinct topics that co-occur in documents. The motivation for this approach is that topic distributions tend to be distinct by definition. We refrain from this approach, because standard LDA is unable to model relations among topics due to its use of a single Dirichlet distribution, and thus it is not possible to detect correlations amongst topics directly. In order to transform the similarity matrix between topics i and j into a dissimilarity matrix, a frequently applied solution is 1- δ(i, j) and 1/δ(i, j). Based on prior studies, we choose the metrics listed in Table 1 for our evaluation study. The topic distance also indicates how well the topics are separated which is a sign for a high quality LDA model. In order to produce topics that are distinct from each other, a symmetric prior of the topic-word distribution is generally preferred, and the β hyper-parameter needs to be set to values ranging between 0.1 and 0.01, so that the topic vectors concentrate on fewer words (Wallach et al., 2009).

Table 1. Topic Similarity Measures based on the Topic-Word Matrix.

Metrics	***Measure***	***Author***
Divergence-based metrics	*JS Divergence*	Hall et al. (2008)
Coefficient-based metrics	*Jaccard*	Ramage et al. (2009)
Distance-based metrics	*Hellinger Distance*	Aletras et al. (2014)

Summary of Diversity Measures

We apply the Rao-Stirling index (RS) to measure the degree of interdisciplinarity for each institute (aggregate over all publications of the institute) and experiment with different dissimilarity measures. The Rao Stirling diversity is defined as

$$RS(d) = \sum_{i=1}^{K} \sum_{j=1\ (i \neq j)}^{K} P(i|d)\ P(j|d)\ \ \delta(i,\ j)$$

In addition, the broadness of an institute can be determined by means of the Shannon Entropy (H) based on the distribution over latent topics for each institute. The measure combines the variety and balance dimension, while it ignores disparity. A high topic entropy signals an even distribution and broader spectrum of topics. Shannon Entropy is defined as

$$H(d) = -\sum_{i=1}^{K}\ P(i|d)\ \ln P(i|d)$$

The diversity measure can thus be obtained from the topic-document and word-topic distributions of LDA. More concretely, we use Θ (Topic-Document Probability Matrix) for calculating the balance between topics and Φ (Word-Topic Probability Matrix) for computing the distance δ between topics. A limitation in our use case is obviously, that the underlying distributions are unknown and varying over the parameter setting for the number of topics K and hyper-parameters α and β might yield different Rao scores. Also, the size and length of the training data is crucial, since the priors are estimated from the observed counts in the data.

Datasets

In the present work, we use title and abstract from Scopus, a bibliographic database introduced in 2004 by Elsevier. Scopus provides a comprehensive collection of the scientific landscape, covering the world's leading journals, and is a real-time monitor corpus that is both big in size and rich in metadata. It offers, e.g., research institutions of the authors as metadata records.

Scopus World 2018 (Scopus World)

To explore the interdisciplinarity of an institution, we aim to compute the diversity indicator on a balanced corpus that covers all scientific fields. Therefore, we sampled a corpus from Scopus where we seek to give equal weight to all scientific domains to mitigate the minority class problem, since the distribution of papers and journals over disciplines is heavily skewed (e.g., the humanities are underrepresented in the corpus). The result is a corpus of randomly selected publication abstracts and titles from all major fields of Scopus of the year 2018 (see Fig. 1).

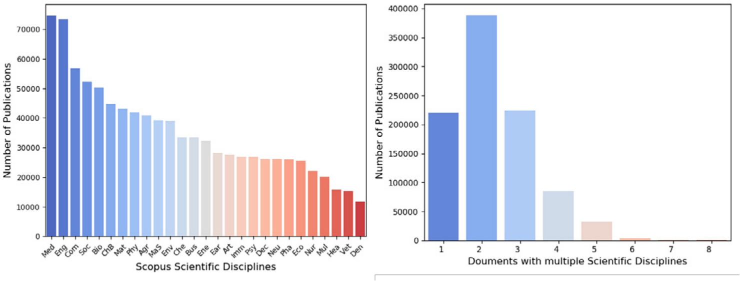

Figure 1: Statistics for Scopus Publications – *Scopus World*

In bibliometrics, the average number of subject categories of a publication, accumulated over an institute, can already serve as an indicator for interdisciplinarity (Levitt und Thelwall, 2008).

The higher the value, the more interdisciplinary the institute. On the publication level, we see that the majority of documents is assigned to more than one discipline, i.e. on average there are 2.3 subject fields per publication (see Figure 1, right).

Institute-specific Publications: Scopus FH and Scopus MPG

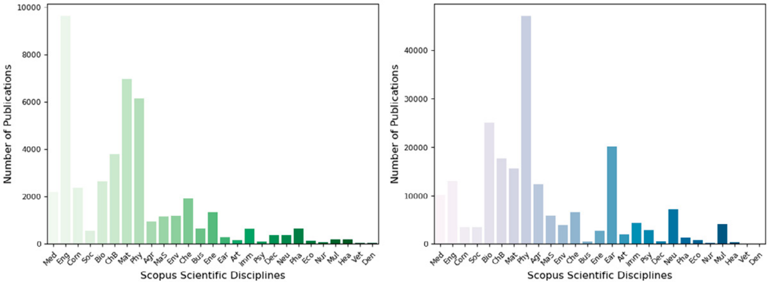

Figure 2. Statistics for *Scopus FH (left) Scopus MPG (right)*

As can be seen in Figure 2, the research profiles of FH and MPG are rather imbalanced, e.g., Scopus FH contains a huge share of publication abstracts from Engineering, while Scopus MPG publishes mostly on Physics and Astronomy. Only a small fraction of articles is dedicated to, e.g., Dentistry. In the FH corpus, 82.41% are assigned to more than 1 field and on average there are 2.47 subject fields per publication, while for the MPG corpus, 70.59% are assigned to more than 1 field and on average there are 2,19 subject fields per publication. Table 2 provides a detailed breakdown of the datasets used in our study.

Table 2. Dataset Statistics

Data Sets	*Number of Institutions*	*Number of Abstracts*
Scopus FH 2010-2018 (Scopus FH)	74	19,661
Scopus MPG 2010-2018 (Scopus MPG)	95	111,986
Scopus World 2018 (Scopus World)		517.516

Empirical Study

Our goal is to test the effects of varying the LDA settings on the diversity measure, composed of disparity, balance and variety. Our research hypothesis is that to provide a good Rao Index of the data, it is desirable that the selected topics are both coherent and interpretable, and have a high coverage of the data.

Choice of the Training and Test Corpora

As training corpus, we use *Scopus World*, and alternatively, *Scopus FH* and *Scopus MPG.* The last two corpora are composed of abstracts from FH and MPG published between 2008- 2018 where we concatenate all abstracts by the same institute to obtain longer documents (with more co-occurrences) that yield better quality topics (Jónsson & Stolee, 2015). We use the institute-specific corpora *Scopus FH* and *Scopus MPG* for testing.

Model Selection and Parameter Settings

Variational inference (Hoffman et al., 2013) as implemented in *gensim* is used for model inference and standard Laplace smoothing factors with $\gamma = 0.1$ and 2,000 iterations. We set the number of topics $K = 100, 150, 200, 250, 300$ topics. As standard parameters of the Dirichlet prior we use a) α = 0.1, b) a non-uniform α estimated automatically from the data (Li et al., 2006) and c) a fixed normalized asymmetric prior of *1/K* (Wallach et al., 2009). Regarding the topics-word distributions, we set a) β = 0.1 and b) β = 0.01, unless otherwise specified.

For pre-processing, we used sentence splitting, tokenisation, lemmatization, and PoS tagging to filter all content words using the Stanford tools[v], keeping only nouns, adjectives, verbs, and foreign words that consist of alphanumeric characters. This resulted in 131,954, 12,598 and 36,381 unique words for *Scopus World*, *Scopus FH* and *Scopus MPG*, respectively.

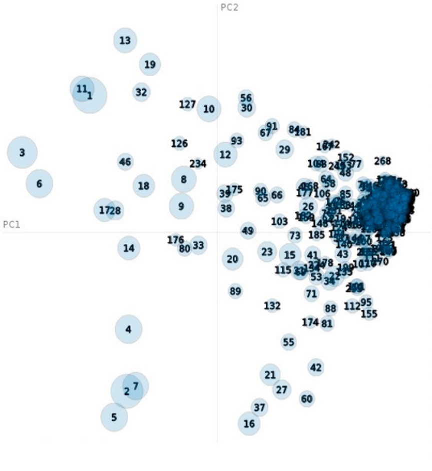
Model Accuracy for Different Settings

We assess modelling accuracy in terms of topic coherence under various settings of hyper-parameters and number of topics. Even though determining the parameters is an established research area and various heuristics exist for real-life applications (Wallach et al., 2009; Lau et al., 2014), Chuang et al. (2012) have shown that a small change in term smoothing and prior selection can significantly alter the ratio of resolved and fused topics. Increasing the number of latent topics often leads to more junk and fused topics with a corresponding reduction in resolved topics. Since LDA results are often difficult to interpret (Chang et al., 2009), we first investigate the outcome of the topic models by humans.

Topic Evaluation by Humans

A qualitative analysis of the topics by manual inspection reveals that there are topics that correspond to scientific domains and others to specific modes of discourse (e.g., description of experimental settings). Topics related to scholarly discourse - signaled by keywords such as *method*, *apply*, or *examine* - are most dominant in the corpus, relative to other topics. In these topics, authors make claims about the key contributions of their paper (Motta et al., 2000). They are more likely in the corpus, because they are relevant for all scientific disciplines.

We also wanted to see how well the topics correlate with an existing categorization schema. To this aim, we compared the topics induced by different LDA models to investigate in how much they correspond to the scientific fields in Scopus ASJC. In order to understand the distribution of topics in terms of size and their overall significance in the corpus, we use the visualization created by LDAvis (Sievert et al., 2014). It also allows assessing how well topics are separated from each other, where topics distance is based on KL divergence.



Alignment	ASJC Category	Topic Words
20,27	Engineering	temperature heat thermal pump
14,25	Materials Science	nanoparticle spectroscopy scanning coating
44	Physics & Astronomy	simulation magnet electron laser controller
12	Chemistry	ratio compound chemical derivative

Figure 3. LDA Intertopic Distance Map

Figure 3 depicts how LDA topics can be aligned to ASJC codes as reference scientific domains in an overlay representation based on human classification. The topics are drawn from a relatively large *Scopus World* model that was able to uncover a high percentage of scientific topics, covering all ASJC topics (i.e., setting $K = 300$, α asymmetric, $\beta = 0.01$).
Opposed to this, models trained on *Scopus FH* or *Scopus MPG* yielded many uninterpretable and fused topics with a low coverage of ASJC topics.

Topic Coherence versus Coverage

The semantic coherence of the topics is measured using word co-occurrences within the original corpus by the *UMass* coherence score on the top 15 words from each topic (Mimno et al., 2011; Röder et al., 2015). We compare the coherence scores for varying model size of LDA trained on *Scopus World, Scopus FH* and *Scopus MPG.* The LDA models trained on *Scopus World* reach an average UMass score between -7.53 ($K = 100$) to -11.74 ($K = 300$) that decreases as we learn more topics. Even though LDA models trained on *Scopus FH* and *Scopus MPG*, and thus less data, achieve higher UMass scores, they are inferior to the *Scopus World* LDA model in terms of coverage (see Table 3).

Table 3. Coherence and Coverage for varying model size of LDA.

Num Topics	*100*	*150*	*200*	*250*	*300*
Scopus Worlds - Average C_{UMass}	-7.53	-8.77	-9.75	-10.90	-11.74
Scopus FH - Average C_{UMass}	-0.83	-0.91	-0.95	-0.95	-0.98
Scopus MPG - Average C_{UMass}	-3.69	-3.41	-3.29	-3.26	-3.01

Experiments to assess the different dimensions of the Rao Diversity Index

Variety & Balance Scenario: We computed the evenness of the document-topic distribution for all FH institutes under various settings using Shannon Entropy, i.e. a high entropy signals *interdisciplinarity*.
Our experiments on *Scopus FH* used for training and testing show that Shannon Entropy ranges between 0.001 and 1 when averaged over all topics. Results confirm that the choice of α impacts on the entropy values: Setting α to a value closer to zero results in a non-uniform document-topic distribution and lower entropy. Likewise, setting α = *asym* instead of α = *auto* confirms a second hypothesis: the first setting has the effect that the probability mass of the distribution will concentrate on fewer topics per document: Accordingly, entropy values are constantly lower for all topics (see Table 4). Additional experiments demonstrate the impact of proper sampling: Institutes show much higher equality and tendency to focus on more topics when the LDA model is computed on a data set, where samples were drawn such as to accommodate for balance beforehand, i.e. *Scopus World.* Table 5 shows that this results in high entropy values of 0.908 (when averaged over all topic settings). More crucially, however, is the fact that in all cases Spearman's correlation is weak, and Pearson indicates only moderate correlation.

Table 4. Mean Shannon Entropy and Spearman/Pearson - Setting *α=auto/asym* and *α =0.1/ 0.01*

K	*100*	*150*	*200*	*250*	*300*	*K*	*100*	*150*	*200*	*250*	*300*
α=0.1	0.127	0.118	0.114	0.118	0.098	**S.**	0.189	0.146	0.209	0.261	0.285
α=0.01	0.072	0.072	0.072	0.072	0.072	**P.**	0.587	0.638	0.667	0.642	0.724
α=auto	0.099	0.095	0.077	0.058	0.075	**S.**	0.030	0.276	0.327	0.228	0.219
α=asym	0.113	0.067	0.067	0.067	0.067	**P.**	0.393	0.688	0.712	0.738	0.662

Table 5. Mean Shannon Entropy and Spearman/Pearson – for two LDA models (*α = auto)*

K	*100*	*150*	*200*	*250*	*300*	*K*	*100*	*150*	*200*	*250*	*300*
Scopus FH	0.099	0.095	0.077	0.058	0.075	**S.**	0.071	0.243	0.28	0.194	0.238
Scopus World	0.918	0.913	0.919	0.911	0.907	**P.**	-0.02	-0.13	0.101	0.087	0.127

Disparity Scenario: We observed that topical distance decreases, when β approaches 0. The inferred topics are a mixture of multiple topics and less separable when β=0.1 instead of β=0.01. Figure 5 shows the degree of semantic similarity between the topics' word distributions for 100 topics and varying β, using Jensen-Shannon as the distance measure. Pairwise dissimilarity of topics is equally high for all other investigated distance metrics, i.e. Jaccard, Hellinger, Cosine. For a model setting with 100 topics we receive Jensen-Shannon scores of 0.98 on average, ranging between 0.898 and 1 for β =0.01 versus 0.79 and 1 for β=0.1, respectively. Furthermore, the data is more separated when the number of topics becomes larger for both β =0.1 / 0.01.

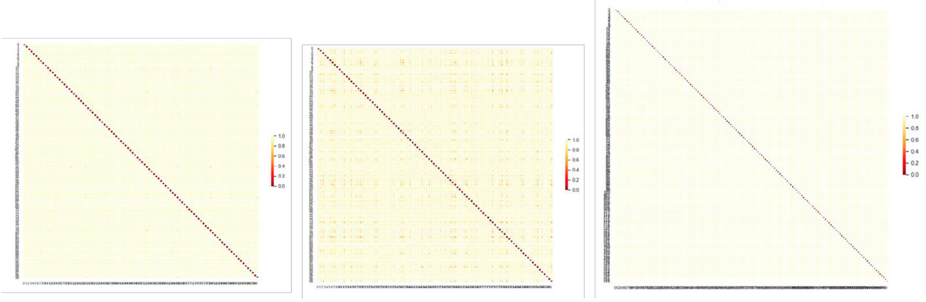

Figure 5. Pairwise Topical Distance based on JS. Topics become dissimilar when β approaches zero and the number of topics becomes larger (*K*=100, β=0.01; *K*=100, β=0.1; *K*=150, β=0.01) (left to right).

Rao Scenario: We investigated the impact of different topic models on the Rao index. First, we calculated the index on the output of the LDA models trained on the institute-specific corpora *Scopus FH* and *Scopus MPG*. In the experiments, we could observe sharp fluctuations of the Rao index when varying over the number of topics (see Fig. 6, left).

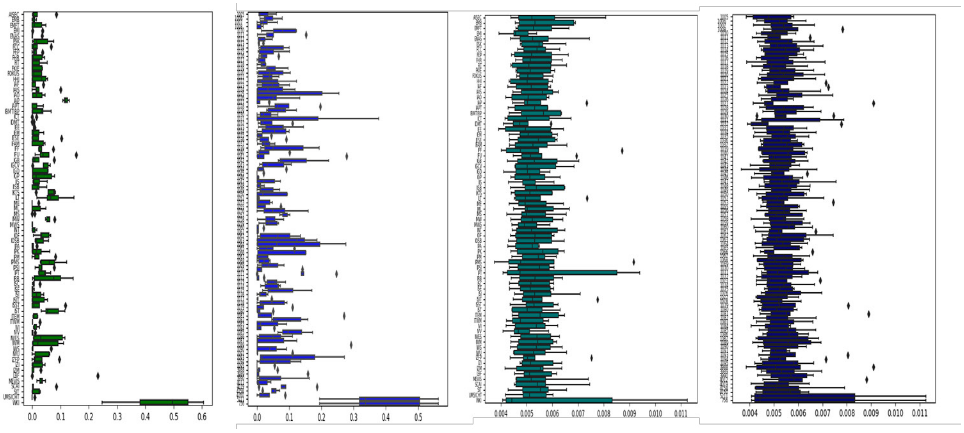

Figure 6. Rao-Index for all Fraunhofer (green) and MPG (blue) institutes; Rao Index is computed for 100, 200, 300 topics on different LDA outputs, i.e. models are trained on *Scopus FH* versus *Scopus MPG* (left) vs. Rao Index computed on *Scopus World* (right)

Rao index values range between 0.001 to 0.605 and 0 to 0.562, with a standard deviation of 0.062 and 0.077 for FH and MPG, respectively. Note that in this case, it was not possible to map the LDA topics fully to all ASJC fields, since the models have a relatively low coverage.
We also calculated the index for various LDA models trained on the *Scopus World* and applied it to the FH and MPG corpora. The setting also makes comparisons between institutes possible and the LDA classifier is less prone to overfitting. However, as shown in section 4, topic quality in terms of qualitative (human judgments) and quantitative (coherence) evaluation showed that many topics were not interpretable or meaningful.
For this setting, the standard deviations are much smaller. In this case, the Rao index takes small values, ranging between 0.004 and 0.011 for both institutes, and thus there is little difference between the values (see Fig. 6, right). The text-based Rao index thus suffers from the same limitations of low discriminating power as the bibliometric-based approach.

Last but not least, we calculated the Spearman and Pearson Rank Correlation of the Rao Index varying on the number of topic and model size. Figure 7 shows the visualization of the coefficients based on the various outputs of Rao, depicting the pairwise correlations as a heatmap. As can be seen, the choice of *K* has a great influence on the Rao results: Pairwise comparisons of Rao results vary a lot, showing that there seems to be no association between the variables. In particular, Spearman correlation is weak, showing that the general rankings amongst institutes is not preserved when varying on the number of topics.

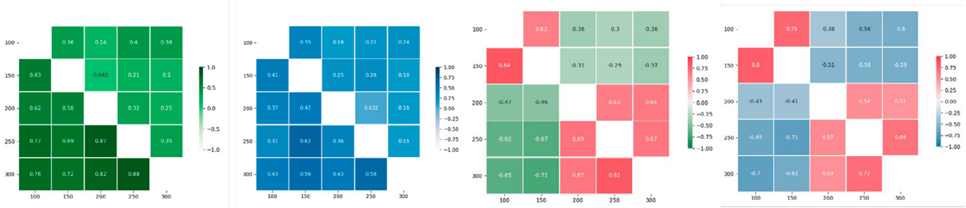

Figure 7: Spearman (upper) and Pearson (lower) Correlation of Rao Index
Computed from various LDA outputs, varying on the number of topics (on x-axis, y-axis) and model size of LDA (small models: left, large models: right), i.e. models are trained on *Scopus FH (green)* versus *Scopus MPG* (blue) vs. Rao Index computed on *Scopus World* (tested on *Scopus FH (*green-red), *Scopus MPG (*green-blue))

Conclusion

In this paper we investigated the Rao indicator for interdisciplinarity based on LDA for two German research institutes. Both institutions are specialised in certain scientific fields and have a more or less high propensity towards interdisciplinary research. It would be a benefit for politicians and decision makers to have an indicator that is able to truly reflecting this trend and which can be computed automatically from any data set.
Yet, our experiments show that the LDA-based Rao metrics has serious limitations and due to its instability might not be a useful indicator of interdisciplinary. Contrary to Bache (2013), who claim that the method could be applied fully automatically and would be largely invariant to the number of topics in the model, our experiments on Scopus and two major German research associations show the opposite. It results in sharp fluctuations that make it an unreliable indicator. We could not find a strong correlation between Rao results that have been generated from different settings. In fact, all parameter variations seem to have a strong effect on the output, i.e. choice of the number of topics, hyper-parameters, and size and balance of the underlying data used for training the model.
There seems to be a consensus in the research community that in order to select the best value of *K*, a qualitative evaluation of the performance of alternative LDA models with varying *K* is required (Suominen, 2016), ensuring that the topic model is able to represent and cover all major scientific fields. Moreover, it is crucial that hyper-parameters are set in such a way that

they produce a topic model with sparse topic and word distributions. A qualitative analysis of the topics of various models reveals that the models fail to differentiate scientific topics from scientific discourse and junk topics. However, topics related to scholarly discourse not necessarily indicate interdisciplinary studies (apart from Scientometrics).

Abstract

This research in progress reports on an ongoing analysis of submissions and review reports made to Early Career Researcher (ECR) fellowship applications made to the Wellcome Trust between 2009-2019. It combines a small scale, linguistic coding of reviewer reports; interviews with unsuccessful candidates; and a large-scale, text-driven analysis of noun phrases surrounding the use of gendered pronouns (he/his-she/her-they/their/you) within peer review reports provided to applicants as feedback after receiving the outcome. This research in progress reports on the initial findings of the research garnered from the small-scale linguistic coding of review reports, and interviews with unsuccessful applicants. The initial analysis shows that, on average, women receive longer reports than men. Additionally, candidates identified as women by the reviewer's commentary on average receive 16.18 negative comments compared to 9 for those identified as men. In addition, many negative comments for women are based on assessments of personal competence and measures of performance up until the time of the application in addition to the project assessment, whereas negative comments for men are focused on characteristics of the proposed research project. When triangulated with one-on-one interviews with male and female candidates who were unsuccessful, where present, gendered notions in reviewers report provided as feedback were identified by applicant and this influenced the applicants' future career decisions, as well as how the applicant perceived the fairness of the evaluation governed by Wellcome, as well as the use of peer review in academia more generally. The large-scale analysis of noun phrases is ongoing, will feed into the analysis briefly discussed above, and will form part of this presentation in July.

Introduction

The peer review process used to aid the decision of competitive grant funding is a cornerstone of academic governance. When functioning well, it provides funding agencies with tools to aid decision-making that is driven by expert and/or peer evaluations, and it provides applicants with feedback and performance assessment that can ideally be used to strengthen future research activities and decisions regardless of the outcome. However, when functioning badly, the single-blind peer review process adopted by the majority of funding agencies (Tomkins et al, 2017) allows peer reviewers to exercise unconscious bias blindly, with little repercussions for the reviewer for when these biases subsequently influence outcomes. In addition, how applicants receive these 'signals' (Derrick et al, in progress) in science influences how their future research and career choices, as well as decreases their trust in the peer review process and personal sense of social justice.

It is widely recognized that gender bias is widespread in academia and academic institutions, including peer review (Monroe et al, 2008; de Paola & Scoppa, 2015) Addressing this bias, however, is not straight-forward with its unconscious forms influencing how research, and research careers are governed; and expectations of performance is assessed, globally. By examining reviewers reports and using interviews with unsuccessful candidates for ECR fellowship applications at The Wellcome Trust (2009-2019), this research in progress investigates how gender-bias is manifested in how reviewers assess researchers and their research proposals.

Methods

Survey and Wellcome Trust database

A database of proposals submitted to the Wellcome Trust, and their relative reviewer reports for both successful and unsuccessful applicants from 2009-2019 was constructed. Five funding fellowship calls were chosen due to their focus on ECR research, these included;

1. Sir Henry Wellcome Postdoctoral fellowships;
2. Research Fellowships in the Humanities and Social Sciences;
3. Sir Henry Dale Fellowships;
4. Research Career Development Fellowships; and
5. Starter Grants for Clinical Researchers.

From these proposals (n=4109) a survey of respondents (n=411) was then used to query whether a resubmission after an initial (T_0) failure at the Wellcome Trust was attempted; to establish how many resubmissions were made prior to success ($T_1 \ldots T_x$); and to collect subsequent funding applications.

For reasons outlined in (Derrick et al, in progress), this project focused on analysing the review and provision of feedback for unsuccessful applications only. From the survey, unsuccessful applicants who had reapplied; (1) Once after T_0 (=T_1); (2) more than once after T_0 (T_0 + x (T_x)); and (3) had not reapplied, were identified. Feedback provided to each group of applicants was then collected for the linguistic analysis, and respondents invited for an interview with the research team. Publication data on all participants (n=4109) was also collected and used to track career data following the initial application (T_0) to The Wellcome Trust.

Qualitative coding of reviewer comments

From the initial database, and cross referencing with data from the survey, 27 documents from ECR fellowship applications made to the Wellcome Trust, comprising 81 reviewer comments, were extracted and thematically-coded using NVivo11. Coding was linguistically-informed and built upon conversations between the research team and the Wellcome Trust and coded as: (1) negative; (2) positive; or (3) questionable[1].

In parallel, reviewer comments were coded for their use of pronouns associated to the applicant ((1) he/his; (2) her/she; (3) they/their/you)) within sentences. In addition, coding for pronouns also included the entire review if the reviewer announced the gender of the applicant continuously throughout their comments (Male (M) or Female (F)). If the gender is not announced (they/their/you), the comments were coded as Non-Gendered.

Sections of the reviewer comments were also coded where comments discussed the (1) candidate (*Candidate*); (2) research setting (both on an institutional level or in reference to a particular supervisor) *(Setting*); and (3) discussion of the proposed project (*Project*).

Using the compound query function in Nvivo11, the instances of overlap between the location of an emotional response coding and the 3 topic identifiers listed above were determined for each reviewer's comments. The instances of overlap where then separated based on whether or

[1] 'Questionable' was a category where the statement could not be interpreted as 'negative' or positive' but where the response from the applicant to the reviewer's comment would from the applicant was anticipated to be associated with a confused response, or where the negative connotations could have been an accident on the part of the reviewer's word choices.

not the reviewer had explicitly used gendered pronouns in their text. The sums of the instances of overlap were then divided by the number of reviewers for each gender.

The emotive response to reviewer comments was triangulated with interviews with the applicants, and their description of their response to the feedback was feedback to enhance the coding of the reviewer comments.

Findings

The preliminary results showed that reviewers that used female pronouns in reference to the candidate wrote on average 16.19 comments that could potentially evoke a negative emotional response, 15.22 positive, and 1.63 questionable.

In addition, for reviewers that used gendered pronouns in the review, the use of male pronouns was associated with, on average, 9 negative comments, 12.91 positive comments, and 1.26 questionable comments. In comparison, comments that used no gendered pronouns (they/their/you) had 5.5 negative, 3.85 positive, and 0.4 questionable.

Table 1. The number of comments by reviewers that could elicit potential emotional responses for applicants in the sections that discuss the applicant, their research setting, and the proposed project – analyzed by identified gender.

Table	*Candidate*			*Setting*			*Project*		
	Neg	*Pos*	*Off*	*Neg*	*Pos*	*Off*	*Neg*	*Pos*	*Off*
Female	1.85	3.74	0.41	0.11	2.74	0.41	11.85	6.40	0.78
Male	0.56	3.88	0.29	0.38	2.24	0.09	7.6	5.53	1.01
Non Gendered	0.45	1.1	0.05	0.5	0.6	0.05	3.5	1.6	0.25

The preliminary linguistic analysis for negative emotional words of the larger dataset by applicant-identified gender, showed a small trend towards the use of more negative adjectives in situations where the applicant's gender was specifically referred to by the reviewer (e.g. he/his; she/her). It should be noted that the occasional negative comment is excepted, if not beneiuficial to the applicant's development. It is in the frequency and intensity of the negative comments that issues may arise.

> *"The 'idea' of a flowchart and checklists, though, has already been pioneered in patient safety in surgery by a* medical professional." (emphasis theirs) (2.36% of reviewer comments were a direct attack, 19.15% were generally negative)[2]
>
> *"First of all, the applicant does not demonstrate that she has any knowledge of the social science literature on areas such as…"* (3.79% of reviewer comments were a direct attack, 28.73% were generally negative)
>
> **Reviewer Feedback for female applicants**
>
> ***"****However, the proposal as currently constituted appears premature and insufficiently though through. "(*0.35% of reviewer comments were a direct attack, 11.29% were generally negative)
>
> **Reviewer Feedback for a male applicant**

Interviews with applicants exploring their response to the language of reviewer reports, found that in many cases, the negative framing of the comments elicited negative reactions from

[2] Percentages are derived by NVivo as percent of total characters in the document coded to that category. This includes the form email prior to the review comments, as well as all reviewer comments submitted to the applicant.

applicants. This was particularly the case for female applicants, who are reportedly sensitive to feedback identified as 'gendered' by the above thematic coding, regardless of whether the focus of the feedback was on either the Candidate, Setting, or Project. For example, for a Female candidate;

> *However, the application, as it now stands, does not do enough to highlight her career progression or connect the dots between her past, present and future career aspirations. Put simply, it does not explain where she has been and why and how this links with where she is going. There is a complicated mix of broadcasting, journalism, publishing and law training. It appears erratic without explanation and discussion (the form provides several places to do this which are not used well). There is a problem with structure (and good use of word limitations) to convey the applicant's suitability to a fellowship and how this fits with her past and future academic career intentions.*
>
> **Reviewer feedback**

Compared to a Male candidate on the same topic;

> *His track record shows promise due to a laudable willingness to learn and employ cutting edge techniques and use different experimental organisms to address the topic being addressed.*
>
> **Reviewer feedback**

And;

> *His dual training in medicine and law, along with his experience and high-level training as a physician, will no doubt serve him well throughout his career.*
>
> **Reviewer feedback**

In some cases, it was difficult to ascertain whether the review had simply overlooked polite convention related to the use of salutations;

> *"It is terrific that Ms. **** is able to produce translations of Persian works that will no doubt of interest to future scholars and be significant to her own work."*
>
> **Reviewer feedback** - (every other reviewer called her Dr.)

The negative comments are not the only oness with a gendered imbalance – the effusiveness of praise can also vary based on the pronouns used in the review.

> *"From my exerience I would consider this at the international forefront of work in this area and am not aware of better modelling work of this nature ongoing elsewhere ."*
>
> **Reviewer Feedback for a male applicant**

> *"This is strong proposal that by collaboration takes an interdisciplinary approach to an important research question. I think the methods are entirely feasible."*
>
> **Reviewer Feedback for a female applicant**

Or whether this was examples of the operationalization of embedded gender bias in research culture more generally. The large-scale, linguistic word analysis will be used to explore this further.

Discussion

The input of external expert (peer) assessments is a hallmark of the peer review process. At the Wellcome Trust, external review reports are considered by a separate panel assessment process that uses these reports to aid their decision-making about who will successfully receive research funding, and those that will be unsuccessful.

Although, the results cannot indicate if the funding outcomes were influenced by gender bias, the analysis of the way that gendered language in reviewer comments on unsuccessful grant applications is associated with positive and negative comments about the applicant, their environment and research project, is concerning. In addition, it cannot reliably be concluded that a higher proportion of negative comments used in comments is associated with either negative outcomes for the applicant, or the existence of gender-bias in the decision-making process of peer review panels; it is known that the authority that these peer review reports hold over these decision-making processes is large. Therefore, these results show the potential of how unconscious gender-bias of reviewers can influence the language used in peer review reports and by supplying these reports to the decision-making panel could be used to influence outcomes. This is especially the case if the reviewer reports are received by the panel as objective assessments of research value and therefore seemingly free from influences of bias. In this way, the influence of gender-bias in academic decision making is not just unconscious, but also embedded into systems of academic governance and evaluative practice.

Acknowledgments

This project was supported by funding from the Wellcome Trust as part of the project "Minimising the career cost of first failure: Creating a peer review process that treats failure as a learning tool for ECRs".

Abstract

While interdisciplinary research has attracted much attention, this has not yet resulted in a coherent body of knowledge of interdisciplinarity. One of the impediments is a lack of consensus on its conceptualization and measurement. Some of the proposed measures have shown to misalign empirically, meaning that conclusions about IDR can differ across measures. To clarify this disagreement conceptually, and to stimulate better coherence in measurement, this paper starts with a review of the IDR definitions. From a synthesis of these definitions, we provide a conceptual definition of the construct along with evaluation criteria for its measures. We use these to evaluate current measures of IDR. The results show that most measures meet the usability criteria, but measures vary widely in meeting other criteria, which can explain some of the observed inconsistencies in earlier studies. The "Integration score" from Rafols and Meyer performed best. By using the results in selecting measures, researchers can, in our view, draw more consistent conclusions, aiding in the development of a coherent body of knowledge of this ever-important phenomenon.

Introduction

Many complex problems arising in society require the integration of knowledge beyond the boundaries of a single discipline (Wang et al., 2017; Choi & Richards, 2017; Okamura, 2019, MacLeod & Nagatsu, 2016), such as climate change, food security, peace, social justice (Al-Suqri et al., 2017), and environmental issues (Steele & Stier, 2000; Morillo, Bordons, & Gómez, 2003). Engaging in interdisciplinary research (IDR), however, is challenging. Specialised disciplines have defined research practices, languages, philosophies and communities that often seem inconsistent or incompatible. Understanding these problems and how they are to be overcome is best achieved by meta-research.

However, to date, studies on IDR have not constructed a coherent body of knowledge due to a lack of consistency in measuring interdisciplinarity (Leydesdorff & Rafols, 2011; Wang & Schneider, 2020). Choosing data sets and methodologies produce "inconsistent and sometimes contradictory" results (Digital Science, 2016, p. 2; Wang & Schneider, 2020). Partly this may be due to different indicators capturing different aspects of interdisciplinarity (Leydesdorff & Rafols, 2011). For example, they may capture one or multiple of the three dimensions of diversity: variety, balance, and disparity (Leydesdorff, Wagner , & Bornmann, , 2019). Some take into account the varying distances between fields; others do not. Some assume a network view, and others a more hierarchical structuralists perspective (Wagner et al., 2011). Yet even when measures purportedly capture similar aspects, they may still be empirically inconsistent (Wang & Schneider, 2020).

These inconsistencies stem from diversity in conceptualization and operationalization of interdisciplinarity. First, some authors (e.g., Karlqvist, 1999) have approached interdisciplinarity qualitatively, others quantitatively. The range of quantitative conceptualization of interdisciplinarity covers two distinct perspectives. One is considering the processes and dynamics that contribute to interdisciplinary research and the other one focuses on research publications and to what extent they integrate different research disciplines (

Mugabushaka, Kyriakou, & Papazoglou,, 2016). Other operationalizations provide more details about the integration of different fields of knowledge, in terms of methods, tools, theories, and data (Rafols & Meyer, 2010; Porter et al., 2007). Each of these approaches can lead to different definitions, measures and indicators. Thus, the choice of a specific view and its operationalized indicators produce inconsistent results (Wang & Schneider, 2020).

If IDR would be quantified with more consistent measures, it is more likely that conclusions about this phenomenon, including how to maximise its success, will also be consistent, allowing for a more coherent body of knowledge.

In this paper we aim to take a first step towards this. We first review and synthesize the conceptual definitions of IDR. Based on this we develop conceptual evaluation criteria and apply them to extant measures. We then discuss the results in the context of empirical evaluations elsewhere, and how researchers can choose the best measure toward more consistency and coherence in developing an understanding of IDR.

Definition of IDR

Our review of 25 definitions of interdisciplinarity provided in the literature[1] reveals various similarities. Within the context of quantitative, each definition of interdisciplinarity either explicitly or implicitly refers to multiple disciplines, or similarly, *fields*, or *bodies of knowledge or research practice*. Regardless of the name given to them, they are treated as distinct collections (or systems) of ideas, knowledge, data, tools, theories, practices, specialists, or combinations thereof. Central to most definitions is a connection, communication, or exchange of such items across distinct collections, and/or a resulting intellectual synthesis, fusion, or integration. This result may serve different purposes, but typically relate to understanding issues or solving problems that are not contained to a single discipline.

Most definitions imply these collections must be distant, distinct, or diverse, either sufficiently so for interdisciplinarity to 'occur' or 'apply', or increasingly so for IDR to be more evident or pronounced. Similarly, some definitions imply that a condition for IDR is that the resulting synthesis or integration must be of a sufficient degree or depth. Most definitions do not carry assumptions or criteria about those conducting IDR, such as teams versus individuals, or specialists versus generalists. They also do not tend to constrain IDR as an attribute of particular classes of objects, such as authors, papers, departments, or fields of study.

Based on this review, we define IDR as *the integration of knowledge from diverse disciplines*. This definition allows for two main conceptual dimensions of ID: the extent to which knowledge is integrated, and the diversity of the source disciplines. Yet the definition itself carries no specific implications for the scales of diversity, integration, or interdisciplinarity itself. Nor does it carry implications for the relationship between interdisciplinarity and its two dimensions. In line with the reviewed definitions, this definition allows for describing various classes of objects. Individual papers, authors, author teams, departments, universities, journals, conferences, fields of study and entire disciplines can all be described in terms of the extent they achieve or reflect the integration of knowledge from diverse disciplines. The components of this definition can be understood as follows:

– *A discipline* is a distinct collection of facts, concepts and methods (Braun & Schubert, 2003; Barry, Born, & Weszkalnys, 2008). Therefore, discipline refers to any area of study that has had some level of coherence, by having defined communities, educational programmes,

[1] We searched for keywords such as "interdisciplinarity" and "interdisciplinary research" within academic databases (e.g., WOS, Scopus, and ProQuest). Around 100 sources including books, journal papers, and research reports were retrieved from which we retrieved 25 definitions from various sources. For space considerations, they are not reproduced here.

research culture, and a shared body of knowledge. Since the boundaries of disciplines can vary across communities and geographies, change over time, and be expressed at different levels of granularity, there is no universally accepted or persistent classification of definitions.
- *Diversity,* in the context of disciplines, refers to the variety, balance, and disparity of a set of disciplines (Leydesdorff & Rafols, 2011; Zhou et al., 2012). These dimensions or aspects of diversity are additive: the higher the number of different disciplines in a set, the more evenly their frequency is distributed, and the more disparate they are from each other, the more diverse is the set. By extension, the more diverse the disciplines from which research integrates knowledge, the more interdisciplinary the research.
- *Integration of knowledge* lies at the heart of the concept of IDR (e.g., Klein, 1990; Rhoten & Pfirman, 2007; Porter & Rafols, 2009; Rafols & Meyer, 2010; Chang & Huang, 2012) and aids in distinguishing IDR from similar concepts such as multi-disciplinarity (Holland, 2008). Based on the review, integration must be broadly understood as any combination, fusion, synthesis, or even juxtaposition of two or more ideas, producing a whole idea, a more general idea, or a meta-idea. While philosophically, it is possible to speak of the depth or degree with which two or more ideas are integrated (Rafols & Meyer, 2010), definitions of interdisciplinarity tend to be more consistent with a dichotomous view: ideas are assumed integrated or they are not. While the integration of knowledge is fundamentally a cognitive process (Wagner et al., 2011), it may emerge both from within individuals and from interactions of multiple individuals (Porter et al., 2007).

Based on this synthesis of the definition of IDR, we aim to evaluate how commonly used measures of IDR align with it.

Method

Our conceptual evaluation of commonly used measures vis-à-vis a synthesized definition of IDR will follow two steps. First, from the preceding review we will draw out conceptual criteria for measures, such that measures that meet these criteria are in alignment with the definition of IDR. Next, we identify commonly used measures, and examine whether they meet these criteria.

Evaluation criteria

Good measures meet a variety of criteria: they can be used where needed (usability), they reflect the construct as a whole (construct validity), they cover the content domain of the construct (content validity), and they can distinguish the construct from similar ones (discriminant validity) (MacKenzie, Podsakoff, & Podsakoff, 2011).

Usability

IDR has been studied in the context of individual papers (Porter et al ,2007; Chen et al. ,2015), authors (Qin, Lancaster, & Allen, 1997), groups of authors such as departments or universities (Bordons et al., 1999; Gowanlock & Gazan, 2013), journals (Leydesdorff, 2007) and disciplines (Rinia, van Leeuwen, & van Raan, 2002; Schummer, 2004). Using a common measure across these studies will help develop a common body of understanding of IDR. Therefore:

1; *Multi-object*: The measure is applicable to a variety of objects of study, including individual papers, authors, institutions, journals, and disciplines.

Most research on IR involves evaluations and comparisons within or across these objects of study (Morillo, Bordons, & Gómez, 2003; Leydesdorff, 2007; Wang & Schneider, 2020). For example, one may wish to compare a new journal to an established journal, or a small department to a larger one. Given that they can vary greatly in the quantity of research they represent, such comparisons are only meaningful when controlling for these quantities.

2; *Size independent*: The measure's values for IDR of objects of study are independent of the amount of research (e.g., number of published papers) belonging to these objects.

Measures of IDR have leveraged various classifications of disciplines, such as the Web of Science Subject Classification (Wagner et al., 2011) and the All Science Journal Classification (Leydesdorff, de Moya-Anegón, & Guerrero-Bote, 2015), or proxies of disciplines, such as journal title. All of these have different granularities. Since the identity of disciplines varies across communities and institutions (e.g., Zhang, Rousseau, & Glänzel, 2015), and changes over time (Huutoniemi et al., 2010), there can be no universally or permanently true classification of disciplines.[2] To accommodate multiple classifications within consistent measurement, measures should be able to be applied to any of these without carrying an inherent bias. In particular, measures should not result in widely different scores of IDR if classifications of different granularities are used.

3; *SC unbiased*: The measure is applicable to any subject categorization and is independent of its granularity.

Construct and content validity

Measures with construct validity capture the meaning of the construct (Zwanenburg & Qureshi, 2019), in this case the degree with which knowledge from diverse disciplines is integrated. This involves two dimensions, namely knowledge integration and diversity in disciplines. Content validity refers to the coverage of the content domain of a construct, namely these two dimensions and their content.

4a; *Integration of sources*: The measure reflects the degree to which knowledge from source disciplines is integrated. [3]

Fully covering knowledge integration requires the identification of all disciplinary sources of knowledge that have been relied on to develop the research. It also requires the degree to which knowledge from each source discipline is integrated.

4b; *All sources identified*: The measure is based on a complete identification of disciplinary sources of knowledge that have led to the research.

4c; *Integration of each source*: The measure is based on the degree to which knowledge from each source discipline is integrated.

The content of the diversity construct, as used in the IDR context, consists of disparity, variety, and balance (Wang, Thijs, & Glänzel, 2015).

5a-c; *Disparity, variety, balance*: The measure is sensitive to differences in the (a) disparity, (b) variety, and (c) balance of source disciplines.

IDR measures

From our literature review we included all measures when they were presented as a measure of IDR. This was regardless of them being deployed, the intent or motivation behind their

[3] This goes beyond *representing* multiple disciplines, as is common in studies on multi-disciplinarity.

proposal, or any particular object of study (Wang, Thijs, & Glänzel, 2015). The measures are listed below.

1. *P_multi*: This measure considers "percentage of journals classified in the category analysed and in any other SciSearch category at the same time" (Morillo, Bordons, & Gómez, 2001, p. 205).
2. *p_outside*: This measure indicates "the percentage of journals in i (a WOS subject category) that have been assigned to more than one research area" (Wang & Schneider, 2020, p.242).
3. *Pro*: The percentage of references outside the category of the focal journal (Morillo, Bordons, & Gómez, 2001; Porter & Chubin, 1985)
4. *D_links*: Diversity of links, indicating "the number of links between different SCs [subject categories, red.] established by journals in each category" (Morillo, Bordons, & Gómez, 2003, p. 1241).
5. *Pratt index*: An index to assess frequency distribution to compare journal and subject concentration in different fields (Pratt, 1977).
6. *Specialization index (Spec)*: "This measures the spread of references that publications in SC$_i$ cited over all other SCs" (Wang & Schneider, 2020, p.243). "For the set of journal articles, it counts the number of publications in each SC, squares the count for each SC; and then sums these. Finally it divides that sum by the square of the sum of all the counts" (Porter et al., 2007, p. 138).
7. *Brillouin index*: "A diversity index that combines the concepts of richness (i.e., the number of observations) and relative abundance (i.e., the distribution of observations among categories)"(Steele & Stier, 2000, p.478).
8. *Gini coefficient*: "A measure of inequality or unevenness in a distribution" (Leydesdorff & Rafols, 2011, p. 90). It considers the distribution of references over SCs for a group of publications (Wang, Thijs, & Glänzel, 2015).
9. *Rao-Stirling (RS) diversity index*: A measure of diversity used for interdisciplinarity, including "the number of disciplines cited (variety), the distribution of citations among disciplines (balance), and, crucially, how similar or dissimilar these categories are (disparity)" (Porter & Rafols, 2009, p. 721). Increase in any of these attributes leads to increase in the diversity of the system (Rafols & Meyer, 2010).
10. *Hill-type true diversity index*: Similar to the RS diversity index, the Hill-type indicator gives more weight to variety (Zhang, Rousseau, & Glänzel, 2015).
11. *Coherence*: "The indicator of field coherence quantifies the degree of knowledge integration at the level of fields (or rather subfields), that is, Subject Categories" (Soós & Kampis, 2012).
12. *Betweenness-centrality (BC)*: A measure proposed to assess interdisciplinarity of journals. Betweenness measures the degree of centrality that a node (representing e.g. an article or journal) is located on the shortest path between two other nodes in a network (Leydesdorff, 2007).
13. *Journal interdisciplinarity*: This measure quantifies the degree of specialization versus interdisciplinarity exhibited by a journal based on the bipartite network between scholars and journals (Carusi & Bianchi, 2020).
14. *Author interdisciplinarity*: This measure extends Rao-Stirling diversity measure, with co-author networks and from the perspective of disparity (Zhang et al., 2020).

Results

The outcome of the evaluation is provided in Table 1.

* '1' and '2' refer to one or two of three criteria being met.

** The three dimensions are tapped into, but not as applied to the diversity of disciplines but that of authors.

Only one criterion is nearly universally met, namely *2: Size independent*, as most measures include a division by e.g., the number of papers published All other criteria are met by three to nine of the 15 evaluated measures. Criterion *4a: Integration of sources* was met least. The typical reason for this was that the consideration of multiple disciplines was not in the context of disciplinary sources. For example, the author-journal bipartite measure taps into clusters of communities, without directly tapping into integration of knowledge. Those that met this criterion referred to the references of articles, papers, or other research works, thus more clearly being based on disciplinary sources of knowledge integration.

There was considerable variability in tapping into, or being sensitive to, the different dimensions of diversity. While variety (simply the number of disciplines) was typically met, disparity was met only by few measures, as most did not account for or were not sensitive to the distance between or similarity of disciplines. This means that scores on these measures are more sensitive to the selection of the classification of disciplines, since these vary in granularity. Several measures, most notably numbered 1-6 which comprise Wang & Schneider's Group 1 of measures, meet few of the criteria, without strong reference to integration or an independence of a chosen classification of disciplines. Several measures met nearly all, and one measure, the Rao-Stirling diversity index, met all of the criteria.

Discussion and conclusions

The literature has shown measures of ostensibly the same construct, interdisciplinarity, do not align empirically (Wang & Schneider, 2020). Our results take a step in identifying the underlying conceptual reasons for this disagreement. To some extent, our evaluation mirrors the empirical evaluation of Wang & Schneider (2020) in identifying two clusters of measures, with similarities in terms of the respective fulfilment of conceptual criteria.

There are several take-aways for researchers interested in operationalizing interdisciplinarity:

- First, to develop a coherent body of understanding on IDR caution is to be exercised in terms of the selection of measures. Our results suggest that the observed empirical disagreement is not just noise but there are significant conceptual differences underlying these measures. The danger of picking a convenient measure is that its conceptual foundations do not align with much of the extant literature and that the results will not be able to contribute to it.
- Second, to exercise such caution means clarifying the conceptual definition of interdisciplinarity. Our review has synthesized 25 definitions found in the literature; this synthesis seems consistent with most of the meaning attributed to interdisciplinarity in the quantitative literature on this phenomenon.
- Third, whether this definition is relied on, or another one, it is imperative to be aware of and communicate the assumptions that this choice implies. For example, by emphasizing variety over other dimensions of diversity will imply tie scores on the measure more strongly to a particular classification of disciplines.

This study provides a handle for researchers wishing more conceptual guidance in the concept and measurement of IDR through the synthesized definition, the identification of evaluation criteria, and the application of these two measures of IDR. While these criteria are not exhaustive in the selection of measures to employ – one can think of practical considerations like the ease with which meta-data is obtained – they do cover the conceptual domain of the construct, and are able to point to important differences in existing measures.

Based on the findings, measures that satisfy the majority of criteria include: Rao-Stirling (RS) diversity index, Hill-type measure, Coherence measure, Betweenness-centrality, and Journal interdisciplinarity (Carusi and Bianchi, 2020). Their common properties are that they use cosine similarity between subject categories, and also include three aspects of diversity (variety, balance, and disparity).

This study does not advocate for any one measure in particular, or show that any of the measures are invalid in themselves. It shows that many do not meet most criteria that are based on a synthesis of the literature. This synthesis is not a consensus on the definition of IDR per se: one can argue for different 'flavours' of IDR, and place more or less importance on its dimensions of integration of knowledge, and the dimensions of diversity of disciplines. However, given the empirical disagreement, a continued emphasis on idiosyncratic definitions, conceptually or operationally, will deter the development of a common body of understanding on IDR in which results and conclusions are intercompatible.

We hope that our synthesis and evaluation help in fostering more consistency in measurement and thus coherence in our body of understanding, such that practitioners and academics alike can unlock more of the great potential of interdisciplinary research.

Does Publicity in the Science Press Drive Citations?

Manolis Antonoyiannakis[1,2]

Introduction

Publishing is a selection process. Through a series of selections, journal editors decide which papers merit external review, which papers to send back to referees, and which papers to publish. But increasingly over the past 20 years, the selection of papers does not stop at publication, as editors curate lists of their favorite accepted or recently published papers, sometimes accompanying them with short summaries or longer commentaries by experts.

The community is paying attention. Researchers often promote (in their websites or resumés) their highlighted papers, while funding agencies track their grantees' progress by monitoring coverage in highlighting platforms.

Citation metrics agree well with peer review at the aggregate level (Traag & Waltman, 2019). So, does the post-acceptance "round" of review of highlighted papers produce a citation advantage? We address this question quantitatively, for several publicity markers on papers published in the journal Physical Review Letters (PRL) of the American Physical Society (APS). We thus extend our previous work (Antonoyiannakis, 2015).

Explanation of highlighting platforms

Cover image: Chosen for aesthetic reasons mainly.

Editors' Suggestions: Chosen for potential interest.

Viewpoints: Commentaries commissioned by the APS Physics editors and written by experts. They explain why a paper is important to the field.

Focus stories: Journalist-written news stories that explain the latest research to non-physicists.

Synopses: Short summaries of newsworthy results written by journalists and APS Physics staff.

Research Highlights: Short summaries of papers written by journal editors in the *Nature* journals.

News & Views: Commentaries by experts or (less often) by journal editors in the *Nature* journals.

Multiple Linear Regression

We perform Multiple Linear Regression on the citation data for papers in these highlighting platforms. As a first sample, we chose papers published from 2008–2012 (Figure 1). This amounts to 246 papers in the journal cover, 203 in Focus, 354 Viewpoints, 1232 Editors' Suggestions, 556 Synopses, 84 Research Highlights in Nature Physics, 36 News & Views in Nature Physics, and 91 Research Highlights in Nature. Clearly, the Viewpoint marker is the strongest predictor of citations. All else being equal, a Viewpoint marker allocates 10 additional citations to a PRL paper within 1 year of publication, and 44 citations within 5 years. The second strongest predictor of citations is Research Highlights in Nature. The third strongest predictors are Research Highlights in Nature Physics and Editors' Suggestions; and after that, Synopses and Covers**.** (The coefficients of News & Views in Nature Physics or Focus papers lack statistical significance.) We thus observe the following stratification of citation accrual:

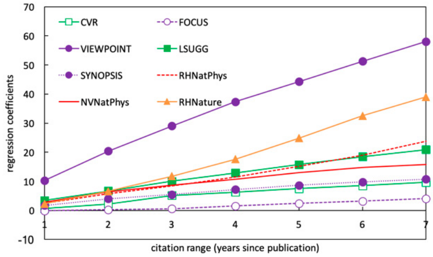

Figure 1. Coefficients of multiple linear regression for each highlighting platform.

$$\text{Viewpoint} > \text{RHNat} > \begin{cases} \text{Suggestion} \\ \text{RH NatPh} \\ \text{N\&V NatPh} \end{cases} > \begin{cases} \text{Synopsis} \\ \text{Cover} \\ \text{Focus} \end{cases} \quad (1)$$

Eq. (1) shows also a hierarchical pattern of decreasing scrutiny regarding importance during peer review. Viewpoints and Editors' Suggestions are internal highlights, for which the editors have the full benefit of peer review. Between these two, Viewpoints are vetted more, since they are discussed both among PRL journal editors and in a committee of Physics editors who seek further advice from experts on whether a Viewpoint is warranted. Synopses, Focus and Viewpoints are mutually exclusive, and since Viewpoints receive the highest level of scrutiny, Synopses and Focus articles are vetted less for importance. Research Highlights in Nature or Nature Physics, and News & Views in Nature Physics are all external highlights, which makes their selection more challenging, since their editors do not normally have access to the peer review files from PRL to aid their decisions. These journals are also more constrained in terms of space since their highlights cover several journals, and, for Nature, several fields. So, it makes sense that these platforms show a weaker prediction of citation accrual than Viewpoints, which receive the highest scrutiny among all platforms studied here. Finally, the difference in citation advantage between Research Highlights in Nature and Nature Physics may be because Nature is more selective than Nature Physics since it covers all fields of science.

The citation advantage of a Cover article, while statistically significant, is small. All else being equal, placement in the PRL cover adds no more than 1.5 additional citations per year. Thus, accidental or serendipitous publicity (recall that covers are chosen for aesthetics mainly) brings a small citation advantage, in direct analogy to the effect of visibility bias reported by Ginsparg and Haque (2009), for papers that accidentally end up in the top slot of the daily arXiv email listings. However, the citation advantage is clearly greater when publicity is deliberate and results from an endorsement of the paper's merit formed through peer review, as in a Viewpoint. So, publicity alone does help in terms of citations, but does not make a big difference unless it is supported by an endorsement, formed through peer review, that the paper has above-average merit.

Citation medians

We can also compare medians. In Figure 2 we show the annual median citation advantage for each highlighting platform. These results confirm our findings from multiple linear regression analysis.

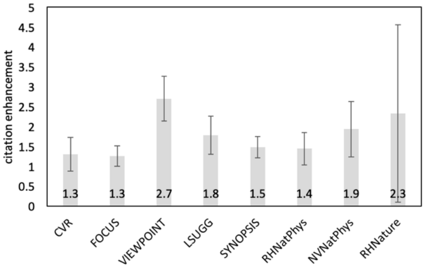

Figure 2. Annual enhancement of median citations per highlighting platform compared to the PRL journal. Publications from 2008–2018. Citation range 1–9 years after publication. Error bars at 99% confidence interval.

Clarivate list of highly cited papers

Can we use highlighting markers as predictors of a paper being *highly* cited? This question takes us beyond the previous analysis, since placement of a paper in a highly cited list is identifying extreme, not average, citation performance. As a benchmark for highly cited papers, we use the Highly Cited Papers (HCP) indicator of Clarivate Analytics. These papers are at the top 1% cited in their subject per year. We downloaded the list of HCP papers in physics published from 2010–2018, among which there are 1371 PRL papers. In Table 1 we show how well each platform predicts placement in the HCP list, i.e., how often highlighted papers are highly cited, which is the positive predictive value, or precision. The hierarchical pattern of Eq. (1) is thus reproduced. Again, we find that highlighting for importance correlates with citations—even for the extreme case of top-1% cited papers.

Table 1. Summary statistics for the precision (positive predictive value) of each platform in identifying highly cited papers.

Highlight	Count	Precision
CVR	446	0.099
FOCUS	378	0.063
VIEWPOINT	638	0.290
LSUGG	3269	0.143
SYNOPSIS	1117	0.117
RHNatPhys	116	0.164
NVNatPhys	33	0.121
RHNature	109	0.239

Conclusions

Our key conclusion is twofold. First, highlighting for importance identifies a citation advantage. Accidental or serendipitous publicity (i.e., mere visibility), gives a clearly smaller citation advantage. Second, the stratification of citations for highlighted papers follows the degree of vetting for importance during peer review. This implies that we can view the various highlighting platforms as predictors of citation accrual, with varying degrees of strength that reflect each platform's vetting level. More details are provided in Antonoyiannakis, 2021.

Introduction

Complexity sciences as a scientific field is an attractive domain that has not been deeply explored by scientometricians. Pollack, Alder & Sankaran (2014) offered evidence on Complexity Theory applied to research in Mathematics and Computer Science, and its growing application on management and organizational problems. Thomas & Zaytseva (2016) developed a more ambitious work, which analyzed approximately 1400 working papers published by Santa Fe Institute, describing the thematic evolution of Complexity research during the period 1989-2015, concluding that it is an intensely interdisciplinary field. The current work assumes the same institutional approach. The main aim is to characterize research developed by the Center for Complexity Sciences (C3) of the UNAM, according to the following questions: Which are the characteristics of mainstream research developed by C3? How does the international scientific community perceive this research? How multidisciplinary has this research been?

Materials and Method

Web of Science Core Collection (WoS) and InCites (supported by Clarivate Analytics), was used as the data source, covering ten years (2010-2019). Search strategies to identify entries for C3 and other eleven Complexity Sciences centers were developed, using the fields "Author Address" (AD) of the database. C3 output was characterized using bibliometric indicators provided by InCites, and multidisciplinary measures based on WoS subject categories (WCs) (Arencibia-Jorge, Vega-Almeida & Carrillo-Calvet, 2021). Self-Organizing Maps (SOM) were constructed using the software ViBlioSOM 2.0, developed at the UNAM. Key-words co-occurrence network was visualized in VOSviewer, developed at the Leiden University.

Results and Discussion

C3 research explores the Complex Systems, focused on strengthening links between science and society. Researchers at C3 usually came from other Faculties or Institutes at the UNAM, and they converge in C3 projects to develop interdisciplinary research. Their WoS output is in growth (432 documents; 13% of annual growth rate), with a remarked effort to publish their research results in high visible journals. H index was 29, showing averages of 8 citations per paper, 312 citations per year, and around 10 authors per article. Citing articles (2,466) came from 102 countries (headed by the United States 26.9%, China 11.9% and the United Kingdom 11.7%), published by 1,198 serials. Citing articles from Mexican institutions only constituted 14.5%. The evolution of C3's multidimensional performance profile (Figure 1) allowed us to confirm the strong publication activity during the last three years (dark/red zones in the graphs at the right side expressed intensively). The main efforts to publish articles in high visible journals (Q1) were observed during the first half of the decade, a period also characterized by an intense activity of international collaboration. The highest values of normalized impact were observed in 2019, which were related to a higher percentage of articles among the most cited publications (Top 10%).

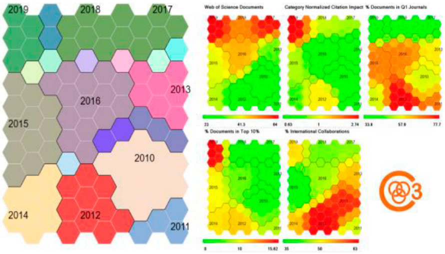

Figure 1. Evolution of C3's multidimensional performance profile (2010-2019).

The international collaboration of C3 (49.8%, with the participation of 98 countries from all continents) has been developed without avoiding the necessary links with Mexican institutions inside (22.4%) and outside the UNAM (27.8%). National collaboration was established with 56 institutions, particularly intense with the educative and health sectors.

The scientific production of C3 was published in 248 serials, covered by 74 research areas (48.7% of WoS research areas) and 105 WCs (41.2%). On the other hand, citing journals belong to 124 research areas (81.6%) and 196 WCs (76.9%). This confirms the diversity of research lines on which the C3 research is influencing. If we analyze the WCs core in articles (Thematic Concentration of production, TCp) and citing articles (Thematic Concentration of citations, TCc), researchers at the C3 published 80% of articles in 29 WCs, receiving 80% of citations from 37 WCs. This implies a Thematic Dispersion Index (TDI) of 32.8 (Figure 2). Compared with some of the most important international institutions dedicated to the study of complex systems, TDI of C3 was much higher than the rest.

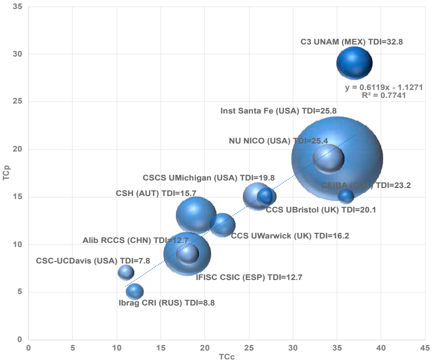

Figure 2. Multidisciplinarity of 12 international centers specialized in complex systems.

The keyword co-occurrence analysis confirmed that research's multidisciplinarity is a significant characteristic of C3, which is expressed by its seven main research fronts (Figure 3). The study of the dynamic of complex systems, gene regulatory networks, biology of systems, innovation, ecology, biodiversity or climate change, using computational intelligence and self-organizing models, with a set of socially-oriented challenges and goals, have been a characteristic of the Mexican institute, which requires a holistic vision and a quite ambitious strategy. This strategy was supported mainly by national funding (more than 50% funded by UNAM, 45.8% by national agencies, and only 30% by international agencies), a distinctive characteristic of C3 regarding the rest of studied international centers. C3 agreements and projects put the focus of C3 not only in mainstream science, but also in solving problems inherent to a country like Mexico, with serious health and mobility problems given its high population density, a huge social gap that generates the risk of internal crises (migration, corruption, violence), a rich ecosystem full of protected species and important natural resources, and a constant exposure to emergencies caused by hurricanes, earthquakes and volcanoes.

Figure 3. Research fronts identified in the C3 scientific output (2010-2019).

Conclusion

Since its foundation, C3 has promoted and integrated multidisciplinary academic groups to collaborate on large projects and face national challenges from the perspective of complex thinking. Scientists, artists, humanists and technicians were linked to C3 to address transdisciplinary challenges of national relevance, taking advantage of the synergy resulting from the interaction between different knowledge areas. During the period 2010-2019, C3 stood out for the growing output with expansive influences on the international scientific community, and an intense international and national collaboration activity. National funds for research were predominant. The multidisciplinary nature of research was evidenced by the diversity of topics addressed, as well as the variety of fields influenced by the published research.

Acknowledgments

This research was supported by the project "Scientometrics, Complexity and Science of Science", developed at UNAM-C3.

Introduction

Mexican science has frequently been studied from a bibliometric approach (del Río, Russell, & Juárez, 2020; Lancho-Barrantes & Cantú-Ortiz, 2019; Villaseñor et al., 2017). Web of Science (Clarivate Analytics) and Scopus (Elsevier) are the main bibliographic databases used by the vast majority of these studies; and productivity, impact and collaboration have been the most studied variables. However, none of the previous papers have exploited the potential advantages of altmetric indicators; and there is no Mexican research that applies altmetric indices to research evaluation at the macro level using Dimensions, the last of the multidisciplinary bibliographic databases launched on the market. In this paper, Artificial Neural Network (ANN) and Self-Organizing Maps (SOM) are applied to create a scientometric profile, combining productivity, impact and altmetric measures to obtain a multidimensional representation of the Mexican scientific domains. The main aim is to characterize the Mexican scientific production in 22 subject categories covered by Dimensions.

Materials and Method

Dimensions, developed by *Digital Science & Research Solutions* (United Kingdom), was used as data source. Data were retrieved on October 8th, 2020. All the Mexican documents during the period 2010-2019 were identified, using the fields "Location-Research Organization" and "Publication Year". The field "Research categories" was analyzed through the Dimensions Analytics interface. In this field, the scientific output is structured in a classification scheme of 22 major fields and related sub-fields of research and emerging areas, based on the Australian and New Zealand Standard Research Classification (ANZSRC). A battery of indicators for each category were obtained: Publications (Npub), Citations (Ncit), Citations means (Ncit mean), Field Citation Ratio (FCR), Publications with attention (Pub Att) and Altmetric Attention Score (AAS), provided by Dimensions (https://www.dimensions.ai). Other three indicators were calculated: Activity Index (AI) (Frame, 1977); Attractivity Index (Attract) (Braun and Schubert, 1997); and the Relative Impact (RI), which was calculated to identify the relative impact of Mexico with respect to the world in each research category: Ncit mean $_{\text{Mexico (category)}}$ / Ncit mean $_{\text{World (category)}}$. The same principle was followed for other three Dimensions indicators (FCR, Pub Att and AAS). In all cases, values higher than 1 express a higher performance than the world. To facilitate the representation, a scale of values between -1 and 1 was used (Glänzel, 2000). The 0 value is the position of the world in each research category.

Tables in Microsoft Excel format with primary indicators relativized for each category were processed using a neural network technique. An artificial intelligence method was developed to automatically carry out the characterization of 22 main research categories in which Mexican scientific output is structured (Figure 1), obtaining a multidimensional scientometric map. The data mining procedure is based on the SOM family of neural networks (Teuvo Kohonen, 2013).

22 research categories
Normalize indicators
AI, Attract, RI, FCR, Pub Att, ASS

Figure 1. Methodology for data clustering and visualization using SOM neural networks.

The method was implemented in LabSOM, a program developed at the National Autonomous University of Mexico (UNAM). The SOM neural network was modeled as a two-dimensional hexagonal grid. Each hexagon represents an artificial neuron and, at the same time, a location where data points can be mapped. A nonlinear projection of data into the neural network was developed. During the neural network iterative training, the network learns to project similar patterns into close locations (hexagons) in the 2D map. Similarities between research area performances can be estimated by calculating the ''scientometric distance'' among their multidimensional representations (Villaseñor et al., 2017).

Results and Discussion

Standard bibliometric measures applied to the Mexican scientific output revealed a profuse activity in *Medical and Health Sciences* (24.7% of articles), which was also noted by Lancho-Barrantes & Cantú-Ortiz (2019). However, our study reveals that Mexican physicians' research has similar behavior to the world. The Mexican multidimensional thematic profile was used to compare the Mexican effort with the world ratio in each subject area (Figure 2).

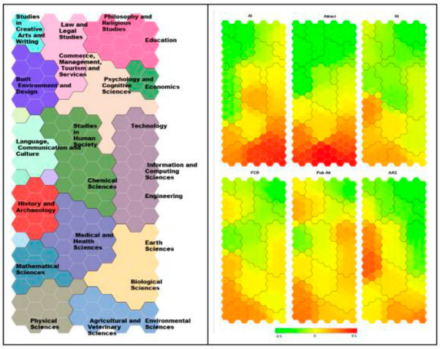

Figure 2. Thematic multidimensional profile of the Mexican scientific output during 2010-2019.

Subject areas were clustered according to the behavior of six indicators. The clusters with a darker color in the density graphs represent the areas in which Mexican scientific production stands out. The thematic areas located in the lower half of the graphs showed a better performance than the world in most of the indicators analyzed. *Agriculture and veterinary sciences* and *Environmental Sciences* experimented the best performance in almost all measures. *Physical sciences* and *Mathematical sciences* also showed values higher than the world, leading the FCR and Pub Att measures. *History and Archeology* achieved relevant citation-based indicators, such as the RI and the FCR, it was also the area with the highest AAS. *Biological Sciences* and *Earth Sciences* completed the number of areas with better national efforts. *Medical and Health Sciences* in Mexico showed values similar to the world; and some disciplines only highlighted using AI (*Chemical Sciences* and *Engineering*), RI (*Language, Communication and Culture*), FCR (*Built Environment and Design*), and Pub Att (*Technology* and *Information and Computing Sciences*).

The fact that Mexican research on *History and Archeology* has shown RI, FCR and AAS values considerably higher than the world average during the analyzed decade should not surprise anyone. Mexican history had strong links with world history before and after the Spanish conquest. Despite the lower AI (Mexican historians publish less than their world counterparts), the impact and altmetric measures expose high-quality Mexican research, relevant to the media. Mexican researchers on *Environmental Sciences* and *Agricultural and Veterinary Sciences* also showed a remarked performance. Particularly, in *Environmental Sciences,* our results demonstrated the Mexican efforts to solve the national environmental problems during the decade. Physics and Mathematics are specialties where Mexico has developed relevant research, which confirmed previous bibliometric reports (del Río, Russell & Juárez, 2020). However, with the solitary exception of *History and Archeology*, humanities and social sciences still showed low performances.

Conclusion

SOM-based science mapping allowed a better comprehension of Mexican research areas during the last decade. *Agriculture and veterinary sciences*, *Environmental Sciences*, *Physical sciences*, *Biological Sciences*, *Earth Sciences*, *Mathematical Sciences* and *History and Archeology* achieved the best bibliometric performances in relation to the world. Altmetric indicators offered an interesting approach that would be seriously analyzed for future research evaluation policies.

Introduction

Multidisciplinary research deals with the work of specialists from different fields in a disciplinary context, without cross its boundaries. If, in this process, researchers integrate knowledge and methods from their disciplines in a new synthetic, coordinated and coherent approach, an interdisciplinary domain emerges. There is a fuzzy line among both contexts, which still is a challenge for scientometricians. Usually, and not without criticism, researchers use a top-down approach dependent on existing classifications schemes to create a knowledge domain's taxonomy (Moschini et al., 2020). This approach assumes that assigning journals to multiple subject categories can be considered to analyze interdisciplinarity (Rousseau, Zhang & Hu, 2019). The study of communication between authors, institutions, documents or citations in these complex networks illustrates the diversity of research areas (Porter & Rafols, 2009; Wagner et al., 2011). This paper uses the Web of Science (WoS) list of subject categories (WCs) as a proxy to measure the multidisciplinary scope of knowledge domains, research institutions and individuals. The main aim is to show a new set of WCs-based bibliometric indicators, which takes into account documents/disciplines and citing documents/influenced disciplines in a new approach to measure multidisciplinarity, demonstrating how elements from different disciplines (and probably inter- or cross-disciplinarity concepts inherent to it) are present in the scientific output of entities and in their spheres of influence.

Materials and Method

WoS Core Collection was used as the data source. We developed two indicators to analyze thematic concentration (minimum number of WCs involved) of publications and citations received by each entity (researcher, institution or knowledge domain). Once the scientific production was retrieved, datasets were refined using WCs, following a descending order, until retrieving a number of documents closer to 80% of the total output. The number of refined WCs is the thematic core that involves the entities' scientific production (Thematic concentration of production, TCp). After that, using the option "citation inform", the total amount of citing documents from each entity was retrieved. Following the previously exposed principle, the set of cited documents was refined using WCs, until retrieving a number closer to 80%. In this case, the number of refined WCs is the thematic core that involves documents influenced by entities (Thematic concentration of citations, TCc).

Setting 80% as threshold reduced size-dependence limitations. The assumption that not necessarily a high productive entity, with a wide range of topics studied, implies a high number of WCs in the thematic core, deals with a dichotomy specialization/multidisciplinarity which is quite presented in all cases studied at the macro, meso and micro level. Based on the thematic concentration of documents and citing documents, a new Thematic Dispersion Index (TDI) was calculated, to assess the multidisciplinary scope of research. This measure was calculated using the following formulation:

$$TDI = \sqrt{TCp \times TCc}$$

Values closer to 1 express a high level of specialization or disciplinary concentration. Higher values will determine, in a growing way, the multidisciplinary scope of research. At macro level, we organized our units of analysis in three datasets, according to the following search strategies: a) TS="Solar flare*"; b) TS="Ethnomethodol*"; c) TS="Artificial intelligence", during the period 1970-2019. Results at meso level (eight research institutes belonging to the UNAM) and micro level (Members of the researcher staff of the Complexity Sciences Center (C3) at the UNAM) were also discussed.

Results and Discussion

Although each macro-level dataset showed exponential growth of scientific output ($R^2 > 0.9$) and linear growth of WCs involved ($R^2 > 0.9$), TCp, TCc and TDI calculated for the 5-year stages during the whole period showed a different behavior (Figure 1).

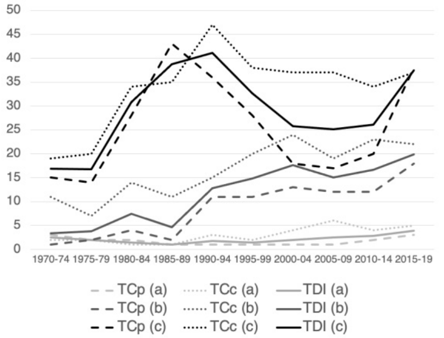

Figure 1. Multidisciplinarity measures applied to a) solar flares, b) ethnomethodology, and c) Artificial Intelligence.

Research on "solar flares" was highly productive (293 to 1839 documents per stage) but showed the classic disciplinary behavior (Astronomy and Astrophysics), with less than five WCs involved in 80% of papers and citing papers. Research on ethnomethodology was less productive (14 to 626). Still, a growing trend was observed in the WCs core during the whole period, putting in evidence the gradual transition from a very specialized topic of Sociology (1970-1989) to a transversal methodology used by linguists, psychologists, physicians and professionals in the fields of management, communication, business, computer science, or even Library and Information Science (LIS). Finally, documents on "Artificial Intelligence" (60 to 24828 documents per stage) showed a seesaw behavior, which could be related to epistemological highlights within the field. After an initial expansion of topics studied (1970-1994), research evolved to a "paradigmatic" phase of development (1995-2009), and then to a re-configuration of the discipline as a technoscience (2010-2019), involving an explosion of technological solutions for productive systems (Arencibia-Jorge et al. Manuscript under review).

At the institutional level, multidisciplinary patterns in research activities from eight research institutes of the UNAM were identified. Two of them stood out above the others: C3 (TDI = 32.8) and the *Instituto de Investigaciones sobre Matemáticas Aplicadas y Sistemas* (IIMAS, TDI = 32.9). In the first case, the study of the dynamic of complex systems, gene regulatory networks, biology of systems, innovation, ecology, biodiversity or climate change, using computational intelligence and self-organizing models, requires a holistic vision that can only be possible through the adoption of a multidisciplinary perspective. In the second case, the transversality of research is an implicit characteristic of the institute. At the micro level, C3 high productive senior researchers were studied, which include Physicists (40%), Biologists (22%), Physicians (12,5%), mathematicians, engineers, chemists, one computer scientist and one information scientist. The diversity of the staff composition and the complex nature of the studied problems were clearly revealed by TDI values, which were higher than 5 in 69% of cases and even higher than 10 in the 34% of cases. Therefore, even at the individual level TDI offered optimal values to assess multidisciplinary research.

Conclusion

The proposed WCs-based measures helped determine the multidisciplinary scope of research at different aggregation levels. Despite the limitations of classification schemes, the new approach used the Pareto principle to obtain a less size-dependent WCs core (not affected by productivity or impact), which allowed characterizing the thematic dispersion of research developed by entities at the macro, meso and micro level. In each of the analyzed datasets, 80% of published documents and citing articles represented the main research lines produced and influenced by an entity. This basic approach could be complemented with diversity measures, which could identify the levels of knowledge integration in the research fronts in greater depth.

‘Larks’ and ‘Owls’: More on Eliciting Human Moods and Chronotypes from Psychometric Variables in Twitter Data

Aparna Basu

aparnabasu.dr@gmail.com

Introduction

Of late, there is increasing interest in Altmetrics, that is, measures of informal mentions of research papers in social media, such as blogs, Facebook, news, Twitter etc. These entities are like citations to scientific papers, but have distinct characteristics. In twitter data one can look at citation contexts or content words. This can give a clue to the mood of the writer (positive or negative). Unlike citations, tweets are subject to variations in time. We re-analyse here the diurnal variation of a sample of tweets studied by Dzogang et al. (2018) and its interpretation in terms of human moods. According to the authors, the variation in the mood of the tweets showed that people were more positive in the mornings, but had more depressive thoughts at night. Our objective is to show that one can re-interpret the same data and analysis to obtain a completely different result. According to our interpretation, human beings can be classed as early risers or ‘larks’ and late risers or ‘owls’. Positive mood is more strongly associated to the ‘larks’ and Negative emotions to the ‘owls’. This makes interesting inroads into psychology and sleep patterns in humans, bringing into the argument the evolutionary reasons for varying sleep patterns.

Background, Data and Methods

Data

Dzogang, Lightman and Cristianini (2018) performed a large scale experiment with 800 million tweets from urban centres in the UK, collecting data over 4 years. Tweets were anonymised. The data was sampled every hour during the day-night cycle. A fairly stable diurnal (day and night) variation of tweet intensity was observed. It was also observed that the all words were not evenly distributed in time.

The analysis was performed in 3 stages. (1) Data collection and anonymisation, (2) Text Analysis/ Sentiment Analysis and (3) Factor Analysis.

Text Analysis/ Sentiment Analysis

In this stage, the words in the tweets were linked to the corresponding ‘mood’ that they expressed, based on a standard source, the text analysis program Linguistic Inquiry and Word Count. Words of positive affect were linked to emotions such as enthusiasm, delight, activeness and alertness – or of negative affect - like fear, guilt, anger, disgust. This process is also known as sentiment analysis

Factor Analysis

Factor analysis was performed on the ‘mood’ associated with the tweet words and their diurnal variation was noted. It brought out two principal factors F1 and F2 in the data which showed distinct diurnal variation, and explained 85% of the variability in the original data. Moreover, they loaded differently on the mood variables. (Figure 1). Dzogang et al. do not offer any interpretation for the factors F1 and F2.

Dzogang’s conclusions

Dzogang et al. state, “Overall, we see strong evidence that our language changes dramatically between night and day, reflecting changes in our concerns and underlying cognitive and emotional processes.”

It implies that the same person instinctively expresses different emotions during different times. What is more, all persons follow the same pattern. Human emotions vary in a cyclical way according to the circadian rhythm, being more positive in the morning and more negative towards evening.

Sleep, ‘Larks’ ‘Owls’: The Sentinel Hypothesis

In the entire discussion, no account seems to have been taken of sleep time when at least part of the population would be inactive. What is missing is the proper place and role of sleep.

Sleep is essential for survival, yet, for animals, it also represents a time of extreme vulnerability to predation and environmental dangers. The sentinel hypothesis proposes that group-living animals share the task of vigilance during sleep, with some individuals sleeping while others are awake. Asynchronous sleeping habits among members of a group, confers an evolutionary advantage, In modern populations asynchronous sleep or the existence of chronotypes may represent a legacy of natural selection acting to reduce the dangers of sleep (Samson, 2017; Beauchamp, 2015; Randler, 2014).

The Sentinel Hypothesis was originally proposed by Frederick Snyder. According to him, “*Man and other animals have learned that under conditions of danger it is safe to sleep only if sentinels ate*” (Snyder, 1966) The tendency to have asynchronous sleep patterns among individuals has been noticed in present human society as well as a legacy of our evolutionary past. Those who rise early, or go to bed late, have been typified by the term chronotype, or Larks and Owls respectively.

Our Interpretation

The factors F1 and F2 discussed earlier represent only the active part of the population and not the part that is asleep. F1 is shifted from F2 by a few hours on the time axis (Figure 1). From the sleep times, we can infer that F1 will correspond to early risers, the Larks, and F2 to the late risers or Owls (see Figure 1). The following description shows that one could also associate cognitive and emotional traits to the Larks and Owls based on the experiment.

"*The first had peak expression time starting at 5am/6am, it correlated with measures of analytical thinking, with the language of drive (e.g power, and achievement), and personal concerns. It is anti-correlated with the language of negative affect and social concerns. The second factor has peak expression time starting at 3am/ 4am, it correlates with the language of existential concerns, and anti-correlates with expression of positive emotions*". (Dzogang et al., 2018)

Discussion

We give an alternative interpretation to the diurnal variation of tweet words in the experiment (Dzogang et al., 2018) by including the role of sleep as a constraint in sending out tweets. We see that tweet data can be used in different ways than just mapping trends or as a proxy for citation. The present example includes sentiment analysis to deal with the psychology of tweeterss. Some advantages of using tweet data is the massive data size, but even more importantly that it is non-invasive, in real time, and does not require people to recollect details as in the case of data collection with questionnaires.

Our re-interpretation of Dzogang's experiment with 800 million tweets gives empirical evidence that we have a binary population of humans with different cognitive characteristics and emotional behaviours, and distinguished by their sleep characteristics, viz. the larks and the Owls.

One might end with just one word of caution. Much of the vocabulary associated with behaviour, cognition or emotion are value loaded (say, positive and negative affect) and one could easily have a situation where people are discriminated against for some intrinsic qualities left over from evolution. The present working day and working hours and its demands, for example, would be quite unsuitable for Owls. The same would be true for Larks on night shifts.

Introduction

Citation networks is a central element in Science of Science (Fortunato et al., 2018). Methods to construct and analyze such networks play a pivotal role in understanding how science is organized and unfolds. With the advent of freely available and comprehensive scholarly datasets, comes the need for techniques to select and extract subsets of records that are particularly meaningful. A common example of that is building citation networks from records associated with a specific knowledge area. One way to accomplish that is by matching publications titles and abstracts against a set of query terms.

Among the most interesting characteristics of citation networks are their community structure. In Silva et al., 2016, community detection was employed to build a hierarchy of topics that can be used to summarize a subset of the scientific literature. This technique was further improved in Ceribeli, de Arruda & Costa (2019), in which a multiscale representation of the communities was considered. However, the choice of the query terms may directly impact the constructed network and consequently its community structure. For instance, suppose a community *A* in a citation network acts as a bridge between two other communities *B* and *C*. In the case such a community has only records recovered from a single search term, B and *C* can become completely disconnected. In other cases, the terms may have a reasonable number of overlapping records that may lead to no significant changes when terms are omitted.

In this paper, we propose an approach to better understand the effects of the initial selection of query terms. In particular, we explore how the community structure of a citation network is affected when some query terms are omitted from the data retrieval and network construction steps. Furthermore, here we test the methodology for a large citation network obtained from the *Microsoft Academic Graph* (MAG) (Sinha et al., 2015) by using a set of query terms related to Machine learning. Preliminary results indicate that the community structure for this network is robust to changes in the set of query terms.

Employed network

As described in (Silva et al., 2016), a network for a scientific field is retrieved from records that match (or contains) a pre-defined set of search terms (keywords), which is employed to limit a given scope to the desired field. Here, we retrieve all documents from the MAG (obtained in 2020) that contain at least one of the keywords in its title or abstract. To create the network, each retrieved document is considered as a node, and the directed edges are created from the citations between them. So as to eliminate undesired documents, only the weakly major connected component is considered. One example of the employed network is illustrated in Figure 1.

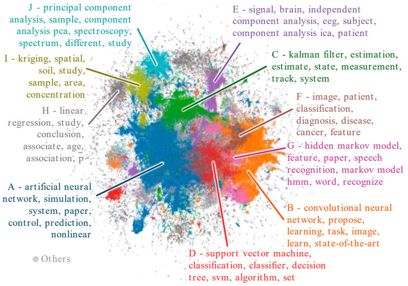

Figure 1. Visualization of the network nodes, where the positions were defined by node2vec and UMAP projection. The detected communities are represented by colors.

Employed methodology

By considering the network described in the previous section, the communities are detected. As in (Ceribeli, de Arruda & Costa, 2019), we use the *Infomap* algorithm (Rosvall, Axelsson & Bergstrom, 2009), which is often considered in science of science applications. From the detected communities, we obtained the subjects (Silva et al., 2016).

In order to test the robustness of the employed methodology, we compare the network obtained from the entire and reduced sets of keywords. The latter type is henceforth called *modified network*. Because the subject identification approach is based on the community structures, we compare the communities identified in the complete and modified networks. More specifically, for each comparison, the Normalized Mutual Information (NMI) is calculated.

Results and discussion

We illustrate our methodology by considering a set of keywords in the field of artificial intelligence. Fig. 1 shows the obtained network, in which colors represent communities. The identified subjects are also shown. Here, the modified versions consist of networks obtained with reduced sets of keywords. For the sake of simplicity, each of the reduced sets corresponds to the entire set minus a single keyword. Documents containing a removed keyword kept in the network if they contain another keyword in the reduced set. Fig. 2 illustrates the obtained NMI and the number of vertices of the networks normalized by the complete network size.

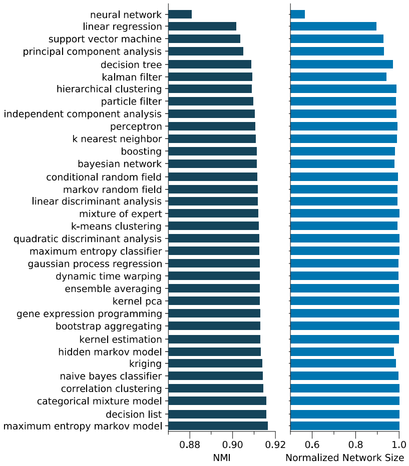

Figure 2. NMI and the normalized network sizes of the comparison between community organizations of modified and complete networks.

The results were found to indicate good stability in terms of the networks' community organization. By comparing the standard deviation of the NMIs (0.006) and the normalized sizes of the modified networks (0.075), we found that the variation of NMI is the lowest. The worst-case scenario was NMI = 0.88 (removal of the keyword "neural network"). This case also corresponds to the smallest obtained network, with 508.027 nodes (56,6% of the complete network size). Even with a drastic reduction of the network size, the community structure was remained stable, as indicated by the high value of NMI.

Conclusions

A citation network was obtained by considering the MAG dataset and a given set of machine learning keywords. The organization of communities was obtained, and the respective subjects were identified. To study the robustness of this methodology, we removed keywords from the original set and compared the original with the obtained networks. The different sizes of the modified networks reveal that the deletion of some keywords can remove a substantial number of scientific documents. However, for the remaining documents, the original community structure tends to be preserved. These results illustrate that missing query terms used to delineate a field may not have huge impact to some network analyses.

Extracting Sentences Concerning Research Results of Citations from Full Text of JASIST

Jiaxin Bian[1], Si Shen[2] and Dongbo Wang[3]

{[1] 120107222870, [2] shensi}@njust.edu.cn
Nanjing University of Science and Technology (China)

[3] db.wang@njau.edu.cn
Nanjing Agricultural University (China)

Introduction

The related work part of an academic paper usually contains a summary of previous studies. These sentences generally appear in the second part of academic papers, and are of great significance for quickly understanding research results in a specific field and discovering research hotspots. However, considering the sparseness of the sentences related to the research results of citations and the time-consuming of reading the literature, it is particularly important to extract and analyze the sentences related to the research results of citations. So far, the research on the extraction of academic full text content has only reached the stage of using regular expression for the extraction. For example, in the work of Wang and Zhang (2020) an algorithm dictionary based on manually annotated paper content was constructed, and sentences containing algorithms were extracted through dictionary-based matching methods, and the impact of algorithms mentioned in academic texts was analyzed. In order to fill this gap, this research adopts a deep learning method to extract sentences related to the research results of citations from the academic full text, and verifies the effectiveness of this method. Then in order to make deeper research at these sentences, clustering experiments were carried out on the academic full text and three types of sentences concerning the research results were identified.

Data Set and Method

Data were collected from full-text articles from JASIST (2017-2020). From 2017 to 2020, a total of 502 papers were retrieved. We annotated the experimental results and conclusions in the citation sentences of academic texts. For example, the sentence "In Egghe and Rousseau (In press), we proved the following results for the moveout Lotka function, extending similar results for the Classical case." was labeled as the research results of citations. The labelling tool is the BRAT platform. After annotation, there are 6,083 sentences concerning research results of citations in these papers. And the specific information of the corpus is shown in Table 1.

Table 1. Basic Information of Corpus.

Num.	Type	Count
1	Papers	502
2	Total Sentences	138,197
3	Research Results sentences	6,083
4	Marked sentences in each article average number	12.12
5	Average words number in each sentences	31.88

The BERT model used in this paper is a pre-training model, which is implemented based on a bi-directional Transformer Encoder (Devlin et al., 2018). Our experiment was trained on the BERT-base Cased version.

In this paper, NVIDIA Tesla P40 graphics processor (GPU) was used for neural network training. The performance parameters of the computer used in the experiment are as follows:

Table 2. Basic Information of Experimental Environment.

Hardware Name	Performance Parameter
CPU	48 Intel(R) Xeon(R) CPU E5-2650 v4@2.20GHz
Memory	256GB
GPU	6 PCS NVIDIA Tesla P40
Video Memory	24GB
Operating System	CentOS 3.10.0

Results

In the training of BERT model, the pre-training model with 12-layer, 768-hidden and 12-heads was chosen, and then 10-fold cross-validation tests were performed, and evaluated by P, R and F values. The evaluation results are shown in Table 3.

It can be seen from Table 3 that the maximum Macro-AVG F-value of the Bert model classification result is 75.11%, which is lower than 61.02%, the Macro-AVG F-value of the SVM model we used before. The experimental results of the SVM model are shown in Table 4.

Table 3. Results of 10-Fold Cross-Validation on BERT.

Num.	Research Results Sentences F-value	Non-Research Results Sentence F-value	micro-AVG F-value	Macro-AVG F-value

AVG-F	15.50%	95.00%	55.88%

A comparison of Table 3 and Table 4 shows that the training effect of the BERT model is significantly better than that of the SVM model, which proves the applicability of the BERT model in extracting sentences concerning the research results of citations. Then, in order to further mine the sentence information related to the research results of citations, the K-Means model was used to cluster the sentences. The result is shown in Figure 1.

As can be seen from the figure above, the research result sentences of citations extracted from the academic full text are divided into 3 types, each of which is represented by different colours. The emotion of citing is often the judgment of subjective emotion, which can reveal the author's attitude towards the citation. Therefore, on the basis of the above clustering experiment, this paper divides the sentences into support, opposition and neutral according to their emotional tendencies.

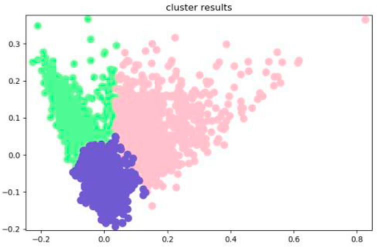

Figure 1. Graph of sentence clusters in JASIST academic full texts.

Conclusion

This paper explores the academic full text corpus. The BERT model was used to automatically extract the sentences concerning research results of citations, and the maximum harmonic mean reached 75.11%. Compared with the extraction effect of the previously used SVM model, it proves the superiority of the BERT model in the automatic sentence extraction task of the citation research results. Then, on the semantic level, K-means clustering was used to divide these sentences into three types according to their emotional tendencies, namely, support, opposition and neutral. This research filled the gaps in the research of methods to extract sentences concerning research results of citations from the academic full text, which provides a basis for further classification of such sentences.

Shifting the ARWU methodology to Q1 journals: what are the consequences for lower-tier universities?

Srđa Bjeladinović[1], Veljko Jeremić[2] and Mladen Stamenković[3]

Introduction

Academic Ranking of World Universities (ARWU) represents one of the most renowned universities' ranking lists (Safón, 2019). Throughout the years, it has been revised to a minor extent to address some of the critiques (Mussard & James, 2018). The majority of effort from the ARWU creators were oriented towards diversification of the ranking lists offered. Thus, several lists emerged, such as the Global Ranking of Sport Science Schools and Departments, ARWU-FIELD and Global Ranking of Academic Subjects (ARWU, 2021). The ultimate one gained much of the attention, with 54 subjects presented in the 2020 edition. The major shift in methodology consisted of including solely Q1 (ranked in the first quarter according to their respective JCR category - Sorz et al., 2020) journals in the 2020 edition. The shift in methodology catalysed the rapid decline of ranks for numerous lower-tier universities, including the University of Belgrade (UB). In the 2018 edition, the UB was among the best universities in as many as 27 of the 54 scientific research areas. In 2020, the change in methodology had led to the University of Belgrade being positioned within 12 scientific research areas (Jeremić & Stamenković, 2020). Having this in mind, we wanted to explore the effects on lower-tier universities when potentially switching PUB score (based on Articles published in SCIe and SSCI journals) to Q1 score (taking into account solely Q1 journals) in major ARWU Rankings published each August 15th.

Methods and Data

As a case study, we obtained the data containing WoS indexed Articles (SCIe and SSCI indexed journals, Q1 journals, year of publication 2019) published by researchers from the selected universities. In total, ten universities are selected, seven universities (*University of Belgrade*, three universities from China: *China University of Mining and Technology – Xuzhou*, *Lanzhou University* and *Nanjing Medical University*, and three universities from Brazil: *Federal University of Minas Gerais*, *Federal University of Rio Grande do Sul* and *Federal University of Rio de Janeiro*) from the cohort of Top 401-500 Universities with similar PUB score and three universities (*Princeton University*, *California Institute of Technology* and *Swiss Federal Institute of Technology Lausanne*) from the Top 100 with the ARWU 2020 PUB score similar to previously mentioned seven universities.

Results

In total, 34,156 papers were scrutinised. As we can see from Table 1, *Princeton University*, *California Institute of Technology* and *Swiss Federal Institute of Technology Lausanne* lead the field with the percentage of papers published in Q1 journals. Although in official ARWU rankings, their score is similar to the seven remaining analysed universities for the PUB indicator. If we narrow down selecting SCIe and SSCI journals to Q1, the difference between universities is widened.

Table 1. Percentage of papers published in Q1-Q4 journals by the researchers from the observed universities

University	Q1	Q2	Q3	Q4
Belgrade	34.39	25.91	17.14	22.57
California	71.49	23.01	4.52	0.98
Lanzhou	50.92	28.28	12.40	8.40
Lausanne	65.85	24.32	7.55	2.28
Minas_Gerais	33.96	30.21	19.84	15.99
Nanjing	32.42	32.20	24.08	11.30
Princeton	68.87	22.30	6.68	2.15
Rio_de_Janeiro	37.39	30.87	19.58	12.16
Rio Grande_do_Sul	36.73	28.08	21.14	14.04
Xuzhou	40.20	26.28	21.80	11.73

Chinese universities (*Xuzhou* and *Lanzhou University*) exhibit excellent results that are aligned with the findings of Gao and Li (2020), which outlined that in 2018, the total number of papers published by Chinese colleges and universities in JCR Q1 journals exceeded 51,000 – an increase of about 18.6% over the year 2017. Brazilian universities are underachieving, with a considerable percentage of papers being published in Q4 journals that is aligned with the previous study (Mcmanus et al., 2020).

Furthermore, between the remaining seven universities, one can notice a significant difference ($p < 0.001$) in performance, with the *University of Belgrade* underperforming with 22.57% of the papers in lowest-ranked Q4 journals. If we dig a bit deeper (Table 2), we can witness many papers from the UB researchers being published in Serbian Q4 journals. Sadly, the trend continues with the similar findings presented in Zornic et al. (2014), Pilčević et al. (2018, 2019), with most of the papers from UB researchers being published in low-tier journals.

Table 2. Journals with the most considerable portion of papers published by the researchers from the University of Belgrade

Journal	Papers	%
VOJNOSANITETSKI PREGLED	94	2.7
SRPSKI ARHIV ZA CELOKUPNO LEKARSTVO	64	1.9
JOURNAL OF HIGH ENERGY PHYSICS	63	1.8
EUROPEAN PHYSICAL JOURNAL C	50	1.5
PHYSICS LETTERS B	44	1.3
ARCHIVES OF BIOLOGICAL SCIENCES	41	1.2
JOURNAL OF THE SERBIAN CHEMICAL SOCIETY	41	1.2
PHYSICAL REVIEW D	41	1.2
THERMAL SCIENCE	41	1.2

Conclusion

The potential inclusion of Q1 journals in ARWU methodology is not expected to trigger changes in the Top 100 tier. However, it will have profound consequences for lower-tier universities such as the University of Belgrade. Although the decline in ranking will be perceived negatively by the general audience, it can also serve as the catalyst of change and shift attention to researchers with admirable Q1 performance and consequently provide better support for their scientific endeavours. One of the potential directions for Universities' authorities might be including financial and other incentives for the publications in Q1 journals. Also, UB included SCIe and SSCI journals as a mandatory requirement for tenure back in 2008. Thus, one potential direction for UB' leaders might be strengthening the role of Q1 journals in academic promotion. In the future, this study could emphasise UB researchers who excel, which would contribute to the growing need to map excellence within the academic staff (Ioannidis et al., 2020; 2021).

Measuring Concentrations of Research Funding: A case of The Czech Science Foundation (GAČR)

Jiri Bures

bures@flu.cas.cz
Institute of Philosophy of the Czech Academy of Sciences, Jilská 1, 110 00 Praha (Czech Republic)

Introduction

In a comprehensive overview of current research on research funding, Aagaard et al. (2020) conclude that the subfield lacks a systemic approach to the analysis of funding concentrations. Independently, Katz and Matter (2020) applied established indices of wealth concentration (Gini coefficient, Palma ratio) to observe the distribution patterns of grants originating from *The National Institute of Health* (NIH). In this study, we respond to Aagaard et al. call for more empirical studies and precision in measuring funding concentrations by following the methodology established by Katz and Matter.

The Czech Science Foundation (GAČR) was founded in 1993 and is the largest public, multidisciplinary, basic research funding agency in Czechia. Since 2010, GAČR has covered on average 68 % (± 7.62) of all projects and 51 % (± 18.26) of all funds. Yearly, it provides on average 523 (± 78.1) projects with a success rate of 26.18 % (± 4.18) across all research areas.

Following this context, rationale, and subject, the study answers the question: What are levels of concentrations of funding originating from GAČR?

Data and methods

Data was collected from GAČR's *The Central register of R&D Projects* (CEP). The quality of the subset of projects was assessed using GAČR annual reports (Annual Reports 2021). The discrepancy between data and reports is -0.87 % (± 0.54) across years for projects and -0.83 % (± 1.79) for average size of funds per project. We assess discrepancy as being insignificant.

Following Katz and Matter (2020), concentrations were measured in "cumulative funding" (ibid p. 8), which is a sum of all funding that either principal investigator (PI-level) or organization (O-level) received in a year. Additionally, because GAČR is a multidisciplinary funding agency, grouping by disciplinary superset was applied (STEM, Social sciences, and humanities (SSH)).

After assessing correlations between Gini and Palma indices (figure 1), we have decided to use only the Palma index (following ibid p. 10). Being a ratio between bottom 40 % and top 10 % shares, it is more intuitive and sensitive to changes between bottom and top of population (Cobham et al., 2016).

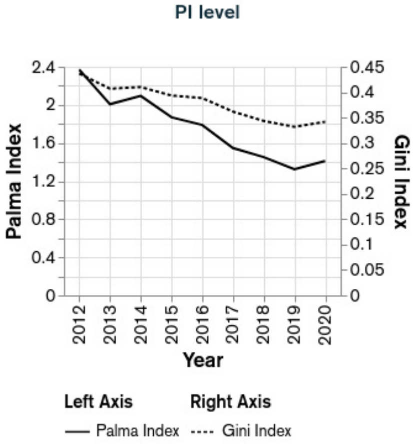

Figure 1. Correlation between Palma and Gini indices on PI-level across all disciplines.

Results

The concentration levels between STEM disciplines and SSH are far less significant than between organizational and PI's level of concentration (see fig. 2 and 3). O-level shows higher levels of concentration with stable development in observed time range, concentration on PI-level shows a decline. The difference between the Palma index is concretized for STEM in 2015 (see fig. 3). We observe that 10 % organizations accumulated 60 % of funding (13 PI), and top 10 % researchers were granted 33 % of funds (2.15 PI) .

Table 1. GAČR and NIH Palma ratio in 2015.

Agency	O-level	PI-level
GAČR*	13	2.15
NIH	~94/124**	~2.1/3.1**

**STEM projects **R and all funds (Katz & Matter, 2020: 8).*

Measured levels of concentrations are similar to those observed by Katz & Matter (2020) (see table 1). Specifically, difference between O and PI levels, as well as slow decline in funding concentration.

For NIH, from 3.5 to 3 for PI-level and from 150 to 124 for O-level.

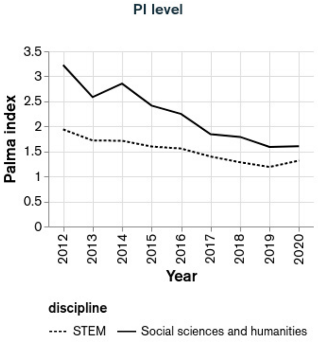

Figure 2. PI- level.

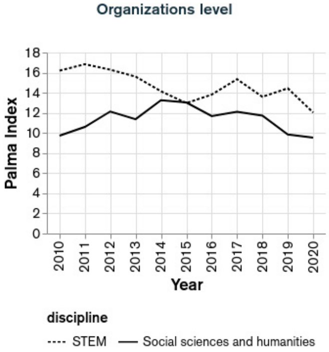

Figure 3. O-level.

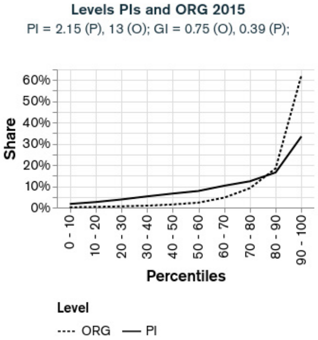

Figure 4. Accumulated share by percentiles of PI-level and O-level grantees in 2015.

Discussion

Two of our observations call for an immediate explanation. Firstly, we have observed a significant difference between concentration levels at O and PI levels. This may be due to the capacity of research organisations to hold not only more grants but also more "expensive" projects. Another reason may be that, unlike organisations, the amount of grants for individual scientists is capped by GAČR policies.

Secondly, we are seeing a similar concentration pattern in GAČR and NIH, especially the downward trend since 2010. For the NIH, this was explained as a response to public reflections about "research elites." A high difference for O-levels can be attributed to a different institutional structure and inaccuracy when comparing all STEM fields and specifically biomedicine (NIH).

Conclusion

This work is research in progress. We have measured levels of concentrations of GAČR's funding system and shown analytical potential of chosen research design. Future work will consist of extending the time dimension, including more agencies and leaving the STEM/SSH dichotomy for a more detailed disciplinary model. In the context of the research area, the study is the groundwork for a systematic approach in measuring and comparing various funding systems. Considering applied methodology, we are concluding that use of the Palma index offers a way to assess structure and change of funding concentrations.

Improving Coupling Metrics with Deep Neighborhood for Local Map of Science

Gaëlle Candel[1,2] and David Naccache[2]

{gaelle.candel, david.naccache}@ens.fr

Introduction

A citation graph is a directed acyclic graph where nodes are documents and links are reference relationships. For scientific papers, the citation graph can be used for multiple purposes: identify the most salient papers which receives a lot of attention from their community; analyze the collaborations between universities (Grauwin, 2011); or build a map of science to identify relationships between scientific areas (Boyack, 2005). The exploration of citation graphs was proposed by Garfield (2004), using similarity metrics between documents. The most used similarity metrics are Bibliographic coupling (BC) proposed by Small (1973) and Co-citation Coupling (CC) proposed by Kessler (1963). These metrics allow us to identify related papers locally. To obtain a larger overview, the generation of a map of science could help identify associated papers' communities.

Distribution over Citation Graph

BC and CC are very simple similarity measures, easy to put into practice. These metrics differ in multiple aspects. BC represents the authors' point of view, while CC represents the crowd's vision of the paper. At publication time, a paper is already coupled to other papers with BC, while uncoupled with any one with BC. Both evolve over time, leading to an increase in the number of related documents. As the number of references is fixed, the BC strength between two papers is fixed, while for CC, this strength can diminish or increase for each new citation received. Additionally, the number of references made by a paper is limited by authors' time and publication restrictions, such as the maximum number of pages allowed. Citations distribution follow a power-law distribution, while references distribution are less extreme. These asymmetries lead to a different outcome depending on which coupling metric is used. We follow the BC approach as it is more stable, and defined for a large majority of papers.

An issue with these types of metric is the graph sparsity. Several factors are leading to this property. *Independent discovery*: For two papers with a very similar idea, one new paper must choose to quote one or the other. *Admitted knowledge*: The community understands certain works so well that there is no longer any need to refer to them, such as principal component analysis. *Visibility*: search engines put the focus on top papers, reducing the visibility of newly published papers. Sparsity impacts reference overlap. For a document coupled with a thousand of documents, the overlap is rarely more than one. For two documents with 20 references each and 2 references in common, the Jaccard similarity score is close to 5%. Changing one coupling reference reduces it to 2.5%. This scoring with the first-order reference makes the score unstable to the reference omission. To limit this problem, documents can be aggregated by journal (Leydesdorff, 2009) or by the institution to artificially increase the number of references (Grauwin, 2011), or documents with insufficient coupling discarded, which drastically reduces the number of nodes and the granularity.

Deep Coupling

To improve coupling metrics, an idea is to look few step ahead to indirect references made by a paper's references. However, the items number grows as a^d, where $a$and $d$are the average number of references per papers and the exploration depth respectively. Metrics based on overlap only would give more credit to ancient knowledge which is not desirable. Instead, the contribution of distant older papers must be discounted. For this purpose, the indirect references $B_a$of $a$are weighted with a Random Walk with Restarts, give the weight $W_c^a$to a node $c \in B_a$. The similarity between two documents is obtained using the Cosine similarity:

$$S^{wc}(B_a, B_b, W^a, W^b) = \frac{\sum_{c \in B(a) \cap B(b)} (W_c^a W_c^b)}{\left(\sum_{c \in A} (W_c^a)^2 \sum_{c \in B} (W_c^b)^2\right)^{1/2}}$$

This measure allows obtaining a similarity score even for documents with no direct reference in common, as long as these documents belong to the same connected component of the graph.

Embedding with t-SNE

TSNE characteristics

TSNE (van der Maaten, 2008) is an embedding algorithm that has received a lot of attention from the machine learning community. This algorithm transforms a distance matrix into a $n \times d$vector, where two items close in the input space are close on the embedding. Items are displayed in a homogeneous scale, leading clusters' size to be proportional to the number of items they contain, allowing the identification of the main groups of interest.

Similarity to Distance

The Deep-BC allows defining the similarity between two nodes, with values in $[0,1]$. A distance metric has the inverse behaviour. The similarity score is simply transformed into distance using the equation $D^2 = (eps + S)^{-1} - (eps + 1)^{-1}$with the epsilon factor, set to $eps = 10^{-4}$ limits the maximal distances between completely unrelated items.

Dataset

We used the DBLP dataset (Tang, 2008), version 12, which contains 4,894,081 papers and 45,564,149 citation links. Documents are tagged, allowing an overview of the paper's topics and sample a subset of weakly related papers. Documents with no reference are discarded as our method cannot measure similarity on it.

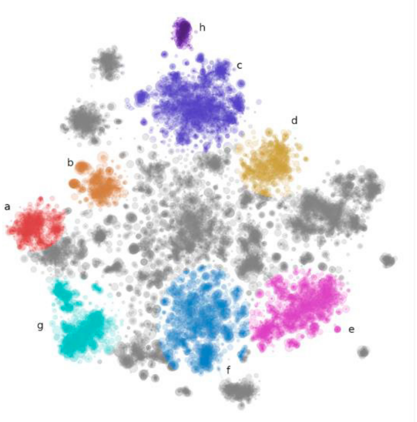

Figure 1. Embedding results for Biometrics. Some groups have been highlighted: a) *Keystroke analysis*, b) *Signature recognition*, c) *Security & Cryptography*, d) *Fingerprint recognition*, e) *Iris recognition*, f) *Facial recognition*, g) *Gait analysis*, h) *Smart card*.

Embedding results

Figure 1. shows the results for the Biometric topic. Dense groups are visually identifiable, each gathering papers from a sub-topic associated (*Iris rec.*) or distant to *Biometry* (Smart card, Security). Topics with similar technology (*Iris rec.*, *Facial rec.*, *Gait analysis* using Image processing; *Keystroke analysis*, *Fingerprint rec.* associated to behavioural analysis) are located nearby. This type of embedding can be easily clustered to extract communities automatically.

Conclusion

We proposed a method to embed a citation graph letting appears documents communities. Our approach is inspired by bibliographic coupling, extended with diffusion. The diffusion gives stability, which allows the preservation of documents with very few references. The embedding with tSNE allows obtaining well-spaced documents, helping to visually identify clusters, which could be used as a starting point for community analysis.

Introduction

According to Merriam-Webster dictionary, women's studies is "the multidisciplinary study of the social status and societal contributions of women and the relationship between power and gender". The advancement of women in scientific and technological activities has been restricted by the structure of the editorial boards of journals in their respective areas. Running a scientific journal as Editor in Chief (EC) or belonging to its editorial board (EBM) is a recognition and honor that indicates advancement in one's career and allows to develop relationships with other colleagues, the formation of new professional networks and greater competence in obtaining resources (Capdeville et al., 2019; Macaluso et al., 2016). Based on previous experiences that reported that women are underrepresented on the EBM in the majority of scientific areas, the purpose of this paper was to examine this representation on the editorial boards in journals in a special scientific area in which women are the majority of contributors: the Subject Category Women Studies of Web of Science Core Collection (WS-WoS) database, analyzing their distribution by gender, countries and quartile. We assume that in this area, the representation of women in these committees should be higher.

Methods

The gender of the EC and EBM of the 45 journals included in 2019 in the subject category WS of the Social Science Citation Index (SSCI) of WoS was analyzed. For the compilation of each journal, its official pages or websites were consulted. For gender assignment of EC and EBM, the statistical package Genderize.io (https://genderize.io) was used, which provides a probability of male or female gender based on a frequently updated database that currently includes greater than 200,000 distinct first names from more than 79 countries and languages. From the data collected, the following indicators were calculated: gender distribution of EC and EBM by journal, publishers, quartile of the journal in JCR and country of affiliation of members. In addition, data on the countries of membership were grouped into three major blocks: United States, European Union and rest of the World.

Results

The total number of editorial members was 1,362. Among the EBM, 1,119 were female (82.16%) and 243 (17.84%) male, and among EC, 69 (92%) were female and six (8%) were male. In five of the 45 journals, all EBM were women. Only two men from the six EC manage a journal as the sole EC, and in the other four journals, a man shared the EC with other women. The EBM and EC belonged to 65 countries. In 28 countries all EBM were women and in 10 countries all EC were women; only in 9 countries were all men. Among the countries with more than 10 members, the highest percentage of women corresponds to France (92.59%), Australia (89.06%) and South Africa (88.24%), and the lowest to South Korea (56%), Brazil (58.33%) and New Zealand (61.54%) (figure 1). The highest percentage of women corresponds to Europe (83.62%); in the United States it is 82.88% and in the rest of the world it is 79.12% (figure 2). In the gender distribution by quartiles of journals in JCR, it is observed that the highest percentage of women occurs in journals belonging to second quartile (84.29%) and the lowest in journals belonging to fourth quartile (79.29%) (table 1).

Figure 1. Percentage of women and men of EC and EBM by countries.

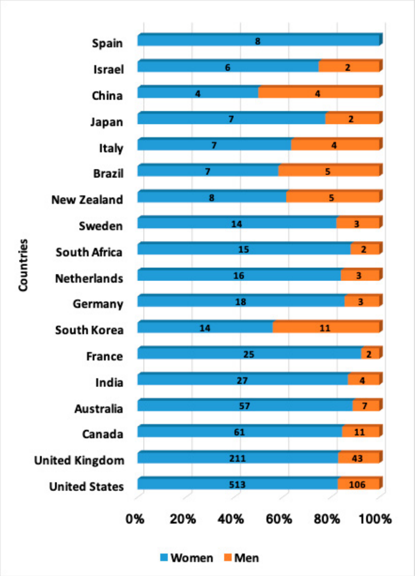

Figure 2. Number and percentage of women and men of EC and EBM by large geographic areas.

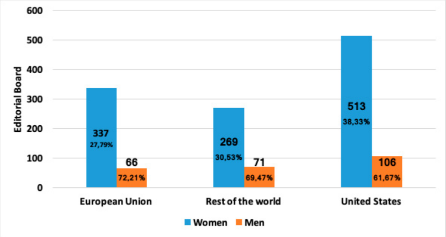

Table 1. Gender distribution of EBM and EC by quartile of journals in JCR.

		EBM and EC				
Cuartile	Nº Journals	Women	% women	Men	% men	Total
Q1	11	284	80.68	68	19.32	352
Q2	11	381	84.29	71	15.71	452
Q3	11	232	83.45	46	16.55	278
Q4	12	222	79.29	58	20.71	280
Total		1,119		243		1,362

Discussion

Previous studies reported a low presence of women on EBM and EC of scientific journals in most areas that does not reflect the gender composition in the corresponding specialties. Is the case, for example, of Medicine (from 1.6% to 41.7%) (Alonso-Arroyo et al., 2021), except for specialties in which women have historically predominated as Nursing, Physical Therapy and other related to Nutrition (lactation and breastfeeding), and General Marketing and Management (22%) (Pan & Zhang, 2013; Metz & Harzing, 2012). However, in the Women Studies area of the JCR, the situation is quite the opposite, since women are better represented in the majority of the journals, in some cases accounting for the total number of editorial members. The high representation of women in the area of WS offers a counterpoint to the structural and cultural conditioning factors which leads to women being under-represented in most of areas, as well as a powerful answer to stereotypical assessments of women's lower qualifications for leadership positions. The reasoning for many of the arguments proposed for the low participation of women in most subject areas is, therefore, insufficient, and the results in the area of WS are proof of this. It confirms that achieving gender equality is, at least in the field of professional and scientific publication, an attainable and solvable objective. Future work could analyze the gender composition of reviewers as a measure of potential future gender diversity, due that potential members of editorial committees are commonly selected from among reviewers.

Differences between using institutional information from curriculum vitaes and publications for tracking scientific mobility

Yu-Wei Chang

yuweichang2013@ntu.edu.tw
Department of Library and Information Science, National Taiwan University, Taipei (Taiwan)

Introduction

According to a review article by Gureyev et al. (2020) and a literature search of the Scopus database at the end of 2020, research on the mobility of researchers has been increasing since 2017. In particular, several studies have employed the bibliometric method—the analysis of publications' bibliographic records including author affiliation information—to track the academic trajectory of researchers in terms of which institutions they were affiliated to during a certain period (Robinson-Garcia et al., 2019; Sachini, Karampekios, & Brutti, 2020). In addition to the bibliometric method, analyzing curriculum vitaes (CVs), which provide a summary of a researcher's academic background and experience, is another nonintrusive method to identify a researcher's institutional footprint (Gureyev et al., 2020).

The bibliometric method requires less effort for collecting and processing data than does CV analysis because a single literature database can provide the required sample data; however, the data revealed in researchers' publications and CVs are distinct. CVs reveal the purpose of each institutional move, such as earning a PhD degree or serving as a visiting scholar, whereas publications reveal only the year of the publication and author affiliation. The situation of researchers with low productivity or publications that are not indexed by literature databases leads to a loss of certain institutional mobility data. The CV method also results in some difficulties during research on scientific mobility because of incomplete personal information. The limitations of CV and bibliometric analyses make the combination of the two methods desirable.

Although a few studies have combined CV and publication data (e.g., Fangmeng, 2016; Jonkers & Tijssen, 2008), these studies have not focused on the different types of institutions that researchers were affiliated to and that they visited during their academic career. To address this research gap, the following main research question is examined in this study: Does the use of CV analysis and publication analysis result in significantly different findings regarding the number of institutions that researchers were affiliated to and visited? The current results may reveal the appropriate method for exploring scientific mobility.

Methodology

A total of 416 recipients of the Sloan Research Fellowship in Mathematics between 1990 and 2019 were selected as the sample researchers. This fellowship is awarded to distinguished junior mathematics researchers. Therefore, the recipients were assumed to have remarkable research performance, resulting in a higher possibility that they may transfer to institutions with greater research resources and a higher reputation than their previous institution.

The names of the recipients and their institutional affiliations when they obtained the fellowship were the basic information used for searching their CVs and other biographical information on the Internet. The institutions where these researchers received their bachelor's, master's, and doctoral degrees were distinguished from those where these researchers were affiliated to or visited temporarily. The period at each institution was also recorded, if available, for the researchers.

Each recipient's author affiliation information and the publication date listed in their publications, obtained from the author profile on Scopus, were retrieved as another information source for monitoring scientific mobility. The CV data helped correctly identify the recipients' author profile on Scopus.

The institutions that the sample researchers were affiliated to after receiving their PhD degrees were divided into home and temporary institutions according to CV data. Home institution was defined as the researchers' affiliated institution, and temporary institution was defined as any institution that the researchers visited temporarily for periods not exceeding 1 year. Institutions not included in CVs and those at which the researcher published their research for more than 1 year were categorized as home institutions, and other institutions were regarded as temporary ones. The main focus of this study was to compare the number of institutions yielded using the CV and bibliometric methods.

Results

Most researchers had visited other institutions for periods ≤1 year according to both their CVs (66.6%) and publications (62.5%; Table 1). The average numbers of home institutions, temporary institutions, and all institutions per researcher according to CV analysis were higher than those yielded from bibliometric analysis. This indicates that some researchers did not publish with the intention of giving credit to certain home and temporary institutions. Moreover, both CV and publication analyses revealed that the average number of temporary institutions per researcher was higher than that of home institutions. CV data indicated that the average total number of institutions per researcher was 4.42, which is higher than the number (3.96) identified using the publication method. A weak positive correlation was noted in the total number of home and temporary institutions between CVs and publications (correlation coefficient: 0.344).

Table 1. Institutional information by information source

	CVs	Publications
Researchers (H)	139(33.4%)	156(37.5%)
Researchers (H&T)	277(66.6%)	260(62.5%)
Ave N. (H) / (T)	2.50 / 5.38	2.42 / 4.88
Ave. N. (H&T)	4.42	3.96

Note: H, home institution; T, temporary institution; H&T, home and temporary institutions.

Half of the researchers (50%) with home and temporary institutions listed on their CVs also had records of the two categories of institutions in their publications (Table 2). This means that consistent institutional data could be obtained from the two data sources. For 17% of the researchers who had visited other institutions, that data were not found in their publications. A surprising finding is that 12% of the researchers had no records of visiting other institutions in their CVs.

Table 2. Number of recipients by category of institution according to CV and publication data

Group	Number (%)
CV(H&T) & P(H&T)	208(50)
CV(H) & P(H)	87(21)
CV(H&T) & P(H)	69(17)
CV(H) & P (H&T)	52(12)

Note: P, publication; CV, curriculum vitae.

Table 3 lists 14 categories of institutional information that integrate both the numbers and names of institutions between CVs and publications. Only 26% of the researchers in Group B had an equal number and the same home and temporary institutions in both CVs and publications. These researchers differed from those in Group E, who had an equal number but not the same institutions. This indicates that the information of institutional mobility of most researcher was inconsistent between CVs and publications.

Table 3. Comparison of numbers and categories of institutions according to CV and publication data

Category		N(%)
A	CV(H) = P(H)* & CV(T) > P(T)	116(27.9)
B	CV(H&T) = P(H&T)*	108(26.0)
C	CV(H) = P(H)* & CV(T) < P(T)	67(16.1)
D	CV(H) > P(H) & CV(T) > P(T)	27(6.5)
E	CV(H&T) = P(H&T)	23(5.5)
F	CV(H) < P(H) & CV(T) < P(T)	19(4.6)
G	CV(H) > P(H) & CV(T) < P(T)	16(3.8)
H	CV(H) > P(H) & CV(T) = P(T)*	15(3.6)
I	CV(H) < P(H) & CV(T) = P(T)*	10(2.4)
J	CV(H) < P(H) & CV(T) > P(T)	8(1.9)
K	CV(H) > P(H) & CV(T) = P(T)	3(0.7)
L	CV(H) = P(H) & CV(T) > P(T)	2(0.5)
M	CV(H) = P(H) & CV(T) < P(T)	1(0.2)
N	CV(H) < P(H) & CV(T) = P(T)	1(0.2)

Note: * refers to an equal number and the same institutions.

Conclusion

This study confirmed that neither CV analysis nor bibliometric analysis provided complete information regarding the institutions that most researchers were affiliated to and visited. Combining the two methods can improve the precision of results, although more time and financial resources are necessary. To obtain a more complete understanding of the two methods, future research should compare them over different periods.

Mapping the Interdisciplinarity of the Arts, Humanities & Social Sciences by Paper-level Classifications of Science

Bikun Chen[1], Shiqin Wang[2], Yuxin Liu[3] and Mengxia Cheng[4]

[1] chenbikun@njust.edu.cn, {[2] 939226312, [3] 283958279, [4] 1291361237}@qq.com

Introduction

Most interdisciplinary researches in scientometrics field rely on journal-level classifications of science. By this approach, papers could be misclassified in journal classification systems (Shu et al. 2019), which may cause bias, especially if there is a significant proportion of multidisciplinary journals in the reference list. In order to avoid these limitations, direct citation, co-citation, bibliographic coupling between publications are applied (eg. Waltman & Eck, 2012).

Different from international journal-level classification system (eg. WoS and Scopus Categories), most Chinese bibliographic databases (eg. CNKI and Wanfang Data) classify publications at the paper level using the Chinese Library Classification Scheme (CLC) (Chinese Library Classification 2010). CLC is also used by all the publishers in China to classify all publications including journals, books, and monographs. Based on paper-level classifications of science, 55,894 research articles published from 2008 to 2018 in 20 core Chinese journals that belong to "Library, information and archival science" are used to map interdisciplinary network of tier-1, 2, 3 and 4 classifications of science (Chen et al., 2019).

As an extension of the former research (Chen et al., 2019), all articles of the Arts, Humanities & Social Sciences published from 2008 to 2018 are incorporated to map interdisciplinary network and more interdisciplinary measures are calculated to measure interdisciplinarity in this study.

Data

The raw data consist of 1,153,838 articles (only 991,034 academic articles are kept in this study) published from 2008 to 2018 in 568 core Chinese journals indexed by CSSCI (Chinese Social Sciences Citation Index, 2019-2020 Version) (http://cssrac.nju.edu.cn/index.html). The raw data are crawled from March to May, 2020 in CNKI (China National Knowledge Infrastructure) (https://oversea.cnki.net/index/) and manipulated from June to August, 2020. Every Chinese journal has a tier-1 or 2 CLC code (detailed in Table 1) and almost each Chinese article has at least one tier-2, 3, 4, 5 or 6 CLC code (detailed in Table 2). Besides, CSSCI has its own unique journal classification system (not strictly follow CLC).

Table 1. Sample journal statistics.

CLC Code	# of Journals	# of Papers
Tier-1	447 (78.7%)	720,482 (72.7%)
Tier-2	121 (21.3%)	270,552 (27.3%)

Table 2. Sample paper statistics.

CLC Code	# of Papers	# of Papers (CLC Code >= 2)
Tier-1	991,034 (100%)	200,464 (20.2%)
Tier-2	991,021 (99.9%)	200,464 (20.2%)
Tier-3	978,341 (98.7%)	197,974 (20.2%)
Tier-4	896,381 (90.5%)	187,059 (20.9%)

Method

Pierce (1999) summarized three ways to conduct interdisciplinary research: borrowing, collaboration and boundary crossing. Based on the theories, two methods are used to construct interdisciplinary networks and network coherence indicators are applied to measure interdisciplinary. Besides, interdisciplinarity diversity of tier-1 CSSCI categories are calculated.

Method 1 (Undirected network): Co-occurrence of article-level CLC codes (>= 2) (proxy of borrowing). When any article-level CLC code i and j co-occur in any article A, their co-occurring value is number one. The total relation intensity φ between CLC code i and j is the sum of CLC code i and j co-occurring in any article A. The total relation intensity is normalized by Jaccard Index.

$$\emptyset_{i\,j} = \sum_{A} One(CLC_i, CLC_j)$$

Method 2 (Directed network): Article-level CLC codes point to journal-level CLC code (proxy of publishing work in other disciplines). When any article-level CLC code k points to journal-level CLC code l in any article B, their value is number one. The total relation intensity φ between CLC code k and l is the sum of CLC code k points to l in any article B. The total relation intensity is also normalized.

$$\emptyset_{k\,l} = \sum_{B} One(CLC_k, CLC_l)$$

Interdisciplinary Measures (Diversity & Network coherence): Different interdisciplinarity diversity

and network indicators are calculated, such as number of specialties, Specialization index, Brillouin index, network density, diameter, average node degree, average path length, average cluster coefficient, node centrality and so on.
Besides, tier-4 categories can be upgraded to tier-3, 2 and 1 categories. So, all upgraded categories are also included in each upper-level network.

Results

Due to the limited pages, only the results of tier-1 categories are shown in Table 3, Figure 1 and 2. From Table 3, "Ethnology & Culturology", "University Journal", and "General Social Science" keep a balance between variety and evenness. From Figure 1 and 2, each node indicates a category (labeled by CLC code), node size indicates its weighted degree, node colour indicates its category type (blue nodes indicate Arts & Humanities, green nodes indicate Social Sciences, red nodes indicate Natural Science). In Figure 1, "Economics" (F), "Culture, Science, Education & Sports" (G) and "Politics & Law" (D) are most closely related. In Figure 2, "General Social Science" (C), "Economics" (F), "Culture, Science, Education & Sports" (G) and "Politics & Law" (D) are most boundary- crossing.

Table 3. Interdisciplinarity diversity of tier-1 CSSCI categories (top 10 Brillouin Index).

Tier-1 CSSCI Category	Brillouin Index	# of Specialties	Specialization Index
Ethnology & Culturology	0.980	21	0.119
University Journal	0.960	21	0.138
General Social Science	0.913	22	0.157
Natural Resources & Environment	0.744	19	0.246
Philosophy	0.698	21	0.249
Human& Economic Geography	0.704	20	0.282
Marxism Theory	0.716	21	0.310
Sociology	0.721	20	0.359
History	0.609	22	0.406
Politics	0.655	22	0.406

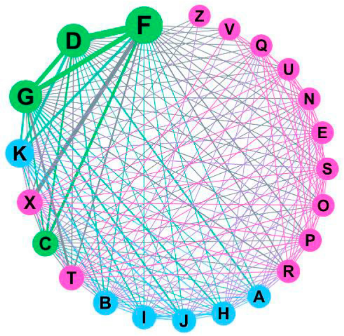

Figure 1. Undirected network of tier-1 categories.

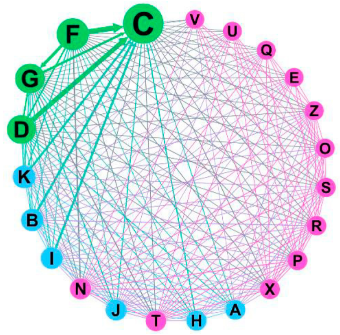

Figure 2. Directed network of tier-1 categories.

Introduction

How science is discussed on social media has become an increasingly popular topic in scientometrics, with most studies focusing on global platforms such as Twitter, Facebook, and ResearchGate. However, the online discussion of science on *local* platforms has been seldom studied, particularly due to the barriers of languages and data infrastructures for analyzing “local altmetrics” (Yu et al, 2017). China, as a non-English speaking country with the largest number of researchers and internet users, has some indigenous social media platforms mostly used by Chinese users, such as Sina Weibo and Tencent WeChat. These social media provide institutions and individuals with platforms not only for entertainment but also for scholarly communication. In China, WeChat is one of the most popular social media platforms for academics to publicly communicate about research developments. According to Zhang’s research (2018), 53.1% of scholarly journals indexed by Chinese Social Sciences Citation Index (CSSCI) had established WeChat accounts until 2017. This study also aims at investigating the WeChat presence of CSSCI-indexed journals. Specifically, the following research questions are addressed:

RQ1. How many CSSCI-indexed journals have WeChat public accounts?

RQ2. At the journal level, how is the correlation between bibliometric indicators and WeChat indicators?

RQ3. Do journals with or without WeChat public accounts perform differently in terms of bibliometric indicators?

Data and Methods

Data collection

CSSCI stands for Chinese Social Sciences Citation Index (http://cssci.nju.edu.cn/), a selective citation index which covers Chinese scholarly journals in the field of Social Sciences and Humanities. In the 2019-2020 edition of CSSCI, there are a total of 782 journals indexed in its core and expanded collections (including 568 journals from the core and 214 from the expanded collection). For each of these journals, we harvested a range of bibliometric data from the database of China National Knowledge Infrastructure (CNKI) between September 28, 2020 and October 8, 2020, such as total number of published papers, total number of citations, total number of downloads, and journal impact factors.

To examine whether these journals have created WeChat public accounts, we manually searched the journals’ names in the built-in search engine on WeChat. For those journals with WeChat public accounts with posts, we used a third-party software to collect the detailed information for each of their WeChat posts (e.g., title, number of clicks, number of likes). The WeChat data collection was conducted during the period from October 10, 2020 to November 9, 2020.

Analytic approach

Figure 1 illustrates the research workflow of the study. Starting from the extraction of both WeChat and bibliometric data for the CSSCI-indexed journals, followed by their aggregation at the journal-level, and finally performing three types of analysis: general descriptive statistics, correlation and factor analysis and finally a comparative analysis of citation performance between journals with and without WeChat accounts.

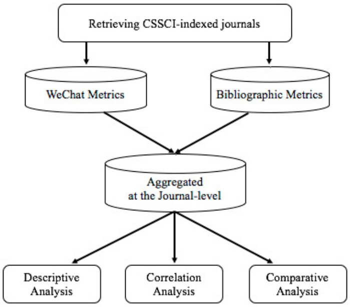

Figure 1. Research workflow

Results

Presence of CSSCI-indexed journals on WeChat

Among the 782 CSSCI-indexed journals, 511 of them have created WeChat public accounts (accounting for 65.3%). However, there are 6 journals with WeChat public accounts that never posted any WeChat post until the dater of data collection. Therefore, we collected WeChat activity indicators for a total of 505 journals. The total number of WeChat posts by CSSCI journals is 193,367. These posts have received a total of 272.9 million clicks and 1.2 million likes, respectively. These large numbers reflect the active interactions that take place in WeChat.

Correlation analysis of bibliometric and WeChat indicators

In this section, we focus on the correlation analysis of bibliometric and WeChat indicators. To examine the relationships between WeChat indicators and bibliometric indicators, Spearman correlation analyses were conducted as shown in Figure 2. Within both bibliometric indicators and WeChat indicators, indicators are moderately or strongly correlated. However, the correlations between bibliometric and WeChat indicators are generally weak or negligible. It suggests that bibliometric and WeChat social media indicators capture substantially different types of interactions and impact.

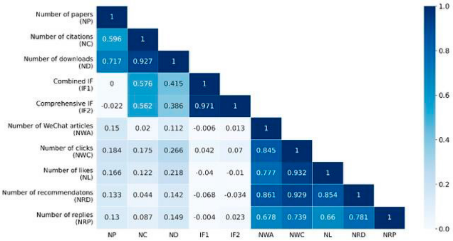

Figure 2. Spearman correlation analyses among bibliometric and WeChat indicators

Comparison of bibliometric indicators between journals with and without WeChat accounts

In this section, we explore whether journals with WeChat accounts have higher values of bibliometric indicators. Figure 3 plots the performance of journals with and without WeChat public accounts from the perspectives of the number of published papers, citations, downloads, and the two journal impact factors. In general, journals with WeChat public accounts tend to have slightly higher bibliometric scores than those without WeChat public accounts.

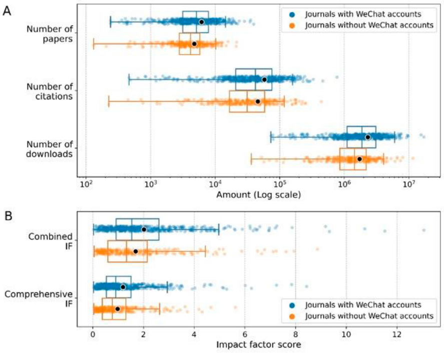

Figure 3. Bibliometric indicators of journals with and without WeChat public accounts

Discussion and Conclusion

This study empirically studied the presence of CSSCI-indexed journals on the Chinese WeChat platform, falling into the category of altmetric studies with a focus on "local research discussed in local platforms" (Yu et al., 2017). The findings of this research contribute to a better understanding of how Chinese scientific journals use local social media platforms to reach broader audiences. Although still in progress, this research already hints to important conclusions that highlight the relevance of incorporating local perspectives in the study of social media metrics across countries.

Understanding Scientific Success: A MacIntyrean Virtue Ethics Approach

Cinzia Daraio

daraio@diag.uniroma1.it
Sapienza University of Rome, Department of Computer Control and Management Engineering A. Ruberti (DIAG), via Ariosto, 25 00185 Rome (Italy)

Introduction

The analysis of the success in science has been a subject of interest and study for a long time. "Success breeds success" or the so called Mattheu effect, as it was named by Merton (1973), was used to explain the cumulative effects observed in the sociology of science, analysing noble price winners. But what are the determinants of scientific success? What makes a tiny proportion of scholars successful? Why a few scholars rise far above the rest, or using the terms of de Solla Price (1963, p. 59), why there are a "few giants and a mass of pygmies" and "neither man nor nature pushes us toward egalitarian uniformity"?

In this work we propose the adoption of a MacIntyrean virtue ethics approach to understand scientific success.

Related Literature

Scientific talent, according to Feist (2013), is nature shaped by nurture. In the "Complexity of Greatness" Kaufman (2013) combines different views and put together research on genes, talents, intelligence and expertise, deliberate practice, creativity prodigies, savants, mindset, passion and persistence to show that success is much more complex than talent and practice. Pluchino et al. (2018) develop an agent-based model which shows that talent is necessary to be successful in life, but the most talented people almost never reach the highest peaks of success, being surpassed by averagely talented but sensibly luckier individuals. Often in the literature success is connected to luck (Pritchard, 2005; Mauboussin, 2012; Frank, 2016). Barabási (2018) defines success as "the rewards we earn from the communities we belong to" and investigates the networking skills that enhance success. Barabási, distinguishing performance from success, states that personal achievements are important but in order to be translated into success, performance requires a community reaction. Hence, success is a collective undertaking. Besides performance, success requires building trust and reputation in order to shape others' perceptions regarding one's achievements. Barabási (2018) illustrates the network science behind why people succeed or fail presenting the following five universal laws of success: *i)* Performance drives success, but when performance can't be measured, networks drive success; *ii)* Performance is bounded but success is unbounded; *iii)* Previous success x fitness = future success; *iv)* While team success requires diversity and balance, a single individual will receive credit for the group's achievements, and *v)* with persistence success can come at any time.

These five rules state that a scientist place in a network is based not only on her performance, but also on the network's perception of her contribution to its goals. Day (2019) in reviewing Barabási (2018) identifies a weakness of the book in "the distance between the simplicity of how Barabási communicates the so-called laws of networks and the actual ability required to identify and master networks in everyday life". We believe that adopting a MacIntyrean approach to understand success can help to fill in this existing gap.

Aim and contribution

The aim of this work is to show that the adoption of the modern ethics of virtues developed by the moral philosopher Alasdair MacIntyre can offer us an interesting broader framework for getting into the mechanisms of scientific success. Using philosophical argumentation, we try to show how the MacIntyrean Aristotelian-Thomistic ethics of virtues allows us to understand a little better what lies behind scientific success by considering *virtues* that are stable dispositions of the character, connected to the psychology and motivation of individuals.

Materials and Method

MacIntyre focuses insistently on the connection between ethical doctrines and the historical-social contexts in which they arise, advancing arguments in favor of a "community" ethics which, unlike the abstract models developed by utilitarianism and neo-contractualism, identifies the ethically relevant principles in the *concrete community* to which individuals belong. In this perspective, his works are aimed at identifying historically the most satisfactory ethical models, and among these he attributes particular importance to the Aristotelian theory of virtues and to the Thomist tradition. Our proposal is based on the consideration of research as a social practice (MacIntyre, 2007). MacIntyre's concept of social practice seems particular suitable for conceptualizing the communal nature of research as illustrated in Bezuidenhout (2017), where scientists mediate their social interactions with peers during daily laboratory research. In Daraio and Vaccari (2020, 2021) applying this notion of research we have identified leaders, good researchers and honest researchers who contribute with their duties and activities to the achievement of the "internal goods" of research practices aiming at overcoming existing knowledge. Making a step further, MacIntyre (1999) develops the concept of "networks of giving and receiving" that are grounded on relationships that involve affective and sympathetic links which are grounded in and governed by norms of uncalculated and unpredicted giving and receiving and the concept of "virtues of acknowledged dependence", the most important of which is *misericordia* or mercy. These relational virtues seem closely connected to the social nature of research practices.

Towards the assessment of success: the contribution of virtue ethics

Extending the evaluation framework to include the ethics of virtues allows us to take into consideration the *character* (Miller et al., 2015) of the researchers and to understand and value how the stable motivations and the traits of the character (i.e. virtues) contribute to the research practices. Snow (2010) shows that virtue may be considered as social intelligence and Albrecht (2006) on a different ground identifies social intelligence as the new science of success. Hence, our framework offers us the possibility to *i)* understand the functioning of research practices in which there is a division of labour, including different kind of researchers and *ii)* design monitoring and controlling systems well suited for the specificities of the activities carried out within research practices.

If we deepen our understanding on why there are "giants" and pygmies within research practices, we can have a better understanding on what is research and what does it mean to carry out a good research. Further this understanding can be helpful to design "good evaluations of scientific research" (those that give values and promote good research) and to discriminate between good and bad research practices. Clearly success has an interplay with luck and merit (Daraio, 2021).

Concluding remarks and further research

The connection between performance, success, merit and luck still remains to be further investigated from an ontological and epistemological point of view. We try to show that an Aristotelian-Thomist moral framework is useful to clarify some connections among these relevant concepts.

Introduction

A patent has not only a technical function but also a legal effect. However, the legal effect of a patent is limited. This limit is in place to ensure that the patent owner can exclusively enjoy the patent's benefits in a limited area within a certain period. World Trade Organization members have agreed that the longest period that patent owners may profit from their patent should be 20 years. Once the patent owner stops paying the maintenance fee, they lose the right to monopolize the patent's benefits. Subsequently, anyone may use the patented technology to obtain benefits.

The patent maintenance system is unique in that the patent maintenance costs increase along with the length of the patent. Therefore, owners are likely to continue paying the patent maintenance fee to maintain the validity of the patent on the basis of rational decision-making considerations (Griliches, 1998; Pakes, 1986). Owners continue paying the maintenance fee as long as the patent's expected benefit is higher than this fee. The implication is that higher-quality patents have longer validity periods (Bessen, 2008; Dong et al., 2018; Maurseth, 2005; Pakes, 1986; Schankerman & Pakes, 1986).

Firm size and the stage of the technical field also affect patent maintenance length. Duguet and Iung (1997) argue that the length of patent maintenance is related to firm size and the stage of technology research and development (R&D) because companies with large-scale and strong technology R&D have advantages in human resources, financial support, and company systems. Such advantages support the realization of patented technology and the maintenance of patent validity.

Few studies have analyzed the length of patent maintenance in terms of firm size. Patent term length is often regarded as an indicator of patent quality, and it has also been verified to have a considerable analytical effect. However, the relevant application analysis aspects still require in-depth discussion. Therefore, this study examines the characteristics of firms of different sizes in terms of patent maintenance and employs mechanical engineering (ME) and electrical engineering (EE) technology as examples to compare the differences between conventional and high-tech industries.

Methodology

This study uses the patentometric method to analyze patent data. This method is widely used for R&D management, technology assessment, competitor monitoring, identification and assessment of potential sources of externally generated technological knowledge, and human resource management (Ernst, 2003).

Data collection and patent term

This study uses patent data from the United States Patent and Trademark Office (USPTO) database because the United States is one of the world's major markets. Filing an USPTO patent is a main strategic action and a meaningful symbol of global technological development for companies. It can help companies remain competitive in the global market. On the basis of the technology fields stipulated by the World Intellectual Property Organisation (WIPO), we download ME and EE technology patents granted from 1995 to 2014 from the USPTO website (USPTO, 2017b).

In the patent maintenance system of the USPTO, the longest patent term is 20 years. During the 20 years, the patent owner must pay patent maintenance fees at 3.5, 7.5, and 11.5 years after the patent was approved. If any payment is not made, the patent becomes invalid. According to these three patent maintenance fee payment times, patents can be divided into four valid durations: 4-year, 8-year, 12-year, and 20-year patents.

Firm size

Firm size in this research is obtained from the USPTO. Firms are divided into three categories according to the number of employees they have: large entities with more than 500 employees, small entities with fewer than 500 employees, and micro entities with low revenue and fewer than 500 employees. The patent fee payment standard of the USPTO is formulated to encourage innovation in small and micro entities through lower patent fees (USPTO, 2017a).

Result

Table 1 lists the number and proportion of patents obtained by firms of different sizes with varying patent term lengths for ME technology. From 1995 to 2014, large entities received 299,016 patents. Among them, 227,240 (76%) of the patents are for 20 years. In total, 28,582 (9.6%) patents are for 12 years, 30,045 (10.1%) are for 8 years, and 13,149 (4.4%) are for 4 years. Small entities received 619 patents in ME technology in 1995–2014. Among them, 390 (63.0%) of the patents are for 20 years, 67 (10.8%) are for 12 years, 98 (15.8%) are for 8 years, and 64 (10.3%) are for 4 years. Micro entities received only six patents during this period, with five (83.3%) of the patents being for 20 years and one (16.7%) being for 4 years.

Table 1. Number and proportion of patents for ME technology by differently sized firms for various patent terms

Firm size	Total patent	Patent-terms			
		4-years	8-years	12-years	20-years
large entity	299,016	13,149 (4.4%)	30,045 (10.1%)	28,582 (9.6%)	227,240 (76.0%)
small entity	619	64 (10.3%)	98 (15.8%)	67 (10.8%)	390 (63.0%)
micro entity	6	0 (0.0%)	1 (16.7%)	0 (0.0%)	5 (83.3%)
ME total	293,934	12,975 (4.4%)	29,497 (10.0%)	28,357 (9.7%)	223,105 (75.9%)

Table 2 presents the number and proportion of patents for EE technology in companies of different sizes for various patent terms. From 1995 to 2014, large entities obtained 1,187,113 patents. Among them, 1,837,003 (70.5%) are for 20 years, 107,673 (9.1%) are for 12 years, 154,641 (13.0%) are for 8 years, and 87,796 (7.4%) are 4 years. Small entities received 7,596 patents. Among them, 5,542 (72.96%) are for 20 years, 682 (8.98%) are for 12 years, 1,081 (14.2%) are for 8 years, and 291 (3.8%) are for 4 years. Micro entities received only 12 patents. Among them, 11 (91.67%) are for 20 years and the remaining 1 (8.33%) is for 8 years.

Table 2. Number and proportion of patents for EE technology by differently sized firms for various patent terms

Firm size	Total patent	Patent-terms							
		4-years		8-years		12-years		20-years	
large entity	1,187,113	87,796	(7.4%)	154,641	(13.0%)	107,673	(9.1%)	837,003	(70.5%)
small entity	7,596	291	(3.8%)	1,081	(14.2%)	682	(9.0%)	5,542	(71.0%)
micro entity	12	0	(0.0%)	1	(8.3%)	0	(0.0%)	11	(91.7%)
EE total	1,175,844	87,140	(7.4%)	152,002	(12.9%)	106,628	(9.1%)	830,074	(70.6%)

Comparison of Tables 1 and 2 reveals that the proportions of 4-year and 8-year patents of large entities for ME technology are less than those for EE technology. However, the proportions of 12-year and 20-year patents of large entities for ME technology are more than those for EE technology. Thus, large entities are more likely to maintain long-term patents for ME technology than for EE technology. In terms of small entities, the proportions of 4-, 8-, and 12-year patents are higher for ME technology than EE technology. However, the proportion of 20-year patents is lower in ME technology than in EE technology. That is, small entities are more likely to maintain long-term patents for EE technology than for ME technology. As for micro entities, the number of patents for both ME and EE technology is small. However, such entities tend to maintain long-term patents in both fields, and the proportion of EE technology patents maintained over the long term is slightly higher than that for ME technology.

Conclusions

The current results reveal that regardless of firm size, patents tend to be maintained over the long term. However, in large entities, the proportion long-term patents in ME technology is higher than that for EE technology. Small and micro entities tend to maintain more long-term patents in EE technology than in ME technology.

Introduction

The quantification and oversimplification of research impact and academic success is harming scholarly communities in all disciplines. Scholarly metrics, such as the h-index, impact factor, and indicators used in university rankings, are widely applied in academic tenure and funding decisions, but often inappropriately. This has created publication pressure, leading to a range of adverse effects and scientific misconduct. To improve the understanding and appropriate use of scholarly metrics in academia, Haustein (2018) proposes the concept of metrics literacies. Metrics literacies are defined as an integrated set of competencies, dispositions, and knowledge that empower individuals to recognize, interpret, critically assess, and effectively and ethically use scholarly metrics in academia.

There have been attempts to address the lack of metrics literacies in the wider academic community (e.g., *The San Francisco Declaration on Research Assessment*, the *Leiden Manifesto*, *the Metric Tide,* and *the Metrics Toolkit*). Other efforts include books and guides. Bibliometric experts have recently begun discussing metrics literacies-related concepts such as "metric wiseness" (Rousseau & Rousseau, 2015), "metric culture" (Hammarfelt & Haddow, 2018), and the "gaming" of bibliometric indicators (Derrick & Gillespie, 2013). Likewise, studies have started focusing attention on individuals' knowledge, usage, and opinions on scholarly metrics [e.g., (Derrick & Gillespie, 2013; Hammarfelt & Haddow, 2018]. Together, these initiatives represent a valuable, yet uncoordinated, first step toward educating the broader academic community on the appropriate use of scholarly metrics while the research studies provide first empirical insights. However, none of these attempts have evaluated the efficacy of those educational initiatives and, most importantly, most of them are published as textual documents, which require hours of reading. We believe that the bibliometric community needs to take responsibility of how scholarly metrics are used. The Metrics Literacies project aims to fill this gap by developing, testing, and disseminating multimedia open educational resources (OERs) to educate researchers and research administrators about scholarly metrics. A wealth of literature demonstrates the educational value of digital multimedia materials. Therefore, multimedia OERs can provide a more effective, efficient and engaging way to increase metrics literacies than using text-based resources [e.g., (Mayer, 2009)].

The Metrics Literacies project

The first part of the project focuses on the h-index, as a popular and widely-used scholarly metric, but also known for its deficiencies (Waltman & van Eck, 2012). The main objectives are to:

1. Develop multimedia OERs (e.g., videos, podcasts, infographics) to inform academics' and research administrators' understanding and appropriate application of research metrics;
2. Experimentally test and evaluate the efficacy of the educational resources and identify the most effective types of educational resources for metrics literacies topics;
3. Openly disseminate educational resources online and evaluate their uptake.

Methodology

This initiative includes three consecutive phases, which utilize a convergent mixed-methods design.

Phase 1 will include the development of the multimedia OERs by specialists. The creation of these resources, especially in regards to format selection, will be informed by the conduct of a systematic review and development of a taxonomy. These resources will include the following materials: *(1.) Five personas*[1] (four researchers and a research manager) to incorporate the use of storytelling elements (the practice of conveying information in a narrative form) and human embodiment. Specifically, incorporating a human presence, a so-called focaliser, can create authenticity and connection between the educator and the learner (Jüngst, 2010). Ensuring ethnic, cultural and gender diversity, personas come from different disciplines, different career stages, and display various levels of experience and challenges with the h-index. To make them reliable and relatable we obtain realistic examples of researchers and their publications as well as incorporate feedback from researchers which can relate in any professional way to one of the personas. *(2.) An h-index briefing note* including information on the metric (e.g., formula, computation) and evidence on the h-index issues, as for example its inconsistencies (Waltman & van Eck, 2012). The note is a textual document and based on a literature review. It builds the theoretical base for all multimedia OERs and ensures that the content of all resources remains constant. *Phase 2* will evaluate the impact of the created resources using a multi-arm randomized controlled trial (RCT), an attitude survey, a survey-based knowledge test, and semi-structured interviews. The multi-arm RCT will be composed of one control (text reading of the h-index fact sheet) and three treatment conditions (exposure of the h-index multimedia OERs). Before and after their exposure to control or treatment resources, the representative participants sample will complete an assessment. The assessment consists of the attitude survey (administered both before and after exposure) and the knowledge test on the h-index (administered as a post-test only). To establish the content validity of the knowledge test, the h-index briefing note will be used as a blueprint for the test. The semi-structured interviews will serve as means to further examine the participants' experiences with the educational resources and to understand their knowledge of the h-index. *Phase 3* will upload all educational resources online on Zenodo and YouTube and distribute them on social media to the academic community to test the engagement, popularity, and sentiment of the resources.

First outputs and next steps

Initial outputs are the first versions of the five researcher personas and the h-index briefing note (*phase 1*). The next steps encompass the completion of *phase 1*, and the implementation of *phases 2* and *3*. With our interdisciplinary project, we would like to make empirical and practical contributions to bibliometrics and multimedia education and promote metrics literacies in the academic community at large. In dependency of the evidence about most efficient OER formats and in a long-term view, the project targets the development of further educational material on the impact factor, other bibliometric indicators, altmetrics, and about the useful procession of metrics, such as field-normalized citation rates or percentile indicators. The project can be followed on Zenodo: https://zenodo.org/communities/metricsliteracies/

How do peer reviewers (mis)interpret funding agency criteria? Results from a survey of Science Foundation Ireland grant reviewers

Thomas Feliciani[1], Junwen Luo[2] and Kalpana Shankar[3]

{[1] thomas.feliciani , [2] junwen.luo, [3] kalpana.shankar}@ucd.ie
University College Dublin, Ireland

Introduction

Although funding bodies rely extensively on peer review to evaluate grant proposals with the highest potential for success, many aspects of review processes have been criticised for lack of reliability, potential for bias, lack of transparency, and heavy reliance on overworked researchers. The literature suggests that peer review bias and unreliability can be resulted from reviewers' heterogeneity in interpreting evaluation criteria established by funding agencies (Abdoul et al., 2012; Cicchetti 1991; Hug and Aeschbach 2020; Lee et al., 2013; Pier et al., 2017). To examine this issue more closely and as part of a larger project on grant peer review, we designed and administered an online survey of highly experienced reviewers for Science Foundation Ireland (SFI), Ireland's largest funding agency, to learn more about their experiences and perceptions of grant peer review criteria. In this poster, we describe some survey results, focusing on reviewers' perceptions of the evaluation criteria on a typical review form.

Survey design

We began with a content analysis of 527 peer review forms of two SFI funding programmes (2014-2017) and identified the twelve topics most often commented on by the reviewers (listed in Figure 2). The twelve topics were then included in two questions on our survey of the same reviewer pool:

- Which topics/criteria do you consider when evaluating the three review sections (applicants, proposed research, and potential for impact)? [Tick all topics that apply]
- In general (i.e. not just for SFI), how do these topics/criteria weigh in your evaluation of the "Impact" section of a proposal? [5-point scale from "not at all important" to "extremely important"]

The survey methodology and questionnaire are reported in full in Shankar et al. (2020). To ascertain the level of experience of SFI reviewers, respondents were asked when they had received their highest academic degree and approximately how many reviews they performed for any funding body. Other survey themes include questions about the procedures by which proposals are evaluated (clarity of review guidance, clarity of evaluation scale, time involved to review), the process of conducting the evaluation (interpretation of the agency's evaluation criteria, interpretation of the grading scale, group dynamics), the inclusion of non-academic reviewers, and transparency of reviewers' identities. There were 36 questions following an informed consent sheet. Question types were phrased as either 5-point Likert scales or open-ended, some questions with spaces for comment.

Survey respondents

The survey link was sent in June 2020 to all 1591 reviewers involved in our addressed funding programmes. The survey was kept open through the end of July 2020. 310 respondents completed the survey. Figure 1 shows the demographic composition of the survey respondents compared with the general demographics of SFI reviewers from 2014 to 2017 (the time period of our study). The funding agency relies exclusively on an international reviewer pool including researchers from academia and industry. Because reviewers are anonymous, SFI sent out the survey on our behalf. SFI did not provide any substantive comments or feedback on the survey, nor were they privy to the identities of individuals who took the survey.

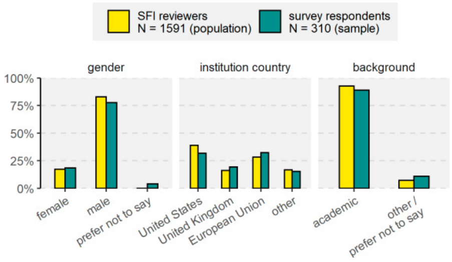

Figure 1. Survey demographics.

Evaluation criteria: Not so clear after all

Like many other funding agencies, SFI provides reviewers with review forms structured in separate sections, each section being dedicated to the evaluation of a specific evaluation criterion, i.e. "potential for impact". Funders also provide instructions as to what should be considered when evaluating these criteria. In the case of SFI, the evaluation criteria and corresponding instructions were roughly consistent through the time period and across the funding programmes we examined.

Despite these instructions, scholars have noted how there is often variation between reviewers in what aspects, or topics, reviewers focus on when evaluating a given criterion (see e.g. Langfeldt, 2001). In order to understand the consequences of such interpersonal variation, we first set out to find whether and to what degree there is variation in the interpretation of the evaluation criteria.

Figure 1 shows the answers to these two questions for the criterion "potential for impact": the plot shows the *frequency* with which each topic was considered for the evaluation of that criterion, and its deemed *importance*. Results show that some of the topics are reported more often than others (with higher frequency). Curiously, the topics that reviewers consider more often (in yellow) are not necessarily the ones deemed to be more important (higher value on the X axis): for example, the topic "research design" is considered of relatively high importance for the evaluation of "potential for impact"; however, it is among the least reported topics. This observation alone shows some degree of dissonance between which topics reviewers claim to consider when evaluating a specific criterion and which they deem the most important.

Furthermore, for all the topics we found large variance between reviewers in both questions. This is illustrated, e.g., by the length of the boxplots in Figure 2: for some topics like "mitigating risk", many responses ranged all the way from "not at all important" to "extremely important". This signals poor inter-reviewer agreement on which topics are considered and which ones are important for the evaluation of a proposal's potential for impact.

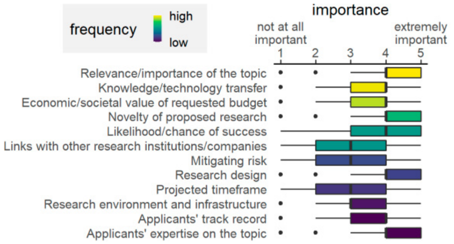

Figure 2. Review topics: frequency and importance for the evaluation criterion "potential for impact".

Future Research

29 survey respondents (9%) left email addresses to arrange follow-up interviews. We conducted 16 interviews and are in the process of analysing the data to explore further the reviewers' perceptions on evaluation criteria and other topics (e.g. grading scales). We will use this data to support simulation studies of reviewers' variant interpretations of evaluation criteria and how such variances would influence inter-rater reliability in peer review.

Conclusion

In this poster we empirically show that reviewers' diversity in the interpretation of evaluation criteria may constitute one reason for poor inter-rater reliability. Our results suggest that to some degree reviewers do what they want in spite of provided instructions. While more research in other funding programmes and agencies is clearly needed, we would point to a need for attention to this reason for any policy changes in grant peer review.

Introduction

The sharing of Brazilian scientific knowledge counts on the Directory of Research Groups (DGP[1]) support, a project created in 1992 by the National Council of Scientific Development (CNPq). The DGP's objectives are to promote the exchange of information between the scientific and technological communities, to provide information for the management of science and technology activities, and to preserve the memory of Brazilian scientific-technological activities (CNPq, 2020). Researchers identify, analyze, and discuss and disseminate knowledge, promoting scientific production (Aman, 2019). Such production is classified before Qualis[2], an evaluation system for the Brazilian postgraduate system through scientific journals' stratification (Rocha, Sabino, and Frery, 2020). In this sense, this work aims to characterize the scientific production of Secretariat research groups in Brazil, observing productivity and impact.

Materials and Methods

We collected data carried out in December 2020, from the current DPG base, with the parameters: "secretariat" in the fields "Name of the group," "Name of the research line," and "Keyword of the research line," and "Certified" and "Not updated" in the field "Situation." This last field identifies if the group has been updated in the previous twelve months. This search resulted in 15 groups, with each research line analysed to identify the relationship's consistency with the Secretariat field. With this, we identified a group that did not present such a relationship, and we excluded it from the search. The 14 groups investigated added up 243 members and 74 lines of research, of which only 29.21% are related to Secretariat. Table 1 shows the groups, the date of their creation, and number of members.

Table 1. Secretariat research groups in Brazil

ID	Group	Data	Members

[2] https://sucupira.capes.gov.br/sucupira/

We kept the original groups' names in Portuguese so the reader may find them in the DGP data base.

Based on the groups mapping, we defined the following research questions: Q1 -How is the scientific production of Secretariat research groups in Brazil distributed quantitatively? Q2 - What is the distribution of this product in the Qualis strata? Q3 - What is the impact of the research groups investigated? We verified each researcher's production in each group to answer these questions. As selection criteria, we define the terms "secretary," "secretaries," and "secretariat" in the title or abstract of articles in the Lattes Platform[3]. Then, we identified the Qualis stratum of the journals using the ChromeQualis tool. Finally, we used the "Publish or Perish" tool, with Google Scholar, to verify the number of citations of the publications to measure the group's impact (H-index).

Results

In response to Q1, we obtained 184 articles published in the period from 2013 to 2020. The groups are identified in the figures below by the corresponding ID in Table 1.

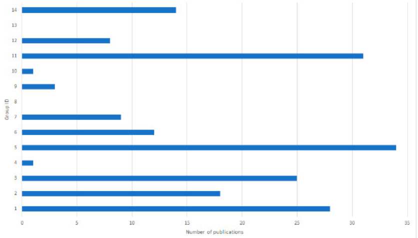

Figure 1. Number of publications per research group, from 2013 to 2020

We analysed the publications in two blocks: Qualis 2013-2016 ("A1", "A2", "B1" to "B5" and "C") and Qualis 2017-2020 ("A1" to "A4", "B1" to "B4" and "C"), the latter being in a preliminary version. In both blocks, the publications are concentrated in strata "B1," "B2," and "B3", the lowest in the rank, as shown in Figures 2 and 3.

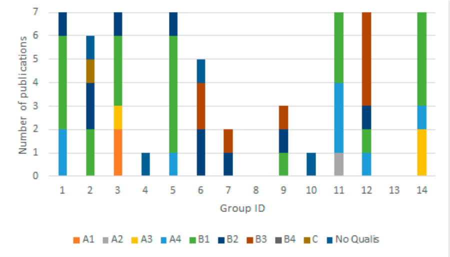

Figure 2. Distribution of publications in Qualis 2013-2016 strata

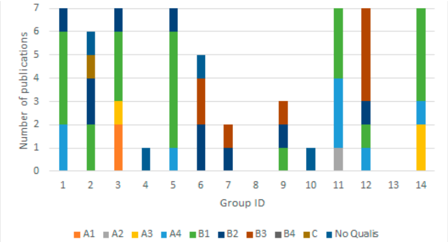

Figure 3. Distribution of publications in Qualis 2017-2020 strata

We analysed the impact of the papers produced in the groups. The largest H-Indexes (6 and 4) were from groups 1, 2, and 3. These are the oldest groups in operation. Of the recently created groups, only two (#13 and #14) have H-Index larger than zero, as shown in Figure 4.

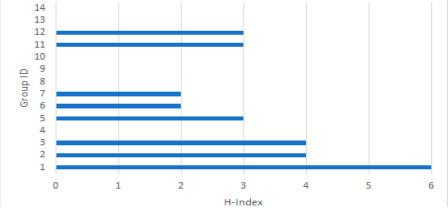

Figure 4. H-Index

Discussion and conclusion

The scenario of research groups in Secretariat indicates significant expansion since the decade of 2010, but with little progress compared to publications in higher strata. From 2013 to 2016, there are only two publications in the "A2" stratum, concentrated in a single group. From 2017 to 2020, there are only three publications in the "A1" and "A2" strata, distributed in two groups. On the impact of the productions, we found that only eight groups have H-Index. Although the groups' time of existence has influence in the productions' impact, some groups do not have any publication since their creation. We conclude that the output of Secretariat is concentrated in a few research groups, with negative impact in the evolution of the field and the National contribution to the scientific community.

Altmetrics for evaluation of medical research in Germany

Nicholas Fraser[1], Paula Bräuer[1,2] and Isabella Peters[1,2]

{n.fraser, p.braeuer, i.peters}@zbw.eu
[1] ZBW – Leibniz Information Centre for Economics, Kiel (Germany)
[2] Kiel University, Kiel (Germany)

Introduction

Since 2004, all medical faculties in Germany have been partially allocated funding according to performance indicators based predominantly on two scientometric criteria: (1) the amount of awarded third party funding, and (2) the number and quality of authored publications. Whilst the exact model by which each medical faculty evaluates their own publication performance varies, the evaluation of publication 'quality' has largely been based on citation-based metrics, namely Journal Impact Factors (JIF). Such JIF-based measures have been widely as indicators of individual publication quality, both nationally by the Association of Scientific Medical Societies in Germany (Hermann-Lingen et al., 2014), and internationally through initiatives such as the San Francisco Declaration on Research Assessment (DORA; https://sfdora.org/).

An additional factor complicating the usage of citation-based metrics for medical research assessment relates to an apparent citation "preference" or "advantage" of basic research (i.e. studies of fundamental functions and systems) in comparison to clinical research (i.e. studies of health and disease treatment in human subjects; van Eck et al., 2013; Donner & Schmoch, 2020; Ke, 2020). Applying citation-based metrics at an institutional level must therefore take into account differences in the research focus of each individual institution.

Altmetrics are metrics that capture countable signals for the access, usage and sharing of research objects on online platforms. They can provide a measure of public interest or discussion of scholarly works (Tahamtan & Bornmann, 2020), which may be an important contribution to multidimensional research evaluation methods, particularly in biomedical and health science fields which have been found to rank highly in terms of sharing rates on social media and news platforms (Costas et al., 2015).

In this poster, we will present results of an investigation into how articles authored by researchers at German medical research institutions are shared on various online platforms. In doing so, we will also assess how individual altmetric indicators vary with respect to their tendencies towards research levels (basic vs clinical research).

Methods

A list of titles and ISSNs for journals indexed in MEDLINE (N = 5007), a biomedical bibliographic database maintained by the US National Library of Medicine, were downloaded. Journals were matched to those indexed in the Web of Science (WoS), leveraging the data infrastructure of the German Competence Centre for Bibliometrics (http://www.forschungsinfo.de/Bibliometrie/en/index.php), on the basis of exactly-matching titles or ISSNs. We excluded journals with the WoS classification of "Multidisciplinary Sciences"; 16 journals), which included journals with a non-exclusive biomedical focus such as *PLOS ONE* or *Scientific Reports*. In total 4,442 MEDLINE journals were matched to journals in WoS.

We subsequently extracted publication metadata (DOI, publication year, article title, abstract) for all articles published in these journals with at least one author associated with a German research institution. Articles were limited to those published between 2012 and 2018, to "Article" and "Review" types, and to those with a valid DOI. In total we extracted details of 336,193 articles.

Altmetrics information were extracted from Altmetric (https://altmetric.com), by iteratively querying the API for each article DOI. We extracted counts from 5 main sources: Twitter, Facebook, mainstream media, blogs and policy documents (which include documents issued from government guidelines, reports or white papers; independent policy institute publications; advisory committees on specific topics; and international development organisations[1]). The Altmetric API only provides a valid response when an article has been mentioned in at least one of the single sources tracked – thus queries resulting in invalid responses ("Not Found") were included with counts of 0 for all sources considered.

To understand how altmetrics vary by indicators and research levels, we rely on visualisations of term co-occurrence maps using the *VOSViewer* software (van Eck & Waltman, 2010). In brief terms, each node in the map represents a term, whereby the size of the node is proportional to the total number of times a term is mentioned in the title and abstracts of our set of articles, and the distance between the nodes is proportional to the number of times that terms co-occur together in the same document.

Preliminary Results

Figure 1 shows three term maps as an indicator of our preliminary results – full results will be presented in the conference poster. Panel A shows clustering of terms present in our sample of articles – notably we see a transition from terms that we consider to align with basic research (e.g. “cell”, “protein”, “property”, “structure”) on the left side (red), to terms that we consider to align with clinical research (e.g. “patient”, “therapy”, “diagnosis”, “participant”) on the right side (blue). Panel B replicates Panel A in structure, but differs in that colors represent the strength of mentions of a term on Twitter (darker red = more-tweeted terms). We observe a slight tendency of articles containing clinical-related terms to be more tweeted than articles containing basic-related terms. In Panel C, colors refer to the number of citations in policy documents. We observe a stronger tendency for articles containing clinical-related terms to be cited in policy documents. The results highlight variation in the response of individual metrics to different research levels in medical research; for conducting evaluation of research at the institutional level, understanding these differences will be of key importance.

Future work will expand on these preliminary results, by considering further factors influencing these relationships, such as author and publication properties, or collaboration networks.

The three-dimensional activity index

Joel Emanuel Fuchs

jfuchs@uni-wuppertal.de
University of Wuppertal, Institute of Sociology, Gaußstraße 20, D-42119 Wuppertal (Germany)

Introduction

In sociological data analysis the comparison of data from different countries or institutions occurs all the time. The comparison of absolute values is often problematic due to the different sizes of the observed entities. One solution for comparing different sized entities is the activity index (AI). It enables the normalized international or inter-institutional contrasting of various fields. Although the AI is a long-used instrument, it lacks self-specific instruments to analyse itself. In this paper, we first want to present the AI. After that, we will introduce a new measure called the three-dimensional activity index (3D-AI) motivated by the statistical expected value. In the last part we will show how to use the 3D-AI to centre the basic activity index.

Used Data

For the sake of comprehension, data is used to visualise the new indices. Data from the European Patent Office (EPO) is open, easy to understand and traceable. So, we decided to use the granted patents per field of technology and per country of residence for 2011-2015 available from https://www.epo.org. The data is smoothed by a 3-year binomial filter to visualize the field and country specific trends better.

From the dataset follows, that the basic population consists of 46 countries plus 1 residual category divided into 35 fields over five years. All 8,225 data points will be used for calculation, but to keep the visual analysis clear, only the two countries Germany and the United Kingdom (UK) and the two fields 'Food chemistry' (FC) and 'Semiconductors' (SC) will be represented. This choice is arbitrary; the focus lies on the formulae presented later.

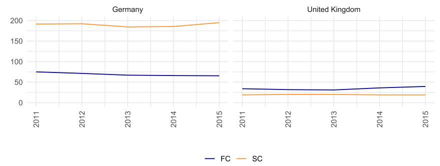

Figure 1. Granted patents.

The activity index

Of course, we can see in figure 1, that the shares of FC and SC of the overall granted patents must be more similar to each other in the UK than in Germany. But 'seeing' or comparing the absolute values is too intangible. Therefore, a relative index is often used, which directly reveals such differences between countries regarding the underlining fields. We will call it the activity index (AI), as denominated by Narin et al. (1987). But it is also known under the revealed technological advantage (Soette & Wyatt, 1983), revealed comparative advantage (Balassa, 1965) or the Balassa index (Ibid.).

Let x_{ijt} be the granted patents of country j regarding the field i in the year t. The AI relates the share of one field of a country $\left(x_{ijt}/\sum_i x_{ijt}\right)$ to the share of the same field but of all countries $\left(\sum_j x_{ijt}/\sum_{ij} x_{ijt}\right)$. So, we get

Formula 1. Activity index.

$$AI_{ijt} := AI\left(x_{ijt}\right) := \frac{x_{ijt}/\sum_i x_{ijt}}{\sum_j x_{ijt}/\sum_{ij} x_{ijt}}.$$

We calculated the AI for all 8,225 data points, but in figure 2 we will again only show Germany and the UK as well as FC and SC. Because of the different sums used for the AI, it is important to mention which values were calculated and which data points were used.

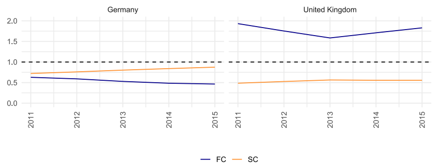

Figure 2. Activity index.

Figure 2 shows the AI corresponding to figure 1. The dashed line represents the average across all combinations of country and field. It is obvious that Germany is closer to the average than the UK. The second observation is that, except of Semiconductors in Germany, all other fields veer away from the average over time.

The temporal activity index

The values of the AI are calculated year by year. This is done, because all 1,645 data points of one year are integrated into the calculation of a single AI value by the composed sums. If we want AI values, that do not depend on the year, we could summarise all values by country and field over all five years. We get an AI that is constant over time so we will denote it the Temporal Activity Index (TAI).

Formula 2: Temporal activity index.

$$TAI_{ijt} \coloneqq TAI(x_{ijt}) \coloneqq \frac{\sum_t x_{ijt} \,/\sum_{it} x_{ijt}}{\sum_{jt} x_{ijt} \,/\sum_{ijt} x_{ijt}}.$$

Arithmetic mean

Let us calculate the arithmetic mean (AM), but not for all AIs, just for the AIs of a single country and a single field. Therefore, y shall be the number of years. Then we get $AM(AI_{ijt}) = \frac{1}{y}\sum_t AI(x_{ijt})$. This describes the AM of the AI values. We could also calculate the AI values of the arithmetic means of each part of the AI, so these would be $AM(x_{ijt}) = \frac{1}{y}\sum_t x_{ijt}$, $AM(\sum_i x_{ijt}) = \frac{1}{y}\sum_{it} x_{ijt}$, $AM(\sum_j x_{ijt}) = \frac{1}{y}\sum_{jt} x_{ijt}$ $AM(\sum_{ij} x_{ijt}) = \frac{1}{y}\sum_{ijt} x_{ijt}$. Using these AMs for calculating the AI, we will get the TAI as aforementioned. We conclude that the TAI is very similar to the AM.

Table 1. Temporal activity index.

Country	FC	SC
Germany	0.535	0.796
United Kingdom	1.759	0.535

The three-dimensional activity index

What does this have to do with the 3D-AI? The 3D-AI is the fraction of the classic AI and the TAI, as

Formula 3. Three-dimensional activity index.

$$3D\text{-}AI(x_{ijt}) \coloneqq \frac{AI(x_{ijt})}{TAI(x_{ijt})} = \frac{x_{ijt} \cdot \sum_{ij} x_{ijt} \cdot \sum_{it} x_{ijt} \cdot \sum_{jt} x_{ijt}}{\sum_{ijt} x_{ijt} \cdot \sum_t x_{ijt} \cdot \sum_j x_{ijt} \cdot \sum_i x_{ijt}}.$$

So, the 3D-AI centres the AI by its average over the years represented by the TAI. We therefore improve the AI by disadvantaging other parts of it, as we can see in figure 3.

The first two indices of the AI can be interchanged, i.e. $ai(x_{ijt}) = ai(x_{jit})$. We denote the newest value the 3D-AI, because all three indices can be interchanged, i.e. $ai(x_{ijt}) = ai(x_{tij}) = ai(x_{itj})$ and so on.

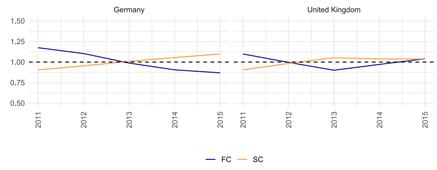

Figure 3. Three-dimensional activity index.

So, what are the advantages and disadvantages? Because we only divide the lines from figure 2 by a constant, the centred 3D-AI values are very similar, as we would expect from centred values. But now we can directly see in which year which country regarding which field performs like its average. For example, UK's FC line intersects with the dashed line about the year 2012 and 2014/2015. Before 2012, UK's FC performed above its own average, same after 2014. This is new information, which the classic AI and the absolute values could not express. The 3D-AI does not replace the classic AI, because it has some disadvantages. Due to the centralisation we cannot measure which field performs above average and which below. There are some more disadvantages, which would go beyond the scope of this paper.

In the future, there is a lot more to do. The TAI can be a better mean for the AI, but for a complete centring we also need an (empirical) variance. Indeed, if we want to analyse data by the activity index, we should think about reconstructing all empirical instruments, not only the mean and the variance, but also differentiation, correlation and so on. Perhaps we would benefit from a whole new toolbox designed especially for inter-institutional analyses.

Acknowledgments

We thank Jennifer Madine for proofreading this paper. Further we thank the European Patent Office for their free data providing service. All graphics and calculations were made by the help of R, RStudio and the huge package service around R, especially magrittr, data.table and ggplot2.

Reasons for Retraction Affect the Impact on Citations

John Gibson[1] and Keruma Gibson[2]

Introduction

The retraction of articles from peer reviewed journals is a growing issue. Retraction notices may be issued for what can be considered as the ‘bad behaviour’ of authors, such as violating ethics and privacy requirements, (self-) plagiarism and other manipulation of citations, missing credit and other authorship issues, and interfering with the peer review process. While bad behaviour could be due to attempts by authors to shield unreliable results from critical scrutiny, there is no inherent reason to consider results of studies to be wrong, just because the authors engaged in bad behaviour.

In contrast, for retractions due to either fabrication or falsification of data, or for errors in the analysis or the data, there are grounds to disbelieve results of the study. To date, the literature on the impact of retractions on subsequent citations (e.g., Furman, Jensen & Murray, 2012) which finds post-retraction citations decline over 60% relative to the citations for a matched control sample, does not examine if the impacts depend on the reason for retraction. On the other hand, research that looks at the reasons for a retraction, such as Cox, Craig & Tourish (2018), does not estimate the impacts of the retraction.

In order to fill this gap in the literature, we examine the impacts of retraction, for articles in psychology journals. We distinguish between retractions due to (a) bad behaviour of authors, and (b) retractions due to data fabrication, falsification and errors, which is a set that we group together as ‘dodgy results’.

Research Design

The analysis is based on 402 articles in psychology journals. The ‘treatment group’ is 143 articles that were retracted; a subset of 160 articles studied by Craig et al. (2020). The reason for not using all articles is that some were retracted due to errors by the journal, and some were not available in *Web of Science* (WoS). The control group is 259 nearest neighbour articles, which were published immediately before or after the retracted article in the same issue of a journal (if a retracted article was first or last in an issue, it only has one nearest neighbor, which is why therefore the control group does not have n = 286). This research design controls for the age pattern of citations, for journal impact factors, and for the effect of position within a journal issue on citations.

The nearest neighbor articles give a counterfactual to what the retracted article’s citations might have been had it not been retracted. One threat to use of these articles as a counterfactual is that they may be affected by the retraction of their neighbour, but there is evidence to suggest that such spillovers are rare (Azoulay et al., 2015). Citations for all 402 articles (including year of each citation) were retrieved from Web of Science (WoS) and Google Scholar (GS), totaling nearly 20,000 and 50,000, respectively.

Results

Articles retracted because of the bad behaviour of authors (e.g. due to plagiarism) had accrued the same citations (by early 2021), on average, as their control group articles (Figure 1a). In contrast, articles that were retracted because they had dodgy results (due to data fabrication, errors in analysis and so on) had accrued only one-quarter as many citations as their control group articles (Figure 1b).

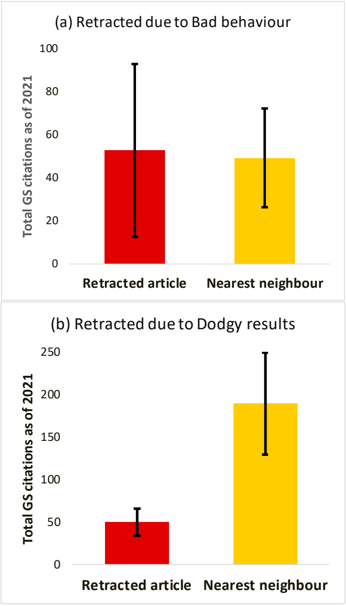

Figure 1. Mean citations (GS in early 2021) for retracted articles and their control groups

Table 1. OLS and median regression estimates of gap in citations between control group articles and retracted articles, by reason for retraction.

	Mean Gap in Citations		Median Gap in Citations	
Reason	**WoS**	**GS**	**WoS**	**GS**
Bad behaviour	-54.68	-144.80	-20.95	-47.67
	(2.69)	(2.47)	(1.79)	(1.75)
	[-0.21]	[-0.20]		
Dodgy results	49.06	135.45	21.35	49.41
	(2.65)	(2.55)	(2.01)	(2.10)
	[0.21]	[0.20]		

Notes: The gap is defined as citations for the control group articles minus those for the retracted article, WoS is Web of Science and GS is Google Scholar. $N = 143$, with t-statistics in ( ) and standard deviation effects in [ ]. Each cell is from a separate regression, with controls for article age and time since the retraction notice was issued also included.

We calculate the gap in citations (as of early 2021) as the amount by which citations for control group articles exceed those for retracted articles. The gap averages 46 (WoS) or 109 (GS), and is larger than two-thirds of mean citations for the control group. The average gap obscures a key difference; the gap varies with the reason for the retraction. We focus on retractions due to bad behaviour (n = 26) and due to dodgy results (n = 109); the other n=8 retractions give unclear or vague reasons for the retraction.

Regression results in Table 1 show that the gap in citations between retracted articles and their matched controls is significantly smaller, by about 0.2 standard deviations, if the retraction is because of bad behaviour reasons. In contrast, the gap is significantly larger if the reason given for the retraction is because of things like data fabrication or errors in the analysis, which we group together as ‘dodgy results’ reasons.

These patterns show up with both GS and WoS as the source of citations data. The patterns also show up when median regressions are used, to account for the skewed nature of citations. In all cases, the regressions in Table 1 control for the article age and time since retraction.

A key question is when does the gap in citations between retracted articles and the matched controls appear. We answer this using WoS citations, as the timing of citations is more easily obtainable from this source. However, given the similarity of results when using GS and WoS in Table 1, the patterns we find should hold more broadly.

For the analysis of these timing effects we restrict attention to the retractions that are due to ‘dodgy results’, as it is only for these that there is a gap in citations (as of early 2021) between the retracted article and the matched controls (Figure 1). Most of this gap in citations occurs after the retraction notice is published (Figure 2). For the three years before the retraction notice, the yet-to-be retracted articles averages two-thirds as many citations per year as their matched controls, while for the three years after, the retracted articles get only 14% of the citations per year of their matched controls. A gap begins to open the year ahead of the retraction notice, suggesting that the findings of the retracted article were already beginning to be discounted (the pattern holds if we weight neighbours by keyword overlap).

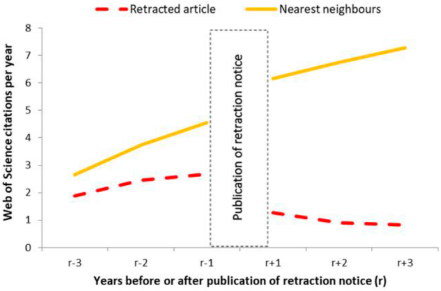

Figure 2. Average citations per year (in WoS), for three years before and after publication of the retraction notice, for subsample of articles retracted due to ‘dodgy results’ reasons.

Conclusions

Retractions of articles in psychology journals have a substantial effect on citations but only when the reason for retraction relates to unreliable findings, stemming from either fabrication or falsification of data, or from errors in analysis or data. If retraction is for other reasons, such as unethical behaviour of the authors, there appears to be no penalty through reduced citations.

Acknowledgments

We are grateful to Dr Adam Cox for sharing a list of retracted articles in psychology journals and to the University of Waikato Summer Research Scholarships program for funding support.

Introduction

Altmetrics was proposed by Preim (2010) in a website declaration, which defined altmetrics as "the creation and study of new metrics based on the social Web for analyzing and informing scholarship". Since then, many scholars have tried to apply altmetrics to evaluate the impact of articles, books, and journals. However, only a few of scholars have focused on author-level altmetrics. Based on the prior literature and the various tools (Altmetric.com, PlumX, et al.) of altmetrics, we summarize the platforms where the altmetrics indicators are usually drawn, and divide these platforms into five categories (See Table 1). It is found that most of the platforms are internationally popular. However, due to the policy restrictions in China and the language differences between international English and Chinese, these platforms are either inaccessible or not widely used by Chinese scholars. Hence, using indicators from them to evaluate Chinese scholars, there will be huge biases in the results of the evaluation.

Table 1. The common platforms where altmetrics indicators are originated

Categories of platforms	Examples of platforms	Examples of indicators
Online library	Scopus, PLoS One	downloads, views
Academic social platforms	Research Gate, F1000, Mendeley	Mentions, views, and likes
Comprehensive social platforms	Facebook, Twitter	Mentions, likes, comments
Encyclopedia platforms	Wikipedia	Mentions, views
News websites	CNN	Mentions

Accordingly, this paper explores the indicators in platforms which are similar with the internationally popular platforms and popular in Chinese scholars at the same time, and tries to build an altmetrics system to evaluate Chinese scholars scientifically.

Methodology and data

Based on the categories of the commonly used platforms, we investigate similar representative platforms which are popular in Chinese scholars. After investigation, we select CNKI, Sciencenet.cn, Wechat and Weibo, and Baidu baike as the representatives of online library, academic social platforms, comprehensive social platforms, and encyclopedia platforms, respectively. Besides, we choose People's Daily Online, Xinhuanet, and China.org.cn, which are the Top 3 of the 2017 news website communication power ranking of China as the representatives of news websites. On the basis of the altmetrics indicators adopted in the prior literatures, 16 new variables are drawn from the platforms above (See Table 2).

Table 2. The selected platforms and variables

Platforms	Variables
CNKI	papers (*CNKI_P*), downloads (*CNKI_Dl*)
Sciencenet.cn	mentions (*Snet_M*), views (*Snet_V*), recommendations (*Snet_R*), comments (*Snet_C*)
WeChat	mentions in WeChat official accounts (*WeCh_M*)
Weibo	mentions (*Wb_M*), reposts (*Wb_R*), comments (*Wb_C*), likes (*Wb_L*)
Baidu baike	views (*BD_V*), likes (*BD_L*), shares (*BD_S*)
News websites	mentions by all news websites (*News_All*), mentions by the Top3 representative news websites (*News_Rep*)

Given the large number of indicators, we use the principal component analysis (PCA) to reduce the number of dimensions. And the receiver operator characteristic (ROC) curve is used to test the discipline specificity of the proposed altmetrics system for evaluating Chinese scholars.

The winners of the Major Program of the National Natural Science Foundation of China (MP-NSFC) and the winners of the Major Program of the National Social Science Foundation of China (MP-SSFC) in 2013-2017 are chosen as the samples of the empirical study. After screening, 567 valid data are collected, including 162 winners of MP-NSFC and 405 winners of MP-SSFC. The time of the collection is from Nov. 8, 2018 to Jan. 8, 2019. We set the subject code Sub of MP-NSFC winners to be 1 and that of MP-SSFC winners to be 0.

Results

Empirical study

Through the PCA, we find that Wb_M and BD_S are equally important in two PCs simultaneously, indicating that they have little significance in the construction of the altmetrics system and should be deleted. The remaining 14 indicators are introduced into the PCA, and rotated by the maximum variance method. Then five PCs are extracted to represent these indicators and it seems that these PCs reflect five dimensions (Table 3): namely, Academic-blog attention, Social-media attention, Public-media attention, News attention, and Online-library attention. The total variance explained by the five PCs is 86%, and their rates of variance contribution are 37%, 18%, 14%, 10%, and 7%, respectively. The minimum weight of Online-library attention displays that altmetrics and traditional bibliometrics may evaluate different dimensions of scholars, which is in line with the general understanding that altmetrics represents social influence rather than academic influence of individuals (Mohammadi & Thelwall, 2014).

Table 3. Matrix of rotated principle components

	PC$_1$	**PC$_2$**	**PC$_3$**	**PC$_4$**	**PC$_5$**
Snet_C	**0.93**	0.22	0.04	0.05	0.05
Snet_V	**0.92**	0.05	0.04	0.10	0.15
Snet_M	**0.90**	0.02	0.04	0.07	0.17

CNKI_Dl	0.07	0.35	0.02	0.10	**0.86**
CNKI_P	0.28	0.12	0.09	0.18	**0.86**

Subject specificity test

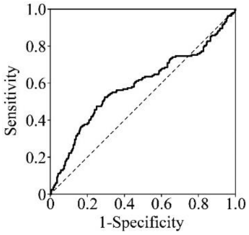

Fig 1. ROC curve when the default of Sub = 1

Setting the altmetrics score S as test variable and the subject code Sub as state variable (let default of Sub = 1), we plot the ROC curve (Fig 1.), in which the area under the curve is 0.588 ($p < 0.001$). It means that the altmetrics score we obtained did not show obvious specificity in the Social Sciences and the Natural Sciences.

Correlation test

We further explore the correlation between the altmetrics scores and the traditional measurements by choosing senior scholars in the field of library and information sciences who won the SSFC or the NSFC from 2013 to 2017 as samples. CNKI and SCI-E are retrieved to collect the data of articles and proceeding papers published by the scholars, from Feb. 21 to Feb. 28, 2019. Three commonly used bibliometric indicators, total number of articles (NA), total number of citations (NC), and h-index are calculated. After data processing, 78 valid data are obtained. Spearman correlation is used to test the relationship among the altmetrics score, NA, NC, and h-index. Results display that the altmetrics score has a positive correlation with the three traditional bibliometric indicators ($p < 0.01$), with a correlation coefficient about 0.67-0.71, implying the rationality of the score (Bornmann, 2014).

Discussion and conclusions

In this study, we introduce a range of author-level altmetrics indicators for Chinese scholars on the basis of those used in the West that are not widely accessed in China. This paper provides a reference not only for promoting the evaluation system of scholars' influence, but for researches on altmetrics system in other countries or other academic entities. While it is necessary to expand more source platforms and altmetrics indicators suitable for the evaluation of scholars, and all kinds of platforms should be encouraged to provide open-access data actively to make relative work more convenient.

Acknowledgments

We would like to thank the ISSI organisers and reviewers for their valuable opinions on the improvement of our work.

Publishing contribution of editorial board members to bibliometric indices of Library and Information Science journals

Nikolay A. Mazov[1,2] and Vadim N. Gureyev[1,2]

{MazovNA, GureyevVN}@ipgg.sbras.ru
[1]State Public Scientific Technological Library, Siberian Branch of the Russian Academy of Sciences,
Voskhod 15, Novosibirsk (Russia)

Introduction

Editorial board members (EBMs) of academic journals are believed to be the most reputable researchers authorized to provide rigorous peer-review processes, maintain ethical principles, guarantee high quality of published materials, and consequently facilitate the advance of science. Considering a sufficient number of studies on the composition, efficiency, and functioning of EBMs, a relatively recent trend evaluating an impact of EBMs on journal bibliometric indices seems to be studied to a far less degree. EBMs may increase bibliometric indices of parent journals via publication activity including publishing in parent journal and citing parent journal in their papers in that journal (self-citations) and other sources ('hidden' self-citations). Direct publication contribution of EBMs to parent journal as compared to common authors was firstly studied by Campanario (1996). Another study (Campanario, González & Rodríguez, 2006) analyzed EBMs contribution to impact factor (IF) detecting the percentage of citations made by EBMs of the analyzed journal. This paper aims at studying the publishing contribution of EBMs to the ranks of Russian LIS journals.

Data and methods

The sample includes 22 leading LIS journals published in Russia. The sample was organized as described in (Mazov & Gureyev, 2019) and divided into three groups according to 2-year IF based on the Russian Science Citation Index (RSCI) as of 2018. The distribution revealed that the low-tiered group (IF 0.4 – 0.799) includes library journals or serials with a long history: *Automatic Documentation and Mathematical Linguistics*; *Automation and Remote Control*; *Bibliography*; *Bibliosphere*; *Information Security Problems. Computer Systems*; *Russian Journal of Library Science*; *Software Engineering*. The middle-tiered group (IF 0.8 – 0.999) includes respectable journals both on library and information science topics with a long history: *Information Resources of Russia*; *Information Society*; *Journal of Information Technologies and Computing Systems*; *Proceedings of Voronezh State University*; *Scientific and Technical Information Processing*; *Scientific and Technical Libraries*; *Systems and Means of Informatics*; *Vestnik NSU. Series: Information Technologies*; *Vestnik of Moscow City University. Series: Informatics and Informatization of Education*. The top-tiered group (IF > 1) comprises journals devoted to information science issues and is characterized by a rather recent foundation: *Business Informatics*; *Computational Technologies*; *Informatics and Applications*; *Informatics and Education*; *Journal of Applied Informatics*; *Ontology of Designing*. We analyzed papers published in 2016–2017 and citations made in 2018.

Results and discussion

Contribution of EBMs by scholarly output

EBMs papers are mainly prepared at a high level and accrue more citations. However, sometimes one may observe the opposite trend of a lower quality preparation of manuscripts by EBMs relying on superficial refereeing due to their official power (Schiermeier, 2008). Thus, it can be concluded that in the former case EBMs papers would gather a high number of citations and increase journal IF, while in the latter case they would adversely affect IF.

We failed to reveal significant dependence between IF and a share of papers by EBMs in a parent journal from the total number of journal papers: all three groups comprised approximately 16% of EBMs papers (Figure 1). Considerable differences were detected between a share of EBMs papers in a parent journal from a total number of EBMs papers in all sources. EBMs of top-tiered journals are published significantly more rarely in parent journals as compared to EBMs of middle- and low-tiered journals. When considering all journals, a share of papers in parent journals from the total number of papers in all sources was 7.6% on average.

In all three groups, we found a relatively uniform distribution of EBMs papers and usual authors, as well as a low share of papers in a parent journal as compared to the total number of papers. EBMs of top-tiered journals were found to be published more frequently in other sources rather than in a parent journal. We failed to detect any relationship between

IF and a share of papers by EBMs as it is, i.e., independently of citations.

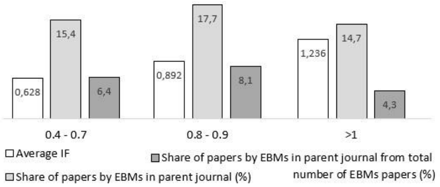

Figure 1. Relationship between IF and a share of EBMs papers.

Contribution of EBMs by citations

Citation contribution of EBMs to journal rank is twofold: either EBMs papers in parent journal can be cited or EBMs themselves can cite a parent journal from other sources ('hidden' self-citations). Figure 2 depicts both types of contributions.

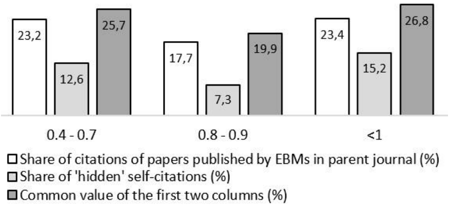

Figure 2. Relationship between IF and a share of citations to EBMs papers and/or a share of citations to parent journals made by EBMs.

Across all Russian LIS journals, 21.1% of citations belong to EBMs papers, and 11.5% of citations are made by EBMs from other sources. The common value of these two indices excluding overlapping is 23.9%. Interestingly, middle-tiered journals demonstrate lower indices as compared to top-tiered and low-tiered journals.

Dependence between IF and EBMs publication activity

To detect a direct effect of EBMs on IF, we (a) removed EBMs papers from the denominator of IF formula, (b) removed citations to EBMs papers from the numerator, and (c) removed citations made by EBMs from other sources to parent journal from the numerator of IF formula (Figure 3).

We detected a significant impact of EBMs in top-tiered and a slightly lower effect in low-tiered journals, while the middle-tiered group demonstrates a zero or reverse trend since the absence of EBMs papers in a parent journal paradoxically would have resulted in slightly higher journal ranks.

Finally, we counted the overall share of EBMs contribution according to three analyzed characteristics, i.e., EBMs publications in a parent journal, citations to EBMs publications in a parent journal, citations to a parent journal made by EBMs from other sources: 10.67% in low-tiered journals, 0.78% in middle-tiered journals, and 14.16% in top-tiered journals.

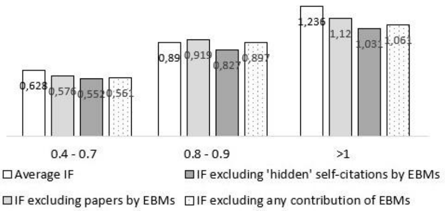

Figure 3. IF values including and excluding EBMs publishing contribution.

Middle-tiered journals stand alone because of the lack of EBMs impact on journal rank. In some journals, we revealed a negative effect (up to 18.9%) of EBMs papers on journal indices. On the contrary, some journals from top-tiered and low-tiered groups revealed a significant positive impact from EBMs publication activity on their rank (up to 34.1%). Interestingly, EBMs contribution may affect journal IF to such a great degree that some journals from our sample fell in a different subsample after the exclusion of EBMs papers and citations.

Conclusions

Analyses of the scholarly output of EBMs in Russian LIS journals enabled us to reveal some patterns in publishing contribution of EBMs to journal rank, which enhance knowledge on editorial board functionality in LIS, as well as can be used by editors-in-chief in optimizing editorial policy or changing editorial board composition.

Automatic Recognition and Classification of Future Work Sentences in Academic Articles in a Specific Domain

Wenke Hao, Yuchen Qian, Zhicheng Li, Yuzhuo Wang and Chengzhi Zhang

{haowk, qianyc, lizhicheng, wangyz, zhangcz}@njust.edu.cn
Department of Information Management, Nanjing University of Science and Technology, Nanjing (China)

Introduction

Nowadays, various digital technologies promote the publication, diffusion, acquisition, and utilization of academic literature. Therefore, researchers, mainly those who are beginners in scientific research, face rapid changes in research dynamics, and it is challenging for scholars to predict future research topics. The research paradigm characterized by 'data-driven' is emerging in the topic detection and tracking. Machine Learning (ML) and Natural Language Processing (NLP) technologies can deeply mine the rules and knowledge hidden in the data and reduce professional requirements for analysts.

Compared with the bibliographic information, full-text of academic papers contains micro-semantic details such as the chapter structure, scientific entities, and argumentation logic, revealing authors' research achievements and innovative knowledge comprehensively. The 'future work' is a pivotal part of an academic paper, where the authors make suggestions for future research, point out what research is underway, or discuss the potential direction of the whole field. Excellent future works should build on existing research and inspire new questions. Taking the field of NLP as a case, this paper extracts Future Work Sentences (FWS) of articles, classifies them into different types, and then discusses the trends of future research in NLP field. This work generates fresh insight into the analysis and mining of FWS from the large-scale full-text corpus, providing data and method support for exploring future research trends in a specific domain.

Related work

Recently, Hao et al. (2020) constructed a corpus, including future work sentences manually extracted from ACL papers published during 1990-2015, and constructed a classification system in accordance with grounded theory. Besides, most prior work is based on rules to identify future work sentences (Hu & Wan, 2015). However, manually established rules can hardly cover all the language features of future work sentences and are susceptible to subjective factors of experts. Therefore, we adopt machine learning and deep learning methods to accomplish automatic recognition and classification of future work sentences.

Method

Dataset

We download 11,952 conference papers of ACL, EMNLP, and NAACL during 2000-2019 from ACL Anthology (https://www.aclweb.org/anthology/). The manually annotated dataset consists of two parts: first, FWS of ACL during 2000-2015 are obtained from the *ACL FWS-RC* corpus (Hao et al., 2020). Second, we extract chapters related to future work in the other papers by manual reading. Subsequently, we annotate the FWS in the extracted chapters of EMNLP and NAACL according to the existing label specification and classification system. Cohen's kappa coefficient (Cohen, 1960) is employed to measure the reliability of the labels and achieves over 0.75. After deleting the connective sentences that do not contain actual meaning and splitting the FWS belonging to multiple types, we get the number of sentences in each type: *method* (4554), *resources* (987), *evaluation* (963), *application* (1150), *problem* (1043), and *other* (402). The information of annotated dataset is shown in Table 1.

Table 1. Statistic information of Dataset.

Type	#
Papers	9,508
Chapters	9,635
Sentences	62,312
Future work sentences	10,622

Model selection

For automatic recognition of FWS, we use four traditional ML models, including Naive Bayesian, Logistic Regression, Support Vector Machine and Random Forest, combining with three feature selection methods: filter, embedded, and wrapper. Then ten-fold cross-validation is performed.

For automatic classification of FWS, we use the BERT pre-training model to represent the input data's features and input the acquired feature vectors into the SoftMax layer for classification. The BERT is a model with 12 layers of Transformer, 768 hidden units, and 12 self-attention heads trained on the English dataset (https://github.com/google-research/bert). Also, we select TextCNN and BiLSTM for comparison and use Word2vec in the word embedding layer. Then the training set, verification set, and test set are divided into 8:1:1. We evaluate the model performance by Precision, Recall, and F_1.

Results

Result of Automatic FWS recognition

The experiment result shows that the Naive Bayesian based on the embedded feature selection method achieves the best F_1 score in the automatic FWS recognition. The result is shown in Table 2.

Table 2. Performance of FWS recognition.

Model	**Precision**	**Recall**	**F_1**
LR	92.46%	81.05%	85.35%
SVM	92.39%	86.87%	89.31%
RF	92.58%	92.63%	92.08%
NB	91.22%	97.58%	93.95%

Then we use this model to recognize FWS from extracted chapters of ACL between 2016 and 2019. 1430 sentences are identified and we add them to our dataset. Figure 1 shows the changes in the number of FWS. Because the amount of papers per year is not stable, the ratio of FWS is used as an indicator, which is the share of papers that contain FWS.

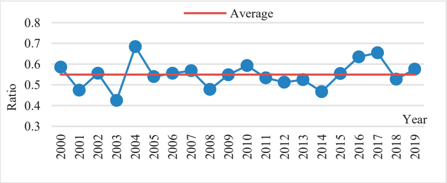

Figure 1. The ratio of FWS from 2000 to 2019.

As shown in Figure 1, the ratio of FWS in 20 years fluctuates to a small extent, with an average value of 0.55. We believe that the different types of papers influence the results, because the average value of FWS share reaches 0.58 when only long papers are considered, while the average value decreases after adding other types of papers.

Result of Automatic FWS classification

The experiment result shows that Bert performs best in the automatic FWS classification, and its performance in the test set is shown in Table 3.

Table 3. Performance of FWS classification.

Type	**Precision**	**Recall**	**F_1**
Method	89.98%	92.66%	91.30%
Resources	87.83%	82.11%	84.87%
Evaluation	91.86%	66.95%	77.45%
Application	81.32%	78.12%	80.00%
Problem	67.57%	96.15%	79.37%
Other	89.92%	63.64%	74.53%
Weighted Avg	**87.20%**	**86.02%**	**85.91%**

Similarly, we use this model to classify FWS without category labels extracted in the previous section. To enhance the result's reliability, we check the classified FWS by sampling according to the year. With a sampling rate of 10%, 22 misclassified sentences are corrected from 143 sampled sentences. Thus, we obtain a complete dataset of FWS with type labels from 2000 to 2019.

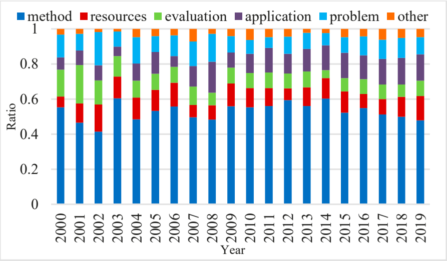

Figure 2. Ratio of FWS types from 2000 to 2019.

The evolution of the FWS types is presented in Figure 2. The ratio of *method* type each year has apparent advantages, and the remaining five types with the year present the small-scale volatility. A change from 2016 to 2019 is the dependence on data appears to increase because the ratio of *method* type is reducing while the ratio of *resources* type is rising, but it is still small compared with *method* type. Based on the result, we can infer that the future research of most papers on NLP should still focus on methods.

Conclusion and future work

This paper constructs two models to recognize and classify FWS automatically. In the future, we will apply the models to other conference papers in ACL Anthology and make the corpus publicly available to the community. In addition, we want to introduce unsupervised methods and transfer learning to reduce manual annotation and explore other areas.

Introduction

Long before the present pandemic took hold of the world, it has been clear that scientific Internationalization is an important aspect to how science is being conducted. Accordingly, there is a vast literature in scientometrics using bibliometric analysis to investigate networks of international cooperation in science (Glänzel & Schubert, 2004; Luukkonen et al., 1993). One previous study by Fry and colleagues (2020) investigated collaboration patterns in COVID-19 research by scrutinizing publications and pre-prints. Importantly they found that at least at the beginning of the pandemic, the earliest research collaborations tended to include fewer participating countries and also fewer emerging countries than pre-pandemic research on corona-viruses. The aim of the present study is to replicate and update these analysis using a data base of clinical registrations as a data-source.

In order to gain a picture of the research output that is as comprehensive as possible, it is often not enough to scrutinize published articles in scientific journals and books. Instead, in different fields dissertations (Andersen & Hammarfelt, 2011), and patents (Narin, 1995) are routinely used to measure scientific activities. In the domain of medicine a specific data source is available; clinical trial registers (CTRs). CTRs are data-source that are only rarely used as a data-source for scientometric analysis (for an exception see: Thelwall & Kousha, 2016). In 2008 the seventh Declaration of Helsinki established that trials involving humans have to be registered in CTRs. As a result CTRs contain information on all studies that are conducted, avoiding the otherwise pervasive problem of publication-bias, i.e. the fact that a large proportion of medical studies that were conducted are never published in scientific journals. Furthermore, since registration should happen before the first participant is enrolled, CTRs do contain information on studies that are not yet finished or have not even started.

Using CTRs as data source we want to test whether - and to what degree - international cooperation on coronavirus-research changed during the COVID-19 pandemic. And how this is influenced by pandemic-dynamics (incidents, deaths, lockdown).

Methods

Clinical Trial Registrations were accessed via the AACT-Database. This database provides monthly snapshots of the ClinicalTrials.gov registry and stores it as a relational database. Of this we used information in the “conditions” and “countries” table to identify link information.
Specifically, we compared two data sets. The first “NON-COVID” data set included interventional studies on viruses in general registered after 1.1.2010. The second “COVID” data set included interventional studies on “COVID”, “SARS”, and “CORONA” registered after 1.1.2020.

Results

Overall, we identified 1.158 NON-COVID trials and 1.955 COVID trials in the data base. As can be seen in table 1 the COVID trials had overall much fewer participating countries than NON-COVID trials.

Table 1. Number of countries involved in the NON-CORONA and CORONA dataset.

Countries	NON-COVID	COVID
1	895 (77%)	1813 (93%)
2	75 (6%)	70 (4%)
3	35 (3%)	13 (1%)
4	18 (2%)	13 (1%)
5	16 (1%)	12 (1%)
More than 5	119 (10%)	34 (2%)

Secondly, we inspected the different cooperation-networks. For this we generated two adjacency matrices; one for the NON-COVID trials and one for the COVID trials. We used scaled heat-maps to visualize these different adjacency matrices and their differences. Thirdly, we used a linear model to predict changes in cooperation intensity between two countries by COVID-19 incident-rate, mortality-rate, and differences in lockdown-start dates in the first half of 2020.

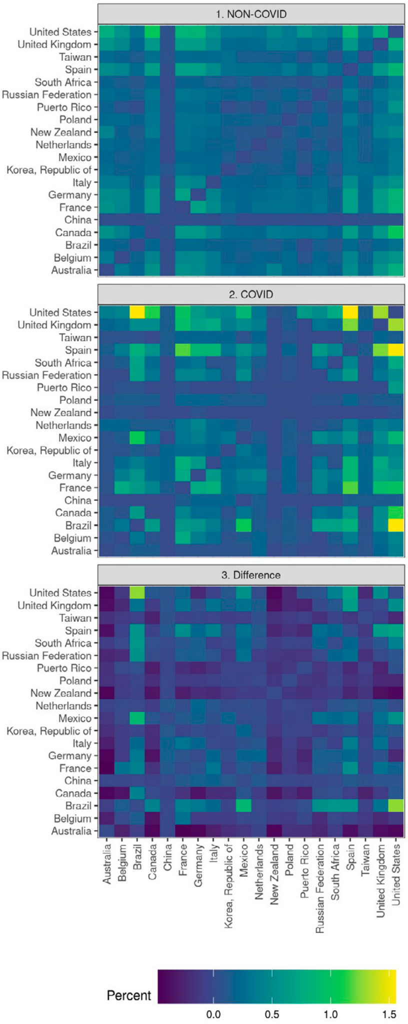

Figure 1. Cooperation networks for NON-COVID (top), COVID (middle) trials and their differences (bottom)

As can be seen in figure 1 there cooperation-pattern of NON-COVID and COVID were different in some important regards. Overall, the collaboration between the 20 countries was much more evenly distributed in NON-COVID trials compared to COVID trials. Looking at the COVID trials in particular, the many trials that were conducted in both the US, Brazil, Spain and some degree Mexico seem to stand out. At the same time, Australia and New-Zealand are less involved in COVID than in NON-COVID trials.

The linear model showed a small albeit significant association between intensified cooperation and the number of fatalities.

Discussion

The aim of the present studies was to compare the internationalization of medical research on COVID-19 to "non-COVID-19" research using CTR as data source. With regard to the overall number of involved nations, were able to replicate results based on bibliographic analysis (Fry et al., 2020) showing that COVID-19 trials conducted by smaller teams. The pattern of collaboration that emerges from our analysis of trials is however different to the pattern emerging from the bibliographic analysis. First, China is not well represented in this analysis, which may be due to the fact that there are alternative CTRs, which could be used to register trials.

Secondly, our analysis shows that emerging countries such as Brazil and Mexico are more tightly integrated into COVID trials. This may be driven by disease dynamics in the sense that countries with higher fatality-rates also increased their cooperation more strongly. Only time will tell, whether this involvement will also translate into authorship of shared publications (Glänzel & Schubert, 2004; Luukkonen et al., 1993) and further research opportunities for emerging countries.

Acknowledgments

This study was funded by the German Federal Ministry of Education and Research (BMBF #01PU17010).

Changes in the Funding Composition of Czech Science

Radim Hladík

hladik@flu.cas.cz
Institute of Philosophy of the Czech Academy of Sciences, Jilská 1, 110 00 Praha (Czech Republic)

The analysis tracks funding acknowledgements of publications published by Czech scientists and reported in the Information Register of R&D results (RIV). As a national database used in authoritative research evaluations, RIV has the major advantage of exhaustive coverage of publication results in comparison with selective commercial indexing services (Sīle et al., 2018). A particular focus is on the Czech Science Foundation (CSF), the major provider of project-based funding for basic research in the Czech Republic. The breakdown of aggregated statistics into six science domains subsequently serves as an indicator of their dependence on different funding sources. The results show differentiated funding composition across scientific fields as well as a shift in the funding policies towards government-controlled sources.

The unit of analysis are the RIV records of financial resources that supported each publication. The analysis considers all publication results (articles, books, book chapters, and contributions in indexed conference proceedings) in the category of basic research, a total of 840149 publications with 1227533 acknowledgments from 2000 to 2019.

It is worth noting that RIV does not systematically record research support from foreign agencies, with some exception for EU programs. The perspective of the dataset is therefore strictly national. Furthermore, if we compare a RIV funding acknowledgment of an internationally co-authored publication with the funding data in, e.g., the Web of Science database, we typically find project acknowledgements of multiple authors. RIV records only the funding of authors based in Czech institutions. On the other hand, the Web of Science would not index non-project types of funding that make up research organizations' budgets, whereas RIV does.

Each record is accompanied by information about the scientific field according to the FORD classification. Older entries in RIV used a bespoke classificatory system, for which matching of ambiguous categories had to be resolved manually and could marginally affect the analysis.

The figure 1 shows the overall role of project-based funding in the Czech science in the structure of various financial resources declared by research organizations. The level of project funding has remained surprisingly stable and, for the past two decades, it has hovered at around 40%. In contrast, there have been substantial shifts funding policy in the composition of the remaining 60% of acknowledgements (cf. Good et al., 2015). Forward-looking institutional funding based on "research plans" has been gradually replaced by institutional "support for the development of research organizations" distributed according to post-hoc research evaluation. Universities have also received earmarked funds for "specific higher-education research," which requires student participation. Other types of financial resources play a smaller role.

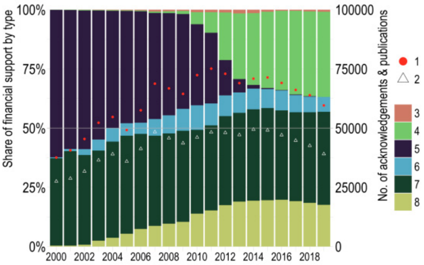

Fig. 1. Financial sources in the publication acknowledgements.

1 – No. acknowledgements. 2 – No. publications. 3 – Other public or private sources. 4 – Institutional support for development. 5 – Institutional support for research plans. 6 – EU Programs. 7 – Projects. 8 – Specific higher-education research.

In the next step of the analysis, we focus only on project dedications, i.e., roughly less than 40% of all acknowledgements. While the overall share of project resources has remained stable, there have been more significant changes within the project segment itself.

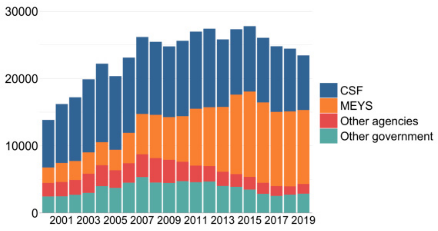

Fig. 2. Project acknowledgments by providers.

As the figure 2 shows, the role of the CSF has weakened over the years. While until 2005 inclusive, CSF could claim more than half of all project dedications, by 2019 its share was just over one third. Smaller funding agencies, regional providers and even governmental sources have likewise seen a comparative decline in the received acknowledgements. The only provider to increase its share has been the Ministry of Education, Youth, and Sport (MEYS) which has been charged with national redistribution of EU funds. By 2019 MEYS has been receiving almost half of all funding acknowledgements.

The section B of the figure 3 shows a mix of project-based funding providers by science domain. It breaks down the aggregated statistics discussed above by major scientific fields in the FORD classification. The simple count of funding acknowledgement implies a degree of standardization, whereby disciplines are compared by the number of publications rather than by the amounts of money required to carry out the research underlying those publications (cf. section A of the figure 3).

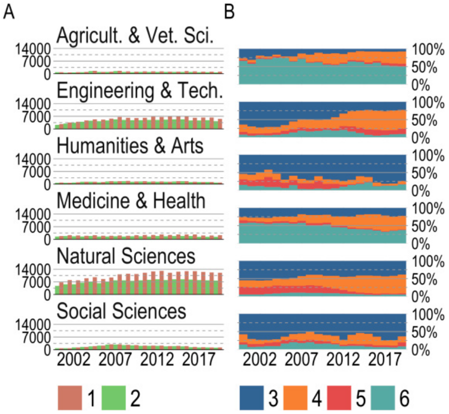

Fig. 3. Project acknowledgements by fields.

1 – No. acknowledgements. 2 – No. publications. 3 – CSF. 4 – MEYS. 5 – Other agencies. 6 – Other government.

The picture reveals three main patterns. 1) Agricultural and medical disciplines are supported primarily by governmental bodies. They too have experienced a greater influence of MEYS projects. 2) Project resources from MEYS dominate in the natural sciences and in engineering, although CSF still holds an important position in the natural sciences. 3) Humanities and social sciences largely depend on CSF for project funding. Their opportunities to obtain project funding from other providers are severely limited.

The figure 4 applies disciplinary resolution again to all sources of funding. Project acknowledgements account for only about 1/5 of all dedications in the humanities and social sciences and for about a half of the acknowledgements in the agricultural, technical and natural sciences. At this level, fields cluster differently than they did in the exclusively project segment. Medical, social and the humanities research report institutional support in the majority of dedications. Although Social Sciences and the Humanities depend most heavily on the CSF for project funding, project-based funding is generally less important in their overall publication output. Support from CSF is of greater importance in the Natural Sciences. This is illustrated by the fact that in 2015-2019, 14% of all dedications (i.e., including non-project sources) were attributed to CSF from the Humanities, compared to 20% in the Natural Sciences.

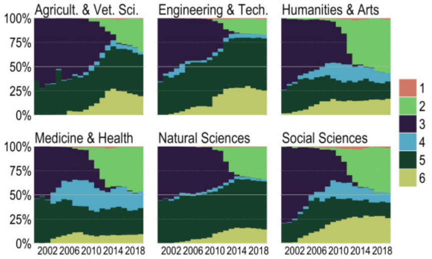

Fig. 4. Financial sources by field.

1 – Other public or private sources. 2 – Institutional support for development. 3 – Institutional support for research plans. 4 – EU Programs. 5 – Projects. 6 – Specific higher-education research.

The analysis did not consider the actual amounts of financial support. It also could not account for the influence of foreign funding providers. Despite these limitations, we can conclude that the strategic role of the national grant agency varies significantly across different scientific fields. Scientific funding agencies are a special space on the frontier of science policy and science itself (Braun, 1998). Thanks to expert panels and an emphasis on peer-review, the voice of the scientific community resonates in them. The state’s growing involvement in the project-based funding of science at the expense of the main national grant agency therefore signals an important shift in the relative autonomy of science funding mechanisms in the Czech Republic.

Acknowledgments

This research was supported by The Czech Science Foundation project no. GJ20-01752Y, “Funded and Unfunded Research in the Czech Republic”.

Using an Entitymetric Approach to Trace Novel Chemical Compounds for Research Impact

David E. Hubbard

hubbardd@library.tamu.edu
Texas A&M University, University Libraries, 5000 TAMU,
College Station, Texas (USA)

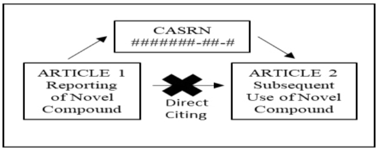
Introduction

This study presents an entitymetric approach (Ding et. al, 2013) to trace the use of novel chemical compounds through the literature to demonstrate additional research impact beyond traditional citations. The development of novel chemical compounds is the intellectual embodiment of the research of many organic chemists, and therefore worth tracing to capture a more complete picture of their impact. Citation-based approaches certainly capture some of the impact, though overlooks other aspects of impact. While this study focuses on chemical compounds, the concept could be more broadly extended to other material objects that contribute to advancing research (e.g., tools, software, etc.). The main purpose of this study is to outline the approach using a small set of journal articles from an individual researcher to illustrate the idea and process, as well as to determine if there are indeed occurrences where the novel chemical compounds are utilized and the original synthesis or isolation are not cited in the traditional manner.

Background

SciFinder is the most comprehensive bibliographic database in chemistry. In addition to abstracting and indexing the literature of chemistry and related disciplines, it assigns a unique Chemical Abstracts Services Registry Number (CASRN) to each new chemical compound reported in the literature that SciFinder indexes. CASRNs are themselves indexed, as well as linked to all future publications that use that compound. This provides a means to trace the first published report, which is often a synthesis or isolation of that compound, to any subsequent uses described in publications. Of particular interest are subsequent articles that use a novel compound in a substantive way (e.g., to facilitate a chemical synthesis or application), but do not cite the original article where the compound was first reported (Figure 1).

Figure 1. Linkage through an entity (CASRN)



There may be legitimate reasons for not citing the original article reporting the first novel synthesis or isolation. For example, the researchers may have synthesized the compound themselves through another synthetic process or purchased it. Furthermore, it is not a norm for chemists to cite articles associated with the first reported synthesis of every chemical utilized in experimental methods. So if such instances exist, this would represent a source of unrecognized research impact that can be traced through the scientific literature.

Literature review

There are no known studies that trace chemicals or CASRNs through the literature as described in this study. There are a few studies that have used the CASRNs to either select publications for a bibliometric study (Bornmann & Marx, 2013) or compound-based bibliometric studies that map and identify research gaps (Barth & Marx, 2012; Tomaszewski, 2019); however, the compounds in those studies were not traced as described in this study. A similar study, at least conceptually, is that of Ding et al. (2013) where an entity-entity citation network for the drug Metformin was used to identify connections with diseases, drugs, and genes. While the present study uses the concept of an entity (novel chemical compounds), its focus is on locating subsequent use of novel compounds where the original article reporting its first synthesis or isolation was not cited.

Methods

The publications of an organic chemist were identified in SciFinder for the following years: 2000, 2005, 2010, and 2015. The chemist's publications were refined to peer-reviewed journals reporting original research, so review articles and other types of publications indexed in SciFinder were excluded. The compounds, or rather the unique CASRNs associated with those compounds and designated as being "synthetic preparations" in the SciFinder record for each article were identified. Each of the hyperlinked CASRNs in SciFinder associated with those synthetic preparations in the article record were clicked resulting in all the publications mentioning that compound within SciFinder. If the oldest publication was the original peer-reviewed journal article of the organic chemist, the compound was deemed "novel" (i.e., the organic chemist was the first to report the synthesis or isolation of that compound in the literature). If the compound was novel, then all publications citing the CASRN were examined to: (1) determine how the compound was used in subsequent research, and (2) determine if the researchers cited the original article reporting on the first synthetic preparation or isolation.

Results

Table 1 summarizes the number of articles, chemical compounds, and number of novel chemical compounds by year for an individual organic chemist. It should be noted that subsequent use by the organic chemist reporting the original synthesis or isolation was excluded (i.e., "self-citation"), as were compounds associated with patent applications filed by the organic chemist since those were filed before the articles and therefore not novel. On average, 62% of the compounds synthesized in those articles were novel. Of the 230 novel compounds, 8 were utilized or mentioned in articles of other researchers (Table 2). Those uses (or roles) were characterized as being an intermediate (I), product (P), or reagent (R). These roles, and others, accompany the CASRNs listed in ScFinder records. The most interesting and potentially impactful instances are the novel compounds being used as reagents (i.e., starting material) to facilitate the synthesis of other chemical compounds; whereas the intermediate and product are reporting on its presence in the middle of a multistep synthetic reaction (intermediate) or new syntheses of the novel compound (product). The focus here was primarily on those being used as reagents, where there were five articles that utilized the novel compound as a reagent. Of those five articles, two did not cite the original article. So among the 230 novel compounds only 2 (or 0.9%) were used as reagents without citing the original article reporting the first synthetic preparation or isolation. Based on SciFinder, one compound is now commercially available (CASRN: 269749-51-1) and the other compound is not (CASRN: 871117-18-9). In the case of the former, the article does not cite an article or commercial source. In the case of the latter (CASRN: 871117-18-9), the article does not appear to contain a synthesis for that compound. Without contacting the authors of these two subsequent articles utilizing these two novel compounds, it is difficult to determine if the citations to the original synthesis were just not included (and therefore unrecognized impact) or if the two novel compounds were obtained through another means.

Table 1. Number of Articles, Compounds, and Novel Compounds

Year	Articles	Cmpds Prepared	Novel Cmpds
2000	8	126	95 (75%)
2005	5	80	65 (81%)
2010	4	123	43 (35%)
2015	3	43	27 (63%)
Total	20	372	230 (62%)

Table 2. Novel Compounds Subsequently Utilized, Roles, and Uncited

Year[a]	Novel Cmpds Utilized	Articles Utilizing Novel Cmpds and Role	Articles Utilizing Novel Cmpds and Role w/o Citing
2000	5	7 (1-I;2-P;4-R)	2 (1-I;1-R)
2005	1	1 (1-R)	1 (1-R)
2010	1	2 (2-P)	2 (2-P)
2015	1	1 (1-I)	1 (1-I)
Total	8	11	5

[a] Year only associated with the Novel Cmpds Utilized column.

Conclusion

This study demonstrated how the CASRN (an entity) can be traced through the literature, and that there were indeed occurrences where novel compounds are used by other authors without citing the original synthesis or isolation (0.9%). Based on the findings of this study, it is recommended that larger quantitative and qualitative studies are conducted to substantiate the scale of this impact and the nature of the omissions since this study was merely proof of concept. The manual methods employed in this study were very tedious and relied on a proprietary database. Therefore, it is also recommended that the process be automated to identify the uncited novel chemical compounds more efficiently, as well as explore the use of open chemical data sources containing CASRNs for increased accessibility and transparency.

A Bibliometric Mapping of Research on Quality Assurance in African Higher Education: a systematic literature review (from 1999 to 2019)

Introduction

The education sector, in general, and higher education institutions (HEIs) in particular, use 'quality' as a common term, yet the notion of quality is disputed and multi-dimensional (Ewell, 2010; Zabadi, 2013). Therefore, quality revolves around a few central ideas: quality as absolute; quality as relative; quality as a process, and quality as culture (Harvey & Williams, 2010; Kleijnen et al., 2013). Furthermore, quality can be based on the ability of an institution to fulfil the requirements of the academic community.

Quality assurance (QA) is the process of establishing stakeholders' confidence that the provision of education (inputs, processes, and outcomes) will fulfil the expectations of stakeholders. From the 1990s onwards, QA has been on the contemporary higher education (HE) agenda and has been prioritised around the world (Cardoso et al., 2019; Elken & Stensaker, 2018).

The economic value of higher education has led some scholars to examine the trends in QA research in higher education (Serrano-Velarde, 2008) to understand how quality can be maintained and improved for higher education systems.

The poster reflects the research we are doing on QA of higher education in Africa. Specifically, it shows a correlation between the increase in the number of students pursuing (higher) education degrees and the rise of literature on QA. We specifically focussed on QA in African higher education because, as African based scholars, we see first-hand the advantages that QA research can bring to the improvement of higher education as whole. Through a research methodology that uses systematic literature review, we have gathered information over a 20-year period (1999-2019) from the following four sources: WoS, Scopus, AJOL, Google scholar, as way to map the emerging field of research on QA in Africa.

Research problem

For over three decades, African countries have looked at tertiary education to make a significant contribution to economic growth and competitiveness, improve the quality of educational programmes and institutions (Wangenge-Ouma & Langa, 2011; Materu, 2007). This has resulted in a growing interest among scholars on how to manage QA through research based evidence (Al Jaber, 2018; Coates, 2005; Federkeil, 2008; Harvey & Williams, 2010). The evidence-based QA management endeavours to make QA processes more intelligible and rigorous. Through research the strong convictions and somehow fragile evidence that informs policy and public debates on QA in African HE is addressed.

However, while there has been a growing stock of knowledge and research-based evidence on QA through research, monitoring, and evaluation of African higher education, QA research remains not widely accessible to policy-makers and the larger public.

The scattered nature, organisation and management of QA knowledge, as in themes and approaches, has led to uninformed policy action to improve QA practice, especially in the African higher education context.

Therefore, this study seeks to produce a synthesised portrayal themes and approaches on the basis of scientific publications on African QA.

Research question

What kind of research has been conducted on QA in African HE published from 1999 to 2019, and its implication on policy and practices in the African higher education?

Methodology

Research design

To map the QA research, and its implication on policy and practices in the African HE, this study undertakes a systematic literature review focusing on QA research in Africa. Moreover, a bibliometric analysis is used to scrutinise books, articles, and other publications on African QA field.

Sampling

In executing this study, a purposive sample search of peer-reviewed articles, books, and proceedings in high rated journals, published from 1999 to 2019 on 54 African countries, has been conducted in the main scientific databases, namely Web of Science (WoS), Scopus, Google Scholar, and African Journal Online (AJOL). These main scientific databases are suitable for in-depth evaluation of complex issues (Creswell, 2014).

Data collection instruments

The data collection process was undertaken, first, through a systematic literature review focusing on QA research in Africa, based on PRISMA Statement (Moher et al., 2009). This procedure was then followed by a Bibliometric analysis and citation mapping process.

Data presentation and analysis

The data presentation and analysis is based on a combination between bibliometric analysis that relies on citation data and the visualization technique (Steinhardt et al., 2017; Alzafari, 2017; Swain, 2014; Hallinger & Chatpinyakoop, 2019). The study follows six steps (i.e., Research objectives; Research design; Bibliometric data collection; Methodology and software; Analysis and results; and Interpretation of findings) as summary of research design (i.e., adapted from Bragazzi (2019), and Zancanaro et al. (2015)).

Preliminary results

The primary purpose of the study was to investigate the state of art of the African QA emerging field of research through a systematic literature review. Table 1 and figure 2, show the rational and structural attributes of the African QA field of research conducted through bibliometric analysis.

Table 1. The African regions and countries evolvement in QA in HE research from 1999 to 2019 and retrieved from Scopus and WoS.

ID	Region	No.Article	Citation	Country with most impact	Percentage	
					No. Article (%)	Citation (%)
1	North Africa	5	9	Egypt (3/4), Morocco, Tuni	6	3,4
2	West Africa	14	29	Ghana (5/16), Nigeria (8/1	16,8	11,1
3	Central Africa	2	4	Angola (2/4)	2,4	1,5
4	East Africa	18	88	Kenya (5/56), Ethiopia (2/2	21,7	33,6
5	**Southern Africa**	44	132	**South Africa (41/127)**, Nan	53	50,4
6	**Whole Africa**	**83**	**262**		**100**	**100**

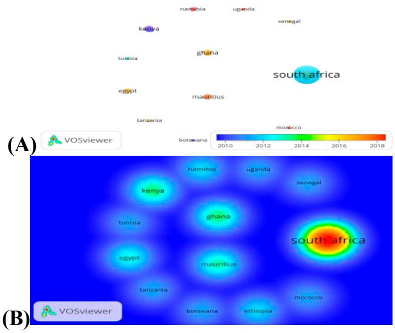

Figure 2: QA in African HE: (A) Countries' Citations Overlay visualization; (B) Countries' Citations Density visualization.

Based on table 1 and figure 2 (data from Scopus and WoS), the evolvement of African regions is visualized, especially from South Africa (SA). Therefore, figure 2A shows that, 50 articles of 83 were published between 2006 and 2015 signalling 56.9% of literature compared to all. Therefore, where 50.4% contribution were published from SA.

Conclusion

In conclusion, there is a lot of research and publication that has been done since 1999 to 2019. Therefore, the review looked at different approaches and themes to QA in African HE. Based on systematic literature review, QA research in Africa approaches to Individual based, Department based or Professional community-based at community level control, Regional level control, National level control, Continental harmonization, and international approaches.

As for the themes, we gathered themes as Definition of QA; Purpose or function of QA systems in different countries and regions; Methodology for quality assessment; Strategies to ensure quality; quality audits; Accreditation, national rankings and global rankings; and challenges, opportunities, globalization of QA.

Based on the data that we have now (table 1 & figure 2), looking into the selected research period, the preliminar results shows that papers published, from four sources, were 3 in 1999 to 503 in 2019 signalling 99.4 % of literature increase. Therefore, we can conclude that a lot of research and publication has been done since 1999 to 2019, when it comes to research on QA in African HE.

Measuring Altmetric Events: The need for Longer Observation Period and Article Level Computations

Mousumi Karmakar[1], Sumit Kumar Banshal[2] and Vivek Kumar Singh[3]

Introduction

The tracking and measurement of social media mentions to scholarly articles has gained a lot of attention during last few years. Some studies have exclusively focused their attention on the speed of accumulation of these altmetric events, concluding that the altmetric attention is quite quick to accrue but at the same time it may also decay quickly (Ortega, 2018; Haustein, 2019; Fang & Costas, 2020). It has been observed that most of the studies on measuring altmetrics use limited observation periods, usually ending when majority of altmetric events were seen. On the contrary, a careful look at the altmetric data for a larger observation period, shows that altmetric accumulation continues beyond the immediate-past of article publication. Further, previous studies have defined half-life value over a set of articles rather than doing an article-level delineation. This may be problematic given the fact that altmetric mentions to scientific articles vary by demography, discipline etc.

This article, therefore, attempts to demonstrate the weakness of using limited observation periods and set-level computations and emphasize the need for longer observation period and article-level computations for measuring the altmetric events. We show, through a large-sized data analysis, that the values of altmetric measures change if a longer observation period is taken. Further, it is also argued that computation of altmetric measures (such as half-life) should be done through an article-level analysis rather than computing for the whole set of articles.

Data & Methodology

The data for analysis was taken from 1,785,149 publication records for the whole world for the year 2016 as indexed in Web of Science (WoS). A total of 1,661,477 of the total records, had altmetric data (tweets) available in PlumX aggregator. PlumX gives the counts, including retweets, but more detailed information like tweet text, tweets, tweet date etc. is available only for the original tweets. Since we needed the date information for the tweets, therefore we have limited our analysis to original tweets only. Out of the total data, we selected 24,290 articles, that had a minimum of 8 original tweets. We obtained the creation date of article from the 'DOI creation date' field in Crossref. For each of the 24,290 articles, dates of all their original tweets are obtained by following the link 'Plum stable url' and scraping their original tweets. The crawling/ scraping have been performed using web-based crawler written in python programming language. To avoid overloading the server a random delay between 10 to 180 seconds has been put after each step. This way we have obtained tweet data along with the time line for the set of 24,290 articles over a period of 4.5 years.

To understand the dynamics of tweet accumulation around a scholarly article, two previously defined time-dependent variables have been examined. These time related measures, discussed and tested in recent studies, are namely, *half-life* and *velocity index*. The half-life measures the number of days to accumulate half of the tweets and can be defined by the following formula:

$$h = d(\sum tweets/2)$$

where, d is the number of days. The velocity index (VI) for any set of articles, at any time can be defined as the proportion of tweets accumulated until that time, defined as follows:

$$VI = \frac{P_i}{TP_i}$$

where, P_i = tweet accumulated until specified time, TP_i = total tweets during the observation period.

Results & Discussion

The article mainly computed two time-oriented measures, the half-life and the velocity index (VI). First, we describe how these computations are affected by taking longer observation period and thereafter the impact of article-level computations are presented.

Longer observation period

While previous studies used a shorter time span for half-life & VI computations, we wanted to demonstrate that taking a longer period is likely to

Table 1: Tweet half-life values for data from different observation periods

	180 days	360 days	540 days	720 days	900 days	1080 days	1260 days	1440 days	1620 days
Half-life	6	8	12	15	19	24	30	36	41

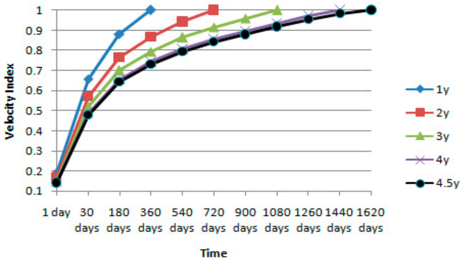

Figure 1: Variation in Velocity Index with different observation period

change these values significantly. **Table 1** presents the half-life values of the set of articles computed for different observation periods, varying by 6 months. These values are computed over the whole set. It is observed that the half-life for 6 months period is only 6 days. For 1.5 years period, it becomes 12 days, indicating that taking data for one more year, doubles the half-life value. For 2-year observation period, the half-life is 15 days. Our results show half-life of 41 days at the end of 4.5 years, which is 3 times more than that reported by Fang & Costas (2020). These values indicate that tweets keep on accumulating over a much longer observation period, unlike the commonly held belief that tweet accumulation decay quickly.

The velocity index (VI) values have also been computed at different time intervals for different observation periods, as shown in **Figure 1.** It can be observed that for a 1-year time window, 19% of total tweets accumulate during 1st day and about 88% tweets accumulate during 6-months. When the observation period is extended further, the velocity index values at the same time interval change significantly. Thus, moving from observation period of 1-year to 4.5 years, it is observed that only 62% tweets are accumulated during the 1st year i.e., 38% more tweets accrue afterwards. This is different from observation of Fang & Costas (2020), which found that 90% of the tweets accrued within the first year. Therefore, it is better to take longer observation period for computing different time related measures of altmetric events.

Article-level computations

The previous studies have computed the half-life and VI values at the level of the whole set of articles. Given that altmetric distributions are highly skewed, computing the half-life and VI values at the set level fails to capture the skewness in the distribution, rather the outliers may introduce distortions in the computations.

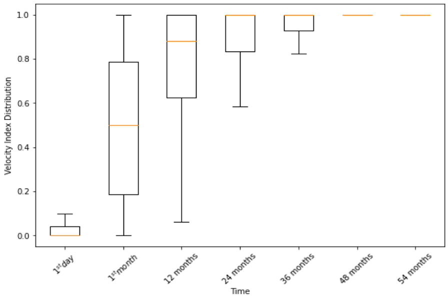

Figure 2: Variation in Velocity Index (VI) for the articles

Figure 2 shows the values of VI for the entire set of articles at different time intervals. On the first day, the VIs of all the articles is nearly 0 except for some outliers. For the 1-month period, variation in VI values is found to range between 0.2 to 0.8. Similarly, for 1-year period, the VI values for articles range from 0.6 to 1.0. Similar variations are observed for other time intervals. The computation of half-life shows a similar pattern of variations. Thus, a set level computation of half-life and VI may not be a suitable representation of the wide range of values for different articles. Further, the high variation in VI observed in the shorter observation periods, which diminish as we go for longer observation period of 4 years or more, also supports the need for longer observation periods.

Conclusion

The analytical results show that using different observation periods change the measured values of the time-related measures. The results imply that longer observation period should be used for appropriate measurement of altmetrics. Further, the use of article-level delineation for computing the measures is advocated as a more accurate method to capture the true values of such measures.

Introduction

Dedicated to specific research tasks applications can vary in the scope of functions, usability degree, audience, specialization, and architecture. Crucial front-end features of software include its structure, language, examples, syntax and form and associated documentation. Video tutorials have an attractive form that can not only help in making decisions but can also educate on the various tool functions. Many well-prepared tutorials help with broadening the audience for these tools; the number of videos about any topic can be correlated with topic's popularity.

Science mapping (SM) and visualization is largely a practical field in which the accessibility of tools and proficiency in their use, as well as knowledge about bibliographic databases, statistics, and visualization techniques, determine the success of complex, multifaceted analyses. SM researchers have analyzed different sets of tools. The largest and most complete set contained 20 software examples (Chen, 2017; Bankar & Lihitkar, 2019; He et al, 2019) and Gephi (Bastian, 2009).

The authors decided to compare a set of SM tools in terms of functionality, usability, and tutorial accessibility on the web. They also strove to determine if these areas had any influence on each other. Information architecture (IA) and usability expertise review and YouTube statistics were used to examine the most significant scientometric tools since their creation.

For the current work, the authors composed a final set of SM software, the common in previous studies. The final list consisted of eight applications: Pajek (1996), CiteSpace (1999), HistCite (2004), Gephi (2009), Sci2 (2009), VOSviewer (2010), SciMAT (2016), and CitNetExplorer (2017). The period of comparison extends over 25 years, distributed across the decades.

Methods

If we study accessibility and the usage of the tools' tutorials published on YouTube or other social media, we can evaluate the popularity of a specified software tool among users (i.e., researchers). This perspective of studying the footprints of tutorials on the web has been termed *tutmetrics*. Usability and feature analysis help determine the best and most versatile ones. In the tool comparison, both the professional experience in user experience (UX) and software usability of the authors were used.

Results

Statistics of tool use

Selected tool references were examined in WoS database. A query was constructed by entering each name in the topic field and excluding the others. The Table 1 contains comparison results according: tools life length and its footprint from the WoS literature and YouTube. The usage index according to the WoS means the number of articles related to the tool, normalized by its life length. Similarly, the second usage index was calculated using the number of YouTube tutorials.

Availability of video tutorials

Data were obtained for 350 uploaded video tutorials. The total number increased from nine (in 2010) to 49 (2018) and then 84 (2019). Dynamic data of the uploaded tutorials is omitted due to publishing limitations. It should be noted that the delay time from the initial publication year of a tool to its first video tutorial varied: 0 (SciMAT), 1 year (Gephi), 3 years (Sci^2), 5 years (VOSviewer), eight years (HistCite), 13 years (Pajek), and 15 years (CiteSpace).

The titles of the video tutorials were also analyzed in terms of frequency (excluding the names of the tools and authors). The most common words in the titles were: "tutorial," "network," "analysis," and "introduction" and the phrases: "network analysis," "avaliar produção," "bibliometric analysis," "citation analysis," and "social network". The languages of the videos are shown in Figure 1.

Expert assessment of usability features

To easily operate the tool and classify it as user friendly, expert review had to be applied in two main categories: information architecture (labelling, navigation, organization, help system) and the tool's usefulness based on its features.

Table 1. Usage of the most important tools for SM since 1996

Application	Cite Space	VOS viewer	Gephi	Pajek	Hist Cite	Sci MAT	Sci^2 Tool	CitNet Explorer
Life length	21	10	11	24	16	4	11	6
Articles	824	754	324	261	151	79	37	20
Usage index in WoS	40.0	75.4	29.5	10.9	9.4	19.8	3.4	3.3
Number of video tutorials	15	40	187	45	43	9	9	2
Usage index on YT	0.7	4.0	13.4	1.8	2.7	1.1	0.8	0.0

The last ones related to the accessibility of functions, such as format compatibility, visual layout choice, clustering, labeling, filtering, statistics, and the manipulation available to the user. The full process of interaction with the software starting from installation and ending with generating visual layouts was evaluated using a 6-point scale. Because of limited space the detailed table cannot be presented. Aspects that needed time measurements were tested on the same larger dataset to standardize the conditions.

Discussion and conclusions

The top ranks in both the scientific literature and YouTube reflect the modern generation software. The ranking put the Gephi, which is highly visible in scientific databases and multimedia resources in the first place, while VOSviewer - in the second. Despite the high popularity of Pajek and CiteSpace in the literature, they were not largely represented on YouTube.

Gephi has been seen on YouTube since its initial release and has shown consistent growth. However, most of the tools had not been represented with any new videos for a few years. Gephi had more tutorials than all the other applications combined. The high number of English, Spanish, and Portuguese video tutorials suggests the dominating languages.

Expert analysis has shown that VOSviewer and Gephi have the best IA. Pajek's and HistCite's older layouts do not prevent them from being functional tools. Contextual hints and official video tutorials explaining features will also be helpful for all of the tools. Despite all the differences in visual and formal attributes, the identified tools can all be very useful for different needs.

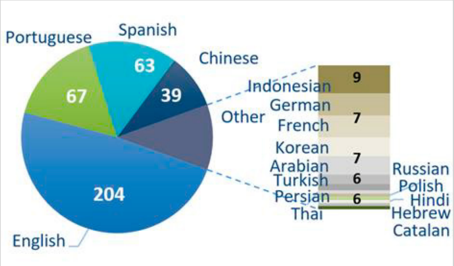

Figure 1. Frequency of the languages of the video tutorials describing SM tools.

SciMAT and CitNetExplorer, the most recent tools examined, were also scored highly in terms of usability and seem to have a focus on widely understood multidisciplinary SM.

The results suggest that there can be a correlation of tool feature usability with its presence in YouTube tutorials. The authors studied and compared these basic SM applications in terms of accessibility for learning and usability. They analyzed the accessibility of video tutorials on YouTube and application interfaces in terms of information architecture. A new term was introduced, tutmetrics, to emphasize the importance of the current study in the context of the multidisciplinarity of mapping scientific literature.

Only three of the considered tools were referenced frequently by both scientific articles and YouTube tutorials: modern generation, user-friendly software VOSviewer and Gephi and Pajek with the longest history. It is worth noting that the very popular, as well as traditional, bibliometric software CiteSpace was practically invisible on YouTube; thus, from these correlations, we cannot make definitive statements about effect-causal relationships. Does high popularity among researchers and high usability generate more tutorials, or does a large YouTube tutorial space imply the use of the tool for research? These questions suggest new possibilities for tutmetrics in future research.

Introduction

Academic journal covers are important tools for attracting reader attention. Major journals regularly promote covers and featured papers, resulting in high traffic on their websites (Wang et al., 2014). Citation count is a prominent indicator of a paper's influence (Didegah & Thelwall, 2013), considered a standard, objective, and straightforward measure (Yan et al., 2012). Article usage data allow direct exploration of usage preferences (Wang et al., 2016; Chen, 2017). Usage reflects users' extensive attention behaviour, and summarises two types of use data: (1) times downloaded and (2) times citation exported. We obtained U1 (last 180 days) and U2 (2013–present) usage information.

After comprehensive consideration, we selected papers in Nature as our research objects. This study aims to address the following: What are the differences between cover and non-cover papers in terms of (1) citations, (2) usage, and (3) subject areas and research terms?

Data and Methods

To ensure a specific citation time window, the publication time interval was set to 2011–2015. The dataset collection work, completed in February 2021, yielded 503 cover papers and 5356 non-cover papers. A Python program crawled nature.com article pages for article subjects in physical sciences, earth and environmental sciences, biological sciences, health sciences, and scientific community and society (see Table 1 for number of subjects per discipline). Indicator data tags from WoS are publication year (PY), WoS Core Collection Citation frequency count (TC), U1, and U2. We analysed means, correlation coefficients, and interdisciplinarity. All statistical analyses were conducted using Python and Stata 15.1.

Table 1. Subjects in Nature

No.	Discipline	Disciplinary subjects
1	Physical sciences	576
2	Earth and environmental sciences	44
3	Biological sciences	1518
4	Health sciences	604
5	Scientific community and society	32
Total	5	2774

Results

Analysis of geometric means of citations and usage. The geometric means of TC, U1, and U2 were higher for cover papers than for non-cover papers (Figure 1); a yearly increase is observed in the difference between them. The TC and U2 of the 2012 cover papers are higher because of two important studies, a review of "A roadmap for graphene" (https://www.nature.com/articles/nature11458) and a paper on the healthy human microbiome (https://www.nature.com/articles/nature11234).

These results further show that Nature's papers conform to the citation rule: the best citation period is roughly 3–8 years.

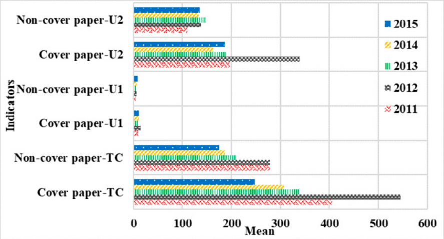

Figure 1. Annual geometric mean of TC, U1, and U2 of cover and non-cover papers.

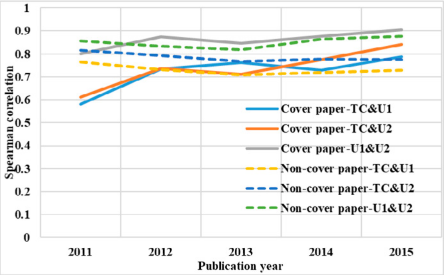

Figure 2. Annual Spearman correlations of TC, U1, and U2 of cover and non-cover papers.

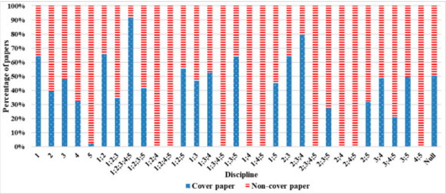
Correlation analysis of citations and usage (Figure 2). Analysis of Spearman correlation annual evolution trends among TC, U1 and U2 shows that the correlation coefficient of cover papers fluctuated significantly and almost higher; for non-cover papers it was relatively stable and almost lower.

Interdisciplinary papers include research terms involving two or more disciplines. First, papers in a single discipline comprise 53.68% of cover papers and 53.70% of non-cover papers. Papers in two or more disciplines comprise 41.95% of cover papers and 40.36% of non-cover papers. Percentages of papers in two and three disciplines were higher in cover papers, but the differences were not significant. The proportion of physical sciences papers in cover papers is higher. The proportion of interdisciplinary physical sciences and earth and environmental sciences and of earth and environmental sciences and biological sciences in cover papers is higher. Moreover, most cover papers have higher cross-disciplinary ratios than do non-cover papers (Figure 3).



Note:1=Physical sciences; 2=Earth and environmental sciences; 3=Biological sciences; 4=Health sciences; 5=Scientific community and society.

Figure 3. Interdisciplinary comparison of cover and non-cover papers.

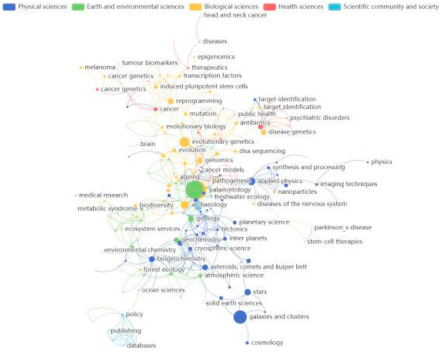


Figure 4. Interdisciplinary subjects of cover papers (Top 50, each discipline).

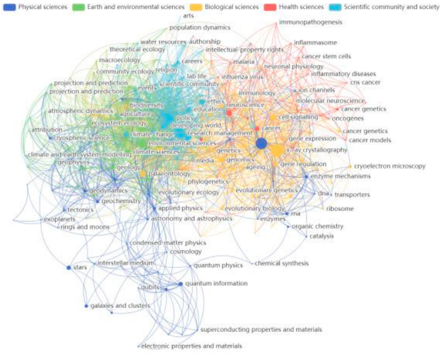

Figure 5. Interdisciplinary subjects of non-cover papers (Top 50, each discipline).

Second, there are significant differences in the Top 50 research subjects by discipline between cover and non-cover papers, and different subject clusters are apparent. Subject concentration and degree of subject crossover is higher in cover papers (Figure 4, 5).

Conclusions

Cover papers, as expected, gain more citations and usage compared to non-cover papers. Cover papers have unique high visibility and knowledge dissemination advantages. Within each discipline, certain research topics show interdisciplinary patterns. Inherently "better" articles are more likely selected as cover papers for their inherent quality and anticipated higher metrics and publicity (Phillips et al., 1991). In the future, we will analyse specific interdisciplinary research topics in cover and non-cover papers with different citation and usage rates. With frequent complexity, comprehensiveness, and integration problems, intersection and integration tendencies among different disciplines are increasing. However, it is necessary to analyse the specific knowledge crossover and fusion in the text content of crossover science.

Introduction

We often read from articles in trade magazines and academic journals that an organization is referred to as a technology leader or follower. These terms are used by the article authors either quite arbitrarily or based on some proxy measures such as number of patents and their forward citation counts. This study is intrigued by the idea that whether this kind of *positioning* can be achieved *quantitatively* and more directly, rather than through proxies or speculation.

Related works may be categorized into two main approaches. The first approach positions organizational entities in a densely/strongly connected core or a loosely/weakly connected periphery following the core/periphery model proposed by Borgatti and Everett (2000). The other approach positions the entities relative to an evolutionary trajectory of the field (cf. Bekkers & Martinelli, 2012; Kim, Lee & Kwak, 2017), where the trajectory is unanimously derived using main path analysis (MPA) (Hummon & Doreian, 1989).

This study also follows the second approach for patent assignees but differs from the prior works in two main respects. Firstly, this study only requires that there are a number of representative patents reflecting knowledge evolution, regardless of how they are derived. Secondly, each assignee is associated with a number of position attributes, reflecting its multi-faceted positioning characteristics, thereby offering finer and more comprehensive analysis.

Position attributes

By considering that a technology field's patent citation network embodies a knowledge system for the field, and that a series of MS patents constitute the evolution trajectory, each patent of the technology field is identified to be at one of five possible positions relative to the series of representative patents: *mainstream* (MS), *forward and backward reachable* (FBR), *backward reachable only* (BR), *forward reachable only* (FR), and *non-reachable* (NR), based on whether they are on the trajectory and their reachability to and from the representative patents.

For the representative patents reflecting the field's knowledge evolution, they are said to be at MS positions, such as those denoted by the black nodes of Figure 1. A NR patent is one whose node cannot reach the nodes of the MS patents and vice versa, such as those denoted as white nodes in Figure 1. A FR patent is one whose node cannot reach those of the MS patent but may be reached by at least a node of the MS patents, such as those denoted by nodes 1-3 and 11-13. BR patents, denoted as nodes 16-17 and 25-27, are those whose nodes may reach at least one node of the MS patents but not the other way around. A patent whose node is both backward reachable from and forward reachable to at least one node of the MS patents, such as the node 15 is referred to as a FBR patent.

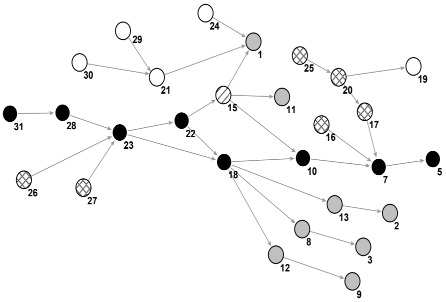

Figure 1. A portion of a real patent citation network.

After the positions of an assignee *i*'s patents are identified, assignee *i* can be characterized by five *position attributes* (MS_i, FBR_i, BR_i, FR_i, NR_i), which are shares of its patents at the respective MS, FBR, BR, FR, and NR positions.

Assignee classification

An assignee can be classified as a *uniquely positioned* or *multiply positioned* assignee, based on its position attributes. There are five types of uniquely positioned assignees referred to as *trendmakers*, *onlookers*, *leaders*, *followers*, and *boosters*, whose definitions are listed in Table 1. Trendmakers are assignees owning at least one MS patent. Onlookers are those having only NR patents, and their patents are completely irrelevant to the field's evolution. Leaders are those having only BR and NR patents, and these BR patents must lead ahead of and furnish knowledge to one or more MS patents. Follower*s* have only FR and NR patents, and their FR patents must lag behind and draw knowledge from at least one MS patent. Boosters have only FBR and NR patents, where their FBR patents not only draw knowledge from some earlier MS patents but also feedback knowledge to some later one.

Table 1. Position attributes for uniquely positioned assignees.

	MS	FBR	BR	FR	NR
Trendmakers	> 0	-	-	-	-
Boosters	0	> 0	0	0	-
Leaders	0	0	> 0	0	-
Followers	0	0	0	> 0	-
Onlookers	0	0	0	0	1

*'-'stands for 'don't care.'

There are four types of multiply positioned assignees as defined in Table 2. These assignees have mixed FBR, BR, and FR patents and, unlike the uniquely positioned, they assignees cannot be classified as having a specific position.

Table 2. Position attributes for multiply positioned assignees.

	MS	FBR	BR	FR	NR
Booster/ leader	0	> 0	> 0	0	-
Leader/ follower	0	0	> 0	> 0	-
Booster/ follower	0	> 0	0	> 0	-
Booster/ leader/follower	0	> 0	> 0	> 0	-

*'-'stands for 'don't care.'

Case study

27,161 U.S. biochip utility patents granted before 2019/3/31 are collected as case study, where the field's evolution trajectory is derived using MPA (with SPNP weight assignment and global search method). It is found that each of the 5,921 assignees involved (after disambiguation) can be classified effectively into exactly one of the uniquely and multiply positioned categories, as shown in Table 3.

Summary and Limitation

In this study, patent assignees are associated with positioning attributes through which they are classified into categories of distinct characteristics. A case study using MPA confirms the validity and simplicity of the proposed method. A major drawback of the proposed method, which will be dealt with in future study, is that it ignores the distance (e.g., number of "hops") to the MS patents. Therefore, the proposed method cannot tell whether some assignees are more directly influenced by or more contributing to the MS patents than others.

Table 3. Distribution of biochip patent assignees.

	Categories	Share
Uniquely positioned assignees 5,768 (97.42%)	Trendmakers	25 (0.42%)
	Boosters	2 (0.03%)
	Leaders	271(4.58%)
	Followers	1,124(18.98%)
	Onlookers	4,346 (73.40%)
Multiply positioned assignees 153 (2.58%)	Booster/ leader	3 (0.05%)
	Leader/ follower	118 (1.99%)
	Booster/ follower	12 (0.20%)
	Booster/ leader/follower	20 (0.34%)

Introduction

The goal of this paper is to analyse how research has been undertaken during the Coronavirus pandemic. Scientific production about Covid-19 has increased rapidly along with conventional reviews, research synthesis studies and bibliometrics analyses. This paper is not about Covid-19 per se, rather scientific research in general during the pandemic. What types and volumes of research outputs have institutions, countries and disciplines produced during this time?

Research questions

• What research has been produced during 2020?
• What relationships are there between research entities e.g. number of publications/grants received?
• Which research institutions and countries have been the main actors in research during this period?
• Which disciplines have produced the most outputs?
• Has there been a greater number of open access publications than in the previous year?
• Have more preprints been shared in 2020?

Data and methods

The Dimensions database was used to collect data. We have focussed on the year 2020. Dimensions was used rather than Web of Science or Scopus as it contains the types of data we needed for this study: grants, datasets, publications (including preprints), citations, clinical trials and patents. The searches for retrieving the data were last updated on 5 Jan 2021.

Results

There was no significant increase in the number of publications produced in 2020 compared to previous years. In fact, there was higher growth in 2019 compared to 2018 than in 2020 compared to 2019. Although this could be affected by the fact that it has been possible to produce less in general but more COVID related which could make to balance the total amount of scientific production. A future analysis could analyze this circumstance in more detail to expose the reasons.

The Publications score shows high statistical correlation for Citations (0.940), Grants (0.90) and Clinical trials (0.82). Citations are highly correlated with Patents (0.83) and Grants (0.798). The Citations metric is also correlated with Datasets (0.774).

Table 1. Correlation matrix (Spearman) of content types.

Variables	PUBLICATIONS	CITATIONS	DATASETS	GRANTS	PATENTS	CLINICAL TRIALS	POLICY DOCUMENTS
PUBLICATIONS	**1**	0.940	0.749	0.909	0.811	0.826	0.335
CITATIONS	0.940	**1**	0.774	0.798	0.833	0.709	0.246
DATASETS	0.749	0.774	**1**	0.816	0.660	0.577	0.302
GRANTS	0.909	0.798	0.816	**1**	0.728	0.824	0.357
PATENTS	0.811	0.833	0.660	0.728	**1**	0.723	0.097
CLINICAL TRIALS	0.826	0.709	0.577	0.824	0.723	**1**	0.280
POLICY DOCUMENTS	0.335	0.246	0.302	0.357	0.097	0.280	**1**

Results indicate that the main types of research objects are highly correlated, indicating that the entire research ecosystem from inputs (grants) to outputs (publications) are interconnected.
N.B. correlation does not necessarily mean causation, there may be additional factors involved.

Comparing scientific production

The US and China have the highest number of publications, citations, datasets, grants, patents and clinical trials. Along with the UK they have also received the highest number of citations. Japan has more grants but does not generate more research outputs compared to other countries.
Harvard University, the University of the Chinese Academy of Sciences and the University of Toronto produced the most research. However Huazhong University of Science and Technology (HUST), Tsinghua University (THU) and the University of Oxford are have received the greatest academic impact. The University of Tokyo (UT), University of São Paulo and Shanghai Jiao Tong University have received the largest number of Grants.

Fields of research

The fields with the highest number of publications during 2020 were: Medical and Health Sciences (1,411,939), Engineering (721,491) and Biological Sciences (402,377). These have also received the highest number of Grants. However Biological Sciences (108,699), Information and Computing Sciences (100,270) and Environmental Sciences (57,752) are those with the highest number of Datasets.
Medical and Health Sciences, Engineering and Biological Sciences have both the highest number of publications and the highest number of Grants. There are fields e.g. History that have received a greater number of Grants but have published comparatively

fewer outputs. We take into account the different publication patterns across different disciplines.

Open access and preprints

Through the pandemic, researchers have embraced open publishing platforms and preprint servers to share their findings.

Table 2. Comparison Articles and Preprints

	2020- >2020	2019	2020- >2020	2019
	Articles		**Preprints**	
	4,501,885	4,274,495	401,375	271,830
Academic impact				
Citations	3,620,290	9,803,129	120,662	52,668
Citations (mean)	0.8	2.29	0.3	0.19
Publications with citations %	22.5	44.13	6.9	8.06
Altmetric Attention				
Publications with attention %	26.37	25.28	53.22	50.54
Altmetric Attention Score (mean)	15.97	12.74	11.04	6.77

The growth of preprints has been greater than articles, however articles have received higher citations. Total citation rate of preprints has increased presumably associated with time lag for citation in peer reviewed literature. This may indicate that preprints are citing other preprints. The Altmetric attention score is higher for articles than preprints but Preprints have more publications with Altmetric attention.

Table 3. Comparison by different type of publications

OPEN ACCESS	Publications	Citations	Citations mean	Publications with citations %	Publications with attention %	Altmetric Attention Score (mean)
Closed	3,111,542	1,513,034	0.49	18.64	19.04	9.54
All OA	2,856,997	2,350,072	0.82	18.33	29.56	18.92
Gold	2,283,109	1,900,341	0.83	18.56	24.21	21.75
Green, Accepted & Submitted	391,495	187,038	0.48	15.13	52.75	8.31
Green, Published	182,393	262,693	1.44	22.35	46.77	26.3

The number of closed publications exceeds that of open access. However, All OA has a higher citation mean (0.83) than Closed (0.49). Publications made open access via the green route have received the highest rate of citations per publication (1.44).

In Medical and Health Sciences, Biological Sciences and Physical Sciences more articles have been published open access than closed. Engineering, Information and Computing Sciences and Chemical Sciences have published more closed than open access. Citations per document from OA publications are higher in the Medical and Health Sciences (1.87) than from Closed publication (0.52), however Engineering has received more citations to Closed publications (1.03).

The following graph shows three variables, number of datasets, publications and citations. The US and China have the largest number of Datasets and Publications. However, despite fewer publications and datasets, the United Kingdom and Italy surpass them in citations per publication.

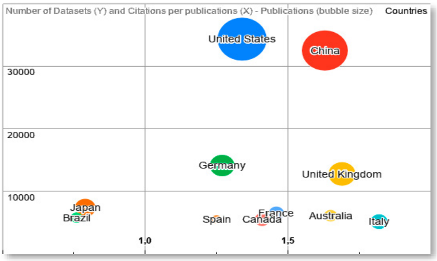

Figure 1. Comparison of datasets per countries

Conclusions

Our results suggest the following:

- Total scientific production in 2020 was 5,949,189 research outputs (Dimensions)
- The fields with the most publications are Medical and Health Sciences, Engineering, and Biomedical Sciences
- The three countries that have produced the most research are the US, China and the UK
- Research activity has not been unduly affected by Covid-19
- OA publications have higher citations (mean) than the closed publications. In particular via the Green route
- The growth of Preprints has been greater than for Articles.
- As expected the entire research system from inputs (grants) to outputs (publications) is interconnected. It is worth clarifying that not all research begins with a grant.

Introduction

Named-entity recognition is a fundamental and critical task in natural language processing, which is widely used in relation extraction, question and answering systems, semantic analysis, machine translation, etc. The current main approaches to named-entity recognition can be grouped into 3 categories: rule-based approaches, statistical-based approaches, and deep-learning-based approaches. Among the statistical-based approaches, CRF (Conditional Random Field) performs the best. Han et al. (2013) conducted a study on Chinese named entity recognition using the CRF model based on the characteristics of Chinese. In recent years, deep-learning-based approaches have become the mainstream approach for named- entity recognition research. Ali et al. (2019) used a method that combines multi-attention layer mechanism with LSTM (Long Short-Term Memory) for Arabic named-entity recognition. Jia and Xu (2018) proposed a CNN-BiLSTM-CRF based neural network model to simplify the Chinese named-entity recognition task. Li et al. (2020) used BERT (bidirectional encoder representations from transformers) and LSTM-CRF models to deal with the problem in Chinese clinical named entity recognition.

Citation author is the author whose work has been cited in an article. There are many studies on the subject of author co-occurrence network, however, recognition of citation author in academic texts is still insufficiently studied. Therefore, this study applies BERT and CRF models to recognizing citation author in academic texts, which may be helpful for subsequent analysis of author co-occurrence and deduction of author's similar research domains.

Data source and methods

Data source

In this study, data were from 696 published articles in *Journal of the Association for Information Science and Technology* (*JASIST*). These articles were published during the period 2016-2020.

After manual labelling, the citation author entities in JASIST full text are tagged. Some of the sentences that labelled with the citation author are shown below.

"An ontology is a semantic scheme that comprises the main classes (concepts) of a given domain of knowledge, their properties, interrelationships, and instances (<Citation Author> Noy </Citation Author> & <Citation Author> McGuinness </Citation Author>, 2001)."

"<Citation Author> Magatti </Citation Author>, <Citation Author> Calegari </Citation Author>, <Citation Author> Ciucci </Citation Author>, and <Citation Author> Stella </Citation Author> (2009) introduced an approach for labeling topics that relies on two manually labeled hierarchical knowledge resources: the Google Directory and the Open Office English Thesaurus."

The position of the 'citation author' appearing in the sentence can be roughly divided into two categories: one appears in parentheses at the end of each sentence, while the other appears more often at the beginning of the sentence.

Methods

The BIES (Begin, Inside, End, Single) method (Zhenget al., 2017) was used to label the citation author , while the other words were labelled by O. Specifically, citation author containing only one word are labeled as ywzz-S. For citation author consisting of two words, the first word is labeled with ywzz-B while the last word is labeled with ywzz-E. In addition, for citation author consisting of more than two words, they are labeled with ywzz-B, ywzz-I, and ywzz-E for the first, middle, and last words, respectively.

In this paper, the pre-training language model BERT is used, while the machine learning model CRF is used as a comparison experiment.

In the field of deep learning, BERT is a model with a bidirectional transformer structure proposed by Devlin et al. (2019), it applies attention mechanism to mine relationships between inputs and outputs. And In this work, citation author in JASIST texts are recognized by BERT pre-training model.

As for CRF, which belongs to the field of machine learning, is a probabilistic undirected graph discriminative model that solves the problem of labeling bias in sequence labeling for HMM and MEMM models. In this article we have used the open source toolkit CRF++0.58 and set NUM in -f

NUM to 2 (the default value is 1), as in tests -f 2 works better than the default value.

Results

A large number of pre-experiments were performed in the training of the BERT model. The final pre-training model with 12 layers, 748 hidden units, and 12 self-attention heads is applied in this paper. The values of the hyperparameters are as listed below: maximum sequence length 128, batch size 32, learning rate 2e-6, number of epochs 3.0, case insensitive. The reason for setting the hyperparameters in this way is that we found reducing the learning rate was effective in increasing the F1-value, while expanding the maximum sequence length had almost no effect on the F1-value. In addition, the effect when epochs = 10.0 is rather less effective than that when epochs = 3.0.

Then the 10-fold cross-validation tests were performed with BERT and CRF models respectively. The performance of each model was evaluated by P, R and F1 values, and results are as shown in Table 1 in summary.

Table 1. Results of Ten-Fold Cross Validation

NUM.	BERT	CRF
1	93.38%	91.62%
2	93.07%	90.32%
3	95.03%	90.96%
4	87.37%	85.03%
5	96.12%	92.88%
6	94.82%	93.25%
7	97.10%	94.38%
8	91.53%	81.47%
9	87.33%	62.99%
10	89.35%	61.68%
AVG_F1	92.51%	84.46%
MAX_F1	97.10%	94.38%

According to the above data, we plotted the maximum F1value and the average F1 value of the ten trials as histograms displayed in Figures 1.

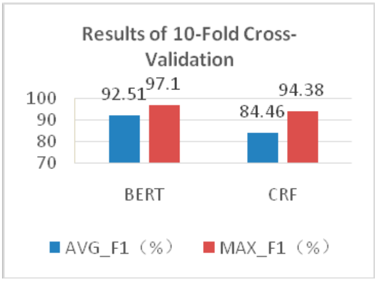

Figure 1. Histogram of average F1 value and maximum F1value of two models (BERT and CRF) in 10-fold cross-validation tests

It can be seen that the results of BERT are higher than those of CRF, regardless of the maximum F1value or the average F1 value. Overall, the average F1 values of both BERT and CRF are higher than 80%, indicating that the recognition effect of both is not generally satisfactory. Moreover, the optimal effect of BERT is better than that of CRF.

Conclusions

This study employed the BERT model and CRF model to extract the name entities of authors from the academic full text of JASIST (2016-2020). The average F1 values of both models is above 80%, and the optimal F1 value 97.10% is obtained by BERT. Although the recognition effect is acceptable, there is still room for improvement in this paper. In the future, to explore the distribution of citation author names in articles and better serve author co-occurrence studies, standardizing entity annotation, making the name of the same author consistent in expression and combining research questions of the citations, research methods of the citations are feasible solutions.

Introduction

In the knowledge mining of academic full texts, the sentences about the research question usually indicate the research purpose and research topic of the paper, and have the function of leading the whole text and revealing the experimental content. Extracting this kind of content from literature is of great value for structural analysis, content analysis and bibliometrics analysis of texts. In terms of textual structure, these sentences tend to appear in the first part of academic texts. In terms of paragraphs, these sentences mainly appear in the abstract and introduction, but less frequently in other paragraphs. However, there are few researches on the recognition of research contents in academic texts. At present, manual and rule-based matching methods are mainly used to extract sentence entities in academic texts. For example, Chu (2017) analyzed the distribution of research methods in different academic journals by means of manual annotation. Gupta (2011) creates vocabulary matching rules for the entities in the paper so as to extract concerning sentences. However, the former of these two methods needs to spend a lot of manpower and time, while the latter needs to manually construct rules from a large number of annotated texts, which is faced with the problem of low accuracy and comprehensiveness of extraction. In this paper, machine learning and deep learning methods are adopted respectively, and three models, SVM, Bert and SciBERT, are adopted to recognize the sentences related to the research questions in *JASIST* academic papers. We compare the effect of three models in identifying sentences, and selects the model with the best effect to provide methods and ideas for subsequent research.

Dataset & Method

Dataset

The data used in this paper came from 502 full-text papers which published in *JASIST* Journal from 2017 to 2020.A total of 19 types of entities in the data set were annotated by manual annotation method, and all sentences labeled as research questions were extracted. The specific information of the corpus is shown in Table 1.

Table1. Basic Information of our Corpus

No.	Item	Count
1	Papers	502
2	Total Sentences	54,479
3	research questions sentences	1,940
4	Marked sentences in each article average number	3.86
5	Average words number in each sentences	27.99
6	The longest sentence words number	255

Sentences labeled as research questions usually contain a description of the specific research object, a description of the specific purpose of the research, and a plan of the experimental process. The contents of some annotated sentences are shown in Table 2.

Table2. The Information of some annotated sentences

Reasonsfor annotating	Annotated example
Research purpose	…,The primary goal of this study was to start to ascertain what impacts the development of … .
Description of the subject	We study the problem of how to detect the temporal patterns of …. .
Planning of theexperimental process	RQ2： What are the spatial（physical） characteristics of indoor web use？

Methods

Our experiment belongs to the text classification task in natural language processing. In this experiment, SVM (Support Vector Machine) was used as machine learning model, and Bert and SciBERT were used as deep learning models to verify the recognition effect of traditional machine learning methods and deep learning methods on data sets. SVM model is dedicated to finding the optimal hyperplane, which can separate the training samples and make the differences between different classes as obvious as possible, and in this experiment, TF-IDF is used to vectorize text. Bert (Devlin, 2018) is a pre-training model open source by Google in 2018. This model is based on multi-layer bidirectional transformation and decoding, and relies on two processes, pre-training and fine-tuning, to perform natural language processing tasks. The model achieved the best performance in 11 different NLP tests, which makes it one of the most effective models in NLP. SciBERT (Beltagy, 2019) is a pre-training model based on the Bert framework and trained by the academic paper corpus containing 1.14 million academic papers. Scibert built a new vocabulary based on the scientific corpuses, which overlapped 42% with the vocabulary of Bert-base. The effect of this model is better than Bert indownstream tasks of identifying academic text. However, this model has not been tested on corpus related to LIS.

Result

Based on a large number of preliminary experiments, the pre-training model of 12 layers, 768 hidden units,12self-attention heads and 110M parameters published by Google was selected. In the experiment, the same parameters were set for both Bert and SciBERT: epoch is 10, max-seq-length is 512, batch size is 32, and the learning rate is 2e-5. The parameters of the SVM model used are set as C= 2.0,kernel= 'RBF', gamma= 0.5. Our data set is divided into a training set and a test set in a 9:1 ratio. Three models were respectively used for 10-fold cross-validation of experimental data. P (accuracy rate), R (recall rate) and F (harmonic mean value) were used as evaluation indexes of the model, and the final results were shown in Table 3.

Table 3. Results of 10-Fold Cross-Validation on each model

Model	MAX-F or AVG-F	Non-Research QuestionsF-value	Research Questions F-value	Micro-AVG F-value	Macro-AVG F-value
SVM	MAX-F	98.09%	25.40%	95.29%	61.74%
	AVG-F	97.33%	18.18%	93.36%	57.75%
BERT	MAX-F	97.60%	56.35%	95.45%	76.97%
	AVG-F	97.07%	42.54%	94.44%	70.45%
SCiBERT	MAX-F	97.78%	59.54%	95.80%	78.86%
	AVG-F	97.78%	53.64%	95.76%	75.81%

The result shows that the SVM model recognition effect is poor. The recognition effect of Bert is not good, and the recognition effect of SciBERT is the best. SciBERT outperformed traditional machine learning models by nearly 20 percentage points. In the classification result, the maximum F value is 78.86%. The optimal result in the experiment is obtained by using SciBERT, which indicates that the use of pre-training method can effectively improve the classification effect on the data set of a specific domain.

Conclusion

In this paper, machine learning and deep learning methods are used to study the sentences of research questions in academic full-text. From the results, the effect of deep learning model is better than statistical learning model, and model pretrained with specific corpus has better performance than the original model in the downstream tasks of the same domain. This study provides a way to identify the content related to the research questions in academic texts. This method can quickly locate and extract the sentences related to the research topic, questions and purpose, so as to quickly understand the knowledge ontology, clarify the research hotspot and construct the knowledge graph. This study provides a new perspective for the bibliometrics analysis based on the full text, and how to improve the recognition effect of the model will be the focus of the next research.

Introduction

Informetrics is a science for studying the value of literature. Informetrics in its broad sense includes bibliometrics, scientometrics, informetrics, webmetrics and altmetrics. However, the development of informetrics has not been free from the framework of using external indicators to measure research value. With the further development of computer technology, the natural language processing technology based on machine learning and deep learning provides new ideas for the development of informatics from the aspect of information internal characteristics.

In recent years, the study of academic full-text has attracted wide attention. Extracting specific types of entities and sentences from texts, such as software entities, algorithm entities, time entities, and research prospect sentences, has become the object of relevant research.

The research method in this research refers to the methods, tools, means, techniques and schemes for solving the problems in the application domain. The section of dataset and method of an academic article usually contains a series of sentences that introduce the research methods it used. These sentences simply and directly indicate the specific methods of the research, and are of great significance for understanding the ideas of the research, repeating previous studies and understanding the progress of the discipline. Research method can measure the level and value of the research to some extent. Previous studies have been carried out on the extraction of specific sentences. Wang and Zhang (2020) build a dictionary of algorithms by manually annotating the contents of papers, and sentences containing algorithms in the dictionary are extracted through dictionary-based matching. However, the research method has greater uncertainty than the algorithm, so the method of matching by building dictionaries does not work. This paper uses machine learning and deep learning models to identify the sentences of the research method.

Data & Method

The data used in this research was from the Journal of Association for Information Science and Technology (JASIST). A total of 502 articles containing 138197 sentences (including 4030 research methods sentence) published between 2017 to 2020 were downloaded and the full text of these articles were used as the corpus of this experiment.

The full text of articles was divided into sentences. We used label B to mark the sentences that belong to the research method and the label O was used for tagging sentences that did not belong to the research method. Sentences belonging to the research method have a lower proportion in all sentences. The following two methods were adopted to increase the proportion of sentences belonging to the research method in the experimental set. The first method is under-sampling. We eliminated sections that do not contain research methods. The second method is Data Augmentation. It is performed by translating sentences to other languages and back to English.

Model

In this study, the following two classification models were used to identify whether a sentence was a research method sentence. First, SVM model; second, BERT model. SVM (Support Vector Machine) is a classical generalized linear classifier that classifies data according to supervised learning. Its decision boundary is to find a hyperplane with maximum margin for the learning sample.

Bert is a language representation model introduced in 2018, which stands for Bidirectional Encoder Representations from Transformers (Devlin et al., 2018). Pre-training is already performed with Bert on linguistic representation before the training begins. The pre-trained BERT model can be fine-tuned with just one additional output layer to create state-of-the-art models for a wide range of tasks, without substantial task-specific architecture modifications. This experiment is based on the following two Bert pre-training models, one is (cased_L-12_H-768_A-12), and the second is the Scibert (scibert-scivocab-uncased), proposed by Beltagy (2018).

Experiment

In an experiment with the original corpus, the recognition effect of the classification model is not ideal. Therefore, in the 2nd stage experiment, we first take the section structure as a unit and remove the section which does not include the research method sentence. At this point, the research method sentences accounted for about 8% of the total sentences, which was still low. Therefore, we used Baidu translation tools to translate the sentences of the research results into Chinese, Cantonese, Korean, Japanese, etc., and then translated the results back to English. The final sentence is semantically the same or similar to the original sentence, so it can be considered as a research method sentence. The enhanced research method sentences accounted for about 10% of the total sentences. When training the corpus before and after the test data enhancement separately, the F-value increased by about 30%.

We divided the corpus according to the training set: validation set 9:1 based on 10-fold cross validation and evaluated the effect using F-value, Micro-AVG F-value and Macro-AVG F-value. In the SVM classification experiment, TFIDF was used to vectorize the text. The Summarized results is shown in Table 1.

Table 1. Summarized Results

Model or Pre-Model	Indicator	Non-Research MethodSentence F-value	Research Method Sentence F-value	Macro-AVG F-value	Micro-AVG F-value
SVM	Avg	95.37%	34.52%	89.24%	64.95%
	Max	95.72%	37.59%	90.06%	66.47%
	Min	94.87%	29.87%	88.14%	62.66%
Bert-Base	Avg	94.52%	34.82%	89.80%	65.95%
	Max	94.80%	39.19%	90.37%	68.27%
	Min	94.10%	29.18%	89.10%	63.00%
SCI-Bert	Avg	94.14%	35.39%	89.67%	65.58%
	Max	94.77%	37.68%	90.35%	67.35%
	Min	93.57%	34.32%	89.39%	64.92%

In general, the recognition effect of the Bert model especially the Scibertis better than that of the SVM model. After data enhancement, the recognition effect is greatly improved compared with that before data enhancement. With further random negative sampling, the effect of SVM model on the recognition of the research method sentence can reach 60%. We also spent a lot of time checking the corpus and the effectiveness of the model has also been improved. The experimental result shows that the number of research method sentences in the corpus of this experiment is still small, and we plan to continue to expand the corpus size, expand the proportion of research method sentences appropriately and reduce the cost of manual annotation based on active learning strategy.

Conclusions & Future Research

This study constructed an academic full-text corpus based on JASIST. By using SVM and Bert respectively, and using under sampling and data enhancement methods, the maximum harmonic mean value reaches 68.27% in the case of extremely uneven samples. This study provides an idea for identifying research method sentences in academic full-text research. Further, cluster analysis and keyword topic recognition can be carried out on the research method sentences according to the experimental results, so as to understand the internal characteristics of the research method sentences at a more microscopic level.

In addition, the research question sentence, the research result sentence, the research prospect sentence and the research method sentence are all important components of the academic full-text research, so it can be considered to construct a corpus containing the pre-annotated data of the four types of sentences, and at the same time carry out the classification experiment on them. Further research can focus on the mutual relations and internal characteristics of these types of sentences.

Previous study (Small, 2018) has classified articles into methods and their types and non-methods. This paper studied the relationship between citations and whether they are methodological papers which provided a further idea for our research. Next, we can categorize the identified sentences (research questions, methods, results, etc.) to summarize the underlying themes of the overview literature and compare and analyze them with their informometric indicators.

Background

For the revolution of clean energy and environmental justice, the current US President Joe Biden vowed to return to the Paris Climate Agreement as soon as he took office, and emphasized that climate change is one of the main axes of US administration in the next few years (Biden, 2019). Since the United Nations Framework Convention on Climate Change (UNFCCC) forced the commitment of technology transfer in 1992, how to fulfill the commitment and effectively promote the international transfer of climate-friendly technologies in reality has been the theme of debate (Zhou, 2019). Since the Bali Roadmap (2007) further emphasized the importance of clean energy technology transfer (UNFCCC, 2008), the "Cancun Declaration" held in Mexico in 2010 placed more emphasis on climate change mitigation and adaptation, and responded to the technology transfer requirements of developing countries. The Paris Agreement in 2015 once again emphasized the commitment of all parties to strengthen climate technology cooperation and the requirements for clean energy technologies (Koskina, Farah, & Ibrahim, 2020; UNFCCC, 2016). In previous studies, it has been pointed out that patents can be used to analyze technology transfer in mitigating climate change (Goldar et al., 2019). However, this study did not explore whether countries have followed the technology transfer requirements mentioned in the Framework Convention on Climate Change.

The objective of this study was: Using patent data to explore whether there is knowledge spillover from developed countries to least developed countries. The completion of this study would help to understand if the mitigation mechanism mentioned in the Climate Change Convention remained consistent with the future outlook of the United Nations Framework Convention on Climate Change, and would also clarify any knowledge spillover from developed countries to least developed countries.

Methodology

This study adopted the citation analysis of patentometrics to measure knowledge spillover among countries. In order to measure the spillover effect of climate change mitigation technologies in various countries, the United States Patent and Trademark Office (USPTO) patent data was used to analyze the status of technology transfer between 129 countries, the code Y02 of International Cooperation Patent Classification was used for calculation. And in accordance with the United Nations Framework Convention on Climate Change to organize important meetings on mitigating climate change, the Cancun Convention held in 2010 and the Paris Agreement held in 2015, two periods of time were respectively classified at the following intervals: 2009 to 2014 and 2015 to 2020. A total of 263,912 patents were analyzed in the two time periods. The Two Mode Analysis in terms of social network analysis was used to identify the importance of each node in the network, and quantify the spillover effect of climate change mitigation technology in different countries, in order to understand the flow of technology spillover to see if there were any from developed countries to least developed countries.

Results

This study was an attempt to explain the spillover network of climate change mitigation technologies. According to the statistics of the World Bank (2020), the per capita GNI calculated by the Atlas method of the World Bank can be categorized as entities of low-income economies, middle-income economies, upper-middle economies and high-income economies. Figures 1 and 2 list the analysis of spillover network in two periods, in which the red circle represents high-income countries, the blue circle represents middle-and high-income countries, and the yellow circle is low-and middle-income countries. The green box node represents how the climate change mitigation technologies of various countries flow in different levels of economies, and the line arrows represent their knowledge flowing out to countries at different levels.

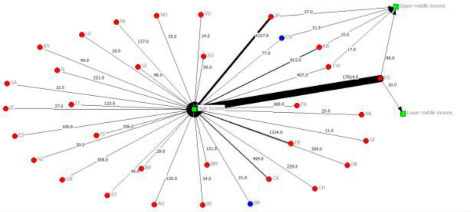

Figure 1. Clean Energy Technology Spillover Map (2009-2014)

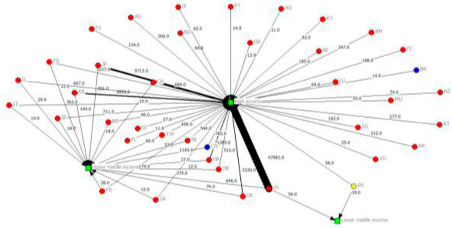

Figure 2. Clean Energy Technology Spillover Map (2015-2020)

According to Figure 1 from 2009 to 2014, climate change mitigation technologies remained mostly within exchange between high-income countries. According to Figure 2, technologies for mitigating climate change were still mainly exchanged within high-income countries, and to a lesser extent from high-income countries to middle-and high-income countries. From Figures 1 and 2, technologies to mitigate climate change mainly flowed in high-income countries and middle-and high-income countries. Compared with Figure 1, Figure 2 clearly shows, as in India, the technologies have begun to flow into low-and middle-income countries, except the United States, but such flow still remained quite low, not to mention the flow to low-income countries.

Conclusion

Using the results of this study, it was determined that climate change mitigation technologies did spill over in time, and the final trend of spillover of related patents and knowledge from countries could help predict the future development of this technology field. However, as found in this study, the knowledge and technology flow to mitigate climate change was still limited to high-income countries and middle-and high-income countries, and the knowledge spillover to low-and middle-income countries and low-income countries was minimal. Therefore, it remained an important topic to repeatedly emphasize the import implication of technology transfer in past and future conferences, that it is imperative to strengthen and actively promote technology development and transfer (Koskina et al., 2020; UNFCCC, 2016). The measures implemented have failed to achieve the necessary commitments mentioned in the Climate Change Convention; thus, the actions and outcomes were inconsistent with the future prospects of the UNFCCC. In term of research limitation, because this study only analyzed data from the U.S. Patent and Trademark Office, if the related technology has not been patented in the United States, it cannot be analyzed.

Introduction

Country profiles reveal interesting aspects of their economic-demographic landscape and scientific research performance. In earlier studies, different authors have used the multidimensional approach to describe national research profiles (Glänzel, 2000; Glänzel, Leta, & Thijs, 2006; Leta, Glänzel, & Thijs, 2006). However, the comparison of national performance profiles has received less attention, perhaps due to composite indices widely used by prevalent rankings.

The current study avoids the rankings approach. The aim is to compare Mexico's scientometric performance with other countries' performance with similar economic demographic profiles. Since multidimensional profiles comparisons are involved, we resort to an artificial intelligence method based on a self-organized neural network (SOM) (Villaseñor; Carrillo-Calvet, & Arencibia-Jorge, 2017).

Materials and Method

We first identify countries with similar economic-demographic profiles to Mexico, and then we compare their scientometric performance. A sample of 108 countries was selected in the Web of Science to calculate four economic-demographic indicators: Population in 2019 (Pop 2019, World Bank Data), Global Competitiveness Index (GCI, World Economic Forum), Economic Complexity Index (Hidalgo & Hausmann, 2009) (ECI), and Gross domestic product per capita (GDP per capita 2019, World Bank Data). Comparing the multidimensional economic-demographic profiles of the 108 countries was carried out automatically using the SOM neural network implemented in the software system ViBlioSOM 2.0 (Jimenez Andrade, Villaseñor-García, & Carrillo-Calvet, 2019). Thus, the neural network identified in one cluster a set of 17 countries with the most similar profiles to Mexico.

To compare Mexico's scientometric performance with the performance of these other 17 countries, we used the Documents per 10000 inhabitants indicator (calculated taking into account data from Web of Sciences (InCites) and the World Bank) and other five indicators from InCites: % of international collaboration; % of Documents in Top 1% and Top 10% of most cited articles in their subject categories; % of Documents in Q1 Journals, and Category Normalized Citation Impact (CNCI). For the comparison of the scientometric profiles we used again the neural network to produce a clusters map that can be interpreted with the help of a collection of associated components maps. To calculate the optimal number of clusters, we used the Davies-Bouldin index (Davies & Boulding, 1979).

Results and Discussion

The neural network grouped the sample of 108 countries in seven clusters sharing the most similar economic-demographic characteristics (Figure 1).

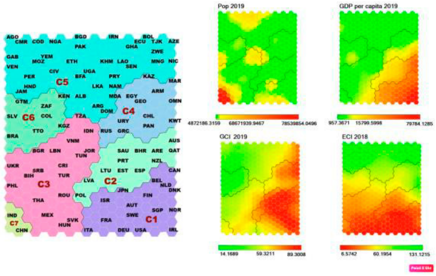

Figure 1. Comparison of 108 countries using economic-demographic indicators. Country codes use the ISO 3166-1 alpha-3 international standard.

Four component maps corresponding to each indicator are also displayed in the figure to interpret the clusters map. The countries with the most complex economies and the highest values of GDP per capita are grouped in clusters C1, C2 and C4.

In cluster C7 China and India appear as outliers due to their extremely high population. Eighteen countries belong to cluster C3, sharing high values of the Economic Complexity Index and medium values in the other indicators. This cluster includes two Latin American countries (Costa Rica and Mexico) and eight European countries (Bosnia and Herzegovina, Bulgaria, Turkey, Romania, Serbia, Hungary, Ukraine, Slovakia), four Asian countries (Indonesia, Philippines, Thailand and Viet Nam), two African (Tunisia and Tanzania), and two Middle East countries (Jordan and Lebanon). Considering that these 18 countries are the most similar to Mexico in terms of demographic indicators, we then compare their Scientometric multidimensional performance profiles using the neural network (Figure 2).

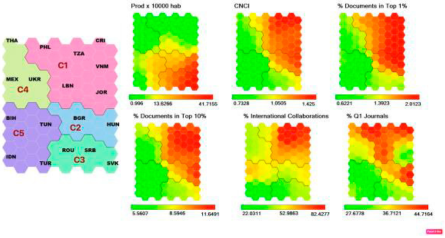

Figure 2. Multidimensional scientometric profiles of countries with similar economic-demographic profiles to Mexico (2017-2019).

Of the five clusters identified by the neural net, the countries with the best performance profiles are located in clusters C1 and C2. Countries in Cluster C2 and C3 stand out as the most productive ones and C1 have the highest international collaboration score. Mexico, Ukraine and Thailand belong to C4. This cluster together with C3 showed the lowest values in the productivity and impact indicators. However, C4 has a better percentage of articles in Q1. Meanwhile C3 has a better productivity level.

Focusing on Mexico`s relative scientometric performance as an example, it is clear from the maps in figure 2 that Mexico is outperformed in productivity and impact by the 11 countries which belong to clusters C1, C2 and C3. For instance, it has a score of 0.94% in documents in top 1% indicator vs a maximum of 2% stained by some countries in cluster C1 and C2; it has 6.69 in documents in top 10% indicator vs a maximum of 11.6 for some countries in these clusters. Similarly, in the Category Normalized Impact Factor, Mexico has 0.84; meanwhile countries with the best score reach 1.4. Regarding the productivity indicator, Mexico has five papers per 10000 habitants; meanwhile the larger score in cluster C3 is 42 and Tanzania has a minimum of 0.8.

Conclusion

The neurocomputational approach facilitated identifying 18 countries which makes sense to compare Mexico, taking into account demography and economic patterns, and comparing Mexican scientometric performance with these countries. Compared with countries with the same economic-demographic landscapes, the productivity and impact of Mexican output were lower than expected. Therefore, beyond the weight of demographic and economic variables, other factors must be analyzed in further studies, such as developing national academic journal ecosystems, the national research evaluation policies, or the level of democracy. Finally, we remark that to carry out the multidimensional comparisons needed by this investigation is not a trivial achievement. The visual output of the neural net provided a clear results' representation.

Analysis of Topic Evolvements of COVID-19 Scientific Literatures based on Probabilistic Modelling

Ma Lili[1], Zhao Yanqiang[1], Yue Mingliang[1,2,3] and Ma Tingcan[1,2,3]

{mall, zhaoyq, yueml, matc}@whlib.ac.cn
[1]Wuhan Library of Chinese Academy of Science, Wuhan (China)

[3]Hubei Key Laboratory of Big Data in Science and Technology, Wuhan (China)

Introduction

Since it was first reported at the end of December 2019, the new coronavirus disease (COVID-19) is undoubtedly the most important health issue of global concern. With the increasing of research papers related to COVID-19, bibliometric analysis becomes a promising way for comprehensively understanding the global research status in the field (Al-Gheethi, 2020). In this paper, LDA model is adopt to recognize the topics of the bibliometric data of the COVID-19 related research paper. We proposed a weighted summation method to get full use of the probabilities reported by the model to analyze the monthly topic evolvements and discuss the potential reasons of the evolvements.

Data and Method

The bibliographic data of COVID-19 were searched and downloaded using TS = (2019-nCoV or SARS-CoV-2 or COVID-19 or COVID-2019 or "Coronavirus disease 2019") as search strategies from Web of Science Core Collection, Science Citation Index Expanded (SCI-EXPANDED) database . The article type was set to include article, letter and review. The data relates to 36913 research papers, among which 30122 papers have been officially published that can be mapped to the month of publication. In this paper, all the papers' bibliographic data is used in the topic modelling to get a more comprehensive topic recognition, while only the officially published papers is used in the evolvement analysis. Considering the publication delay, this paper mainly analyzes the topic evolvement from January to October, 2020.

In this paper, LDA model is used to recognize the research topics included in the COVID-19 related research papers. The model can be formally represented as Ω=Φ×Θ, where Ω, Φ and Θ is document-word distribution, topic-word distribution and document-topic distribution respectively, × represents matrix multiplication (Blei et al., 2003). Given the a set of *m* documents and a topic number *n*, the model returns *m* vectors of length *n* indicating to what extent each of the *m* papers are related to each of the *n* topics and *n* vectors of keywords that can be used to interpret the research topics.

Let $\Theta=\{\theta_{ij} \mid i\in[1,m], j\in[1,n]\}$, each θ_{ij} be the probability of paper *i* on topic *j* returned by LDA modelling. As afore-mentioned, the probability can be interpreted as the weight indicating to what extent a research is related to a topic. For each topic, we can add up the weights relating to the topic of all the papers to get an overall recognition of the focus on the topic in the current research. More formally, we can define $S_j=\sum_i \theta_{ij}$ as the Research Strength of topic *j* in the current research, and define $S_j^k=\sum_i \theta_{ij}, P_i=k$ as the research strength of topic *j* in the research of the *k*th month of 2020, where P_i represents the publication month of paper *i*. In the next section, we analyze the evolvement (of the research strength) of each COVID-19 related research topic.

In this paper, title and abstract of the papers' bibliographic data were extracted as the input of LDA model. Topic number *n* was set as 10 to 50 and the corresponding topic coherences were calculated to find the best topic number, where topic coherence is a quantitative measure that can be used to evaluate the quality of the topic modelling, with higher coherence indicating higher quality (O'Callaghan et al., 2015). The distribution of coherences of our case shows a maximum coherence at *n* = 25.

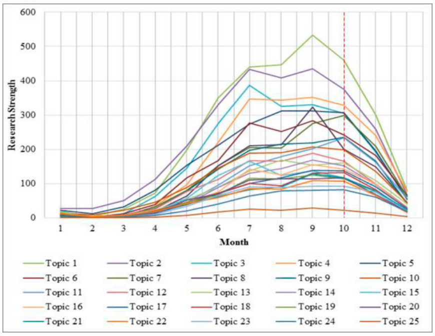

Figure 1. Topic evolvements of the 25 research topics

Table 1. The 25 topics

Topic
Pandemic and its impacts and challenges on medical, social, economic, etc.(Topic 1)
Infection and coinfection of coronavirus disease 2019 (Topic 2)
Guidelines in healthcare facilities and protection for healthcare workers (Topic 3)
Influence of basic disease on COVID-19 infection and mortality (Topic 4)
COVID-19 transmission model and epidemic development trend (Topic 5)
CT and other imaging diagnosis (Topic 6)
Study on psychological and mental problems during the COVID-19 pandemic (Topic 7)
The impact of the epidemic on surgery and education (Topic 8)
Treatment of critically ill COVID -19 patients (Topic 9)
Report and epidemiological characteristics of epidemic situation in worldwide (Topic 10)
The clinical characteristics and prediction indexes of patients with COVID-19 (Topic 11)
Drugs treatment and effects study (Topic 12)
Rapid diagnosis based on nucleic acid detection (Topic 13)
Immunological study for COVID-19 (Topic 14)
Cancer treatment during the COVID-19 pandemic (Topic 15)
Analysis of COVID-19 incidence and mortality among different regions (Topic 16)
Deep learning and AI in the research of COVID-19 (Topic 17)
SARS-COV-2 receptor and infection mechanism (Topic 18)
Systematic review and meta analysis (Topic 19)
The air and contact transmission of SARS-COV-2 and the role of protective equipment such as masks (Topic 20)
COVID-19 inhibitors target screening, molecular simulation and potential therapeutic drugs research (Topic 21)
COVID-19 genome sequence research and vaccine development (Topic 22)
SARS-COV-2 infection in pregnancy and maternal and neonatal vertical transmission (Topic 23)
The effect of the COVID-19 on air pollution and air quality (Topic 24)
Others (Topic 25)

Topic evolvement

Fig. 1 gives the time evolution of the research strength of each topic, and the 25 research topics are shown in Table 1. It can be seen that, from January to February, in the early stage of the epidemic, scientists around the world did not know much about this sudden novel coronavirus and its pathogenic mechanism. The timely sharing and disclosure of epidemic data, the prediction of epidemic development trend as well as the rapid detection and identification of COVID-19 patients played important roles in controlling the spread of the epidemic. Therefore, topic 1, 2, 5, 10, 13 that related to the infection and coinfection, challenge, rapid diagnosis of COVID-19, as well as the epidemiological characteristics and development of epidemic were the most concerned.

From March to July, the COVID-19 pandemic caused the significant influence worldwide, and how to protect healthcare workers became the focus, therefore, in addition to topic 1 and 2, prevention and control guidelines in healthcare facilities and protection for healthcare workers (topic 3) became one of the top third research topics. Besides, the appearances of new major human viral infectious always arise extensive research booms worldwide. Topic 4, 6, 11, 12, 18 that relating to the diagnosis and treatment of COVID-19 also developed rapidly. From July to August, the epidemic prevention and control situation in various countries became normalized. Around September, as some countries faced the second wave of the epidemic, the world COVID-19 epidemic showed a rebound. The development of research topics fell into the following four trends: (*a*) second increase after a brief stabilization: including topic 1, 8, 7, 10, 12, 16 and 22. These topics are much related to the dynamic development of the COVID-19 epidemic. With the continuous of the pandemic, these topics will ongoing. (*b*) stay stable: including topic 2, 4, 5, 6, 19, 20, 18, 23 and 24. These research topics have played an important role in the diagnosis, transmission, prevention and control of COVID-19. After long-term research and accumulation, certain research results and conclusions have been drawn. (*c*) Gradual downward: including topic 3, 15 and 13. The downward trend may due to the gradual maturity of related solutions and technical methods. (*d*) continued growth: including topic 9, 11, 14, 21 and 17. These topics relates to the application of emerging technologies of other research fields, such as deep learning and artificial intelligence, so their development was relatively late.

Conclusion

In this paper, we analyzed the monthly topic evolvements of COVID-19 related research using 30122 research papers' bibliometric data based on LDA model. We believe the results can help researchers and policy makers get deeper understanding of the development of the COVID-19 epidemic and the related research.

Are Non-Journal Citations More Important for Books? Study of Types of Citing Documents in Scopus

Ashraf Maleki

malekiashraf89@gmail.com
Independent Researcher, Tehran (Iran)

Introduction

Numerous studies have shown the fundamental contributions of books to humanities and social sciences in terms of the prevalence of publications (see Hicks, 1999) and the quantity of citations. Books either as research contributions, summary of previous research, educational materials and public and cultural communications have greater quantity of content than journal articles, and relatively the citations received and given are more numerous. For instance, books in Political Science tend to receive more numerous citations than the journal articles (Samuels, 2013), and thus represent important sources of impact in this field.

Despite a general difference between journal articles and books in terms of content and citation, it is less known whether journal citations are as useful as other sources of citations such as books and book chapters for book impact assessment. Formal citation indexing databases such as Book Citation Index (BKCI) and Scopus offer a relatively broad range of citations originating from various sources such as journal articles and in the past decade books and other resources as well. The main goal of this research is to investigate the difference between citations coming from these various document types in Scopus and examine their relationship with other books indicators such, Syllabus mentions as obviously an indicator of educational impact of books (Kousha and Thelwall, 2016), Goodreads Rating and Reviews (Zuccala et al., 2015) as an indicator of cultural impact of books, Library Holdings value of books (e.g. White et al., 2009), Google Books citations (Kousha and Thelwall, 2009) and Altmetric.com indicators. Therefore, this research is an attempt to analyse the types of documents citing books as identified by Scopus of Elsevier. This research is a follow-up investigation to previous research (Maleki, 2020) and aims to answer which types of citations originating from formal indexed document are statistically stronger sources of impact than journal articles for predicting citations to books and explaining other aspects of impact.

Method

In order to address research issue "cited by" feature in Scopus is used to harness the types of documents citing 36,493 books in six fields of Anthropology (1,198), Arts (1,245), Business and Economics (11,987), Law (4,734), Medicine (12,227), and Political Science (5,098). Other book indicators are extracted from Altmetric.com, Goodreads.com, Opensyllabus.org and Google Books, with API using ISBN, title and author names. Details of this data in terms of citedness in Scopus, Google Books (GB), Syllabus mentions (SM), Goodreads Users (GU), Goodreads Ratings (GR), Goodreads Text Reviews (GTR), Goodreads Average Rating (GAR), Library Print Holdings (LPH), Library E-holdings (LEH), and altmetrics indicators (Table 1) are offered in Maleki (2020).

Document Type in Scopus are provided in 18 different formats but the most important forms are Article, Book, Book Chapter, Conference Paper, Editorial, Letter, Note, and Review that are used to answer research questions. Citations originating from various document types are aggregated from Scopus Preview mode "cited by" results with URLs extracted via Scopus API in February 2021.

In response to research question, an Ordinary Least Squares Regression model is used on log-transformed data as proposed in Thelwall (2017) with citation counts across document types as independent variables and each other metric as the predicted one.

Findings and Discussions

Figure 1 indicates the proportion cited of books by each Scopus document type. It shows that more than 60% of books were cited by journal articles at least once in all fields, whereas for about 50% of books, book and book chapters citations was apparent, and about 40% review citations.

As the purpose of research is not to give a prediction formula but to examine the prediction ability of citations made by each document type only standardised coefficients of beta are reported instead of unstandardised B and the coefficients of only three document types out of nine document types entered in the model are reported as their coefficients was the strongest in the prediction of citation by every other citation source or predicted variable.

Results in Table 1 suggest that Book-sourced citations counts are often the best predictor of GB Citations, Syllabus Mentions, Library Print Holdings, and Goodreads related metrics, although the overall prediction are almost weak and never surpass 25.1% (for LPH). This shows that document types can only partially explain statistics of book impact although it would be better to prioritise and use Book-sourced citations instead of journal article citations.

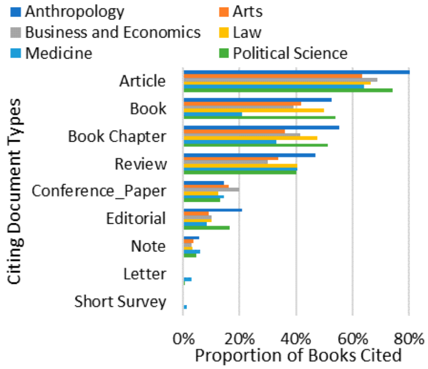

Figure 1. Proportion Cited of books in Document Type across six fields

Another interesting result in Table 1 is that articles-sourced citations to books are better for predicting Mendeley and Twitter and perhaps library electronic uptake of books than any other document type. Perhaps more interestingly is Review-sourced citations that dominate in the tiny prediction (1.4%-7.1%) made for News, Wikipedia and Blog citations to books, perhaps suggesting that reviews have a place in public communications with books.

Table 1. Statistically significant linear regression standardized coefficients (β) in six fields. The independent variables were all nine Scopus citing document types of which only three are reported for strongest coefficients.

Variables	*Article*	*Book*	*Review*	*Adjusted R2*
GB	.143	**.230**	-	19.9%
SM	.106	**.245**	-	21.7%
LPH	.220	**.311**	-.017*	25.1%
LEH	**.095**	.070	.060	4.1%
GU	.093	**.254**	.078	16.8%
GR	.045	**.249**	.088	15.2%
GTR	-.035	**.230**	.094	8.5%
GAR	.118	**.160**	.027	9.5%
Mendeley	**.232**	-.194	.108	9.9%
Twitter	**.156**	-.088	.090	3.6%
News	.075	-	**.098**	4.1%
Wikipedia	.042	-.029	**.105**	1.4%
Facebook	.073	**-.129**	.089	2.1%
Blogs	.092	.061	**.123**	7.1%

All coefficients are significant at p<0.001 except *p<0.05 and ** p<0.01. Bold coefficients represent the strongest document type as a source of citation in prediction of each metric. Negative coefficients are shown in red. Check abbreviations in Method.

Conclusions

This research provided a breakdown of document types of Scopus citations to books, in order to identify which formal source of citations helps in predicting various aspects of impact. Results indicated that although citing publication format is not a strong indicator of book impact there is some evidence to suggest that Book-sourced citation can be better role players in book impact assessment than journal-sourced citations when assessing traditional aspects of impact. However, Article-sourced citations sound to be strongly linked with online uptake of books such as in Mendeley and Twitter, indicating that online indicators mostly represent research value of books. Book Review citations might be linked to cultural value, however. In sum, citations from some document types tend to signal various aspects of impact which is worthy of attention.

Identifying research themes in Finland using topic modeling and word embeddings

Katja Mankinen[1] and Yrjö Leino[2]

{[1] katja.mankinen, [2] yrjo.leino}@csc.fi
CSC - IT Center for Science, P.O. Box 405, 02101 Espoo (Finland)

Introduction

To identify research topics and trends in Finland in a fully data-driven and unsupervised way, we apply natural language processing and topic modeling methods to abstracts, titles, and keywords of research papers published in 2008-2019. Following the previous studies on topic models and mapping of Finnish science (e.g., Suominen & Toivanen, 2016), the present study enhances topic modeling methods by utilizing joint document and word embeddings to capture the semantic knowledge at document level. This work has been done in collaboration with the Academy of Finland in the context of Academy's State of Scientific Research analyses.

Data and methods

In total 106,736 publications (articles, reviews, letters, books) with at least one author with a Finnish affiliation, written in English and published in 2008-2019 were retrieved from Web of Science Core Collection. Only titles, abstracts and keywords of publications were considered for further analysis, excluding other metadata such as author and journal names as well as citations.

During data preprocessing, all words were tokenized, and stop words together with too rare and too common words as well as numbers and special characters were removed, after which unigrams and bigrams were extracted. To improve the quality of topics, the topic modeling method using the bag-of-words approach, Latent Dirichlet Allocation (Blei, Ng & Jordan, 2003), was extended to incorporate joint document and word semantic embeddings based on the model by Nguyen et al. (2015). The embeddings, created using doc2vec (Le & Mikolov, 2014), can better describe the connections between words and documents, and were used to form interpretable topic representations summarizing common words of related documents. Finally, each publication was assigned to the most significant topic.

To evaluate the research impact in these newly identified research topics, the top 10% citation index (proportion of publications belonging to the top 10% most frequently cited publications, with world average of 1.0 (Waltman & Schreiber, 2013) was calculated for each topic.

Results

In total, 1026 research topics were found. Number of publications in each topic varies between 18 and 862 with the mean being 104.0 and median 81.5. Topics with the most publications represent broad disciplines from education and business management to wireless networks, renewable energy and gut microbiota, whereas the smallest topics tend to be very specific such as distinct animal or plant species (e.g. frogs, spruces) or diseases (e.g. carpal tunnel syndrome). In addition, a few small low-quality categories were found, in which no clear connections can be found between more than a couple of words.

Topics with high scientific impact

We found 65 topics with high scientific impact (the top 10 index over 2.0) and 11 topics with very high scientific impact (the top 10 index over 3.5). Examples of these topics from various research disciplines are shown in Table 1.

Table 1. Examples of topics labelled using their most significant keywords, the top 10 index and full count of publications.

Topic	Top 10 index	Publications
RFID technologies	3.59	172
Wireless networks	3.23	801
Arctic maritime	2.91	197
Laser scanning, remote sensing	2.90	388
(Nano)cellulose	2.75	324
Permanent magnet motors	2.68	171
Ecology, climate change and biodiversity	2.25	210
Optimization	2.18	168
Sports and exercise medicine	2.10	102
Customer value, servitization	2.06	352

A majority of the topics with the highest top 10 indices is related to various aspects of computer science, electrical engineering, environmental sciences, materials science, telecommunications and management.

Dynamics of topics

Dynamic changes in the publication volume over time were explored in order to observe emerging research trends. Examples of topics with increasing number of publications are presented in Figure 1. The figure shows that there has been a steady increase in the number of publications especially in renewable energy and education research in recent years. No sharply peaking topics were found, and none of the topics showed a rapid decrease in the number of publications in 2008-2019.

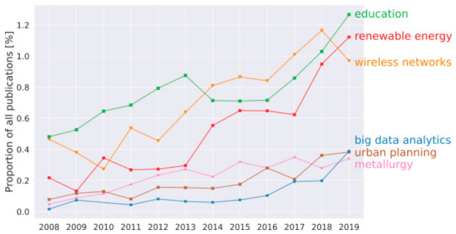

Figure 1. Relative publication volume in selected topics in 2008-2019 normalized to yearly count of publications to account for general increase in publication volume.

National and international collaboration

For each topic, we studied national and international co-authored publications and evaluated their scientific impact. In some topics, such as in “wireless networks”, international collaboration is emphasized while national collaboration is almost an exception. In many other topics, such as in “laser scanning and remote sensing”, national collaboration is extensive and has mostly high impact. Scientific impact in topics can also be strongly polarized: of all organizations active in a topic, maybe only few are doing research on an exceptional level. Therefore, high national impact does not directly imply that impactful research is conducted throughout Finland.

Discussion

A majority of resulting topics represent easily interpretable, large-scale research phenomena. The same general theme can be addressed in many topics from different perspectives. For example, there are many topics related to oncology, usually distinguished by an organ of interest (“prostate cancer”, “cervical cancer”). Topics of global interest with distinct vocabulary, such as one about supernovae, tend to contain publications only from one or two disciplines (astronomy). On the other hand, there are topics with only loosely connected publications from several separate research fields: e.g. a topic “music” covers a wide range of research from emotions (psychology) to brain responses (neurosciences) and from music theory to pedagogy. This also reflects differences between disciplines: some disciplines are inherently further away from others, while others often partly overlap, such as biomedicine, medical and health sciences.

It should be noted that not all publications in the topic are necessarily strictly related to the topic, and not every publication concerning the topic in question has been clustered into it. Even significant topics may remain unrecognized due to limitations in data (only a subset of all Finnish research published in 2008-2019, leading to low coverage especially in humanities and social sciences; occasional short or missing abstracts) and methods (model parameter choices, text preprocessing). While used methods improved the interpretability of topics and are suitable for mapping research themes at scale, they are not suited for accurate classifications or determining the exact size of research areas. Our ongoing work will extend this study by making use of citation information and large, pretrained neural network models.

Conclusions

We recognized several – perhaps even a few previously overlooked – research topics where high-impact research is done in Finland. Combined with a detailed analysis of research collaboration, this study provides data-driven insights of the Finnish research field.

Introduction

Structure of academic research in a particular country is directly linked with the social, economic and political institutions that exist in that country (Graham, 1993). One of the major characteristics of such structure nowadays is the role and scope of international collaboration (Sonnenwald, 2007; Leahey, 2016). Development of science in particular countries can be significantly determined by the type of scientific activity with the other countries (Lauk & Allik, 2018).

In presented work we analyse international collaboration of post-soviet countries in dynamics. Post-Soviet region has several features, which make it a unique unit for analysis of the scientific structure and collaboration (Krementsov, 1996).

Thus, the common past and diverging present make the task of measuring and interpreting international collaboration for ex-USSR very interesting. In this study we address the following questions: Which patterns of international collaboration have emerged and developed in the ex-USSR during the post-Soviet era? What are the changing roles of Russia, EU and other major international forces in this collaboration?

Data and methods

Our sample consists of 15 post-soviet countries. We used data about the total number of journal articles and reviews in 1993, 1998, 2003, 2008, 2013 and 2018. Data was attributed to countries' profiles in WoS (indexes SCI-expanded, SSCI and A&HCI, document types “article” and “review”). We also use data about the number of publications in Q1 and Q4 journals according to their Journal Impact Factor. Our dataset does not cover many local journals including Russian-language venues, which is popular in former USSR. In this work we focus on internationally visible academic output using a well-researched and curated data source (Birkle et al., 2020).

For each country we analyse the total number of publications, number of publications in Q1 and Q4 segments and different research areas, the number of publications written in collaboration with other countries and without them. For the years 2010-2018 we are also able to study precise national composition of authors of collaborative papers using fractional counting (for earlier period this is impossible due to WoS limitations).

Findings

In the observed period the share of international collaboration of post-Soviet countries has increased significantly (Figure 1). All countries have higher values than average global baseline (black curve). In 1993, for different countries the value of this parameter was from 10% to 50%. In 2019 it varies from 40% to 100%. Russia has the lowest share of international collaboration that can be explained by the size of this country, which conforms to global trends of smaller countries being more international (Kamalski, 2009).

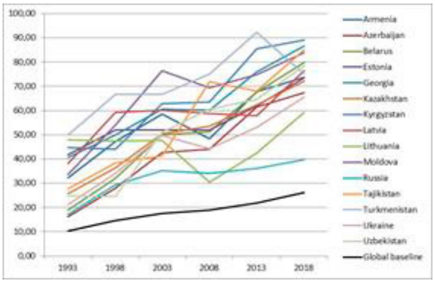

Figure 1. Share of international collaboration of post-Soviet countries.

The highest values of international collaboration are observed in Turkmenistan and Kyrgyzstan, which have the lowest total WoS paper counts. Lithuania is the most stable country by share of international collaboration: during the period it has changed from 47.9% to 59.7%.

International collaboration of post-Soviet countries also varies by disciplines. In 1993, post-Soviet countries most often collaborated with other countries in Natural Science and Engineering & Technology. In 2018, some countries intensified international collaboration in Humanities fields. During the observed period the share of international collaboration in Agricultural Sciences has increased almost tenfold.

We also observe that international collaboration of post-Soviet countries in the Q1 segment is much higher than in Q4. Moreover, in 2018 for all countries in Q1 segment share of international collaboration is more than 70%. Thus, international collaboration is more pronounced in higher-cited journals.

After the collapse of the Soviet Union on average post-Soviet countries collaborate with each other in the same proportion as with other countries (Figure 2). Then the share of collaboration with other countries has increased. In 2018 papers written by post-soviet countries in collaboration with each other constitute 10% from all international publications.

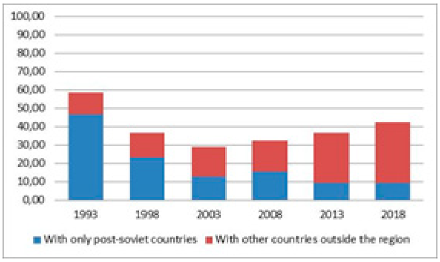

Figure 2. Average share of papers written with countries inside and outside the region.

In 1993 for all post-Soviet countries Russia was the main collaborator. In 2018, Russia isn't the main collaborator for Baltic countries and Georgia. Currently, the main collaborators of post-Soviet countries are also the USA and Germany.

We conduct fractional counting of countries' shares for all Russian papers with all ex-USSR countries published in 2009-2019 and having 2-20 authors (thus we intentionally exclude large-scale international projects and megascience). Such analysis shows that the ratio of Russian to local authors in collaborative papers is almost always less than 1, with the exception of Kazakhstan and Lithuania (Figure 3).

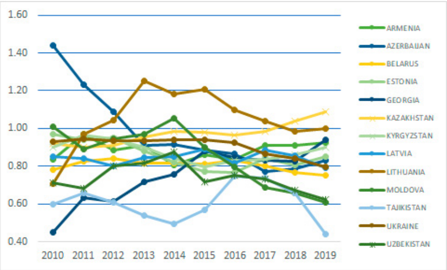

Figure 3. Share of Russian and local authors in collaborative Russian+exUSSR papers with 2-20 authors, 3-year moving average.

Role of non-exUSSR countries in post-Soviet collaborations is very different for various countries, but tends to increase. It varies from 15% for Kazakhstan and Belarus to 30% for Baltic states, Azerbaijan and Georgia.

Discussions and conclusions

Our preliminary analysis shows that after the collapse of Soviet Union post-Soviet countries significantly changed the patterns of international collaboration, and these changes were country-specific. We observe a dramatic decrease of scientific collaboration between post-Soviet countries. While the relative role of Russia as a partner is decreasing for all the ex-USSR nations, this dynamic differs a lot, and tends to be aligned with broader geopolitical and foreign affairs agenda.

Building Multi-level Aspects of Peer Reviews for Academic Articles

Minghui Meng[1], Yuzhuo Wang[2] and Chengzhi Zhang[3]

{[1]mengmh, [2] wangyz, [3]zhangcz}@njust.edu.cn
Nanjing University of Science and Technology, 200 Xiaolingwei Street, Nanjing 210094 (China)

Introduction

Peer reviews for academic articles are domain experts' comments on the paper submitted to a journal or conference, which reflect the overall impression of the reviewer as well as the detailed comments.

By mining peer reviews at aspect level, we can find the aspects concerned by reviewers, which can provide direction for inexperienced paper submitters to optimize their writing. Some scholars have studied it at aspect level, Chakraborty et al. (2020) adopted the reviewing aspects used in the ACL conferences, including *clarity, originality,* etc. However, these aspects are the overall impression of the reviewer on the paper with coarse granularity and lack of more detailed comments. Moreover, reviewers of different disciplines may focus on different aspects.

Therefore, we want to find more fine-grained multi-level aspects from multi-disciplinary peer reviews, including domain independent aspects and domain related aspects, which can provide a well-rounded optimization direction for submitters. We take peer reviews in *Nature Communications* as an example and propose a general method for building multi-level aspects of peer reviews for academic articles.

Method

The process of this paper is shown in figure 1:

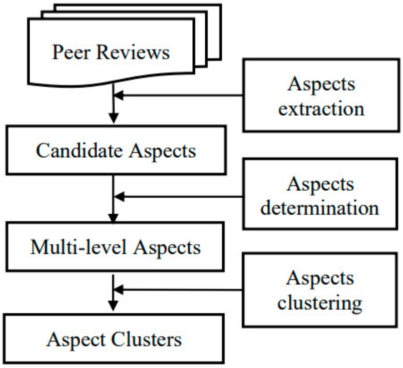

Figure 1. Flowchart of this study

Data collection. *Nature Communications*[i](NC) is a multidisciplinary journal, which has 5 first-level disciplines and 71 second-level disciplines. Besides, we regard "NC" as the zero-level discipline. It has provided the access to content of peer review since 2016. We collect 187,971 peer review documents of articles published from 2016 to 2020, details of the NC's first-level disciplines are shown in table 1:

Table 1. Distribution of NC Peer Reviews

Discipline	Papers	Reviews
Biological sciences	21,683	98,585
Earth and environmental sciences	2,588	11,632
Health sciences	6,090	28,674
Physical sciences	10,180	45,222
Scientific community and society	832	3,858

Candidate aspects extraction. We use the Double Propagation algorithm (Qiu et. al., 2011) to extract aspects from peer reviews. Firstly, we employ the StanfordNLP[ii] tool to tag the part of speech of peer reviews and parse sentences. Secondly, we select words in opinion lexicon from Liu [iii] as seed opinions. Next, we consider aspects to be nouns and opinions to be adjectives and limit the dependency relations between aspects and opinions to mod, subj, etc. Finally, we select all the words matching the above rules as the candidate aspects.

Multi-level aspects determination. We divide multi-level aspects into domain-independent common aspects (DICA), domain-related common aspects (DRCA), and domain-related special aspects (DRSA). Multi-level aspects are determined based on the number of reviews, the distribution uniformity, and particularity of candidate aspects at all levels of domain peer reviews. We use the inter-domain entropy (IDE) and termhood (Chang, 2005) to measure the distribution uniformity and particularity of aspects in various domains, the calculation formulas are as follows:

$$\mathrm{IDE}(w_i) = -\sum_j P_{ij} \log P_{ij} \qquad (1)$$

$$\mathrm{Termhood}(w_{ij}) = n_{ij} \times log_2 \left[\frac{N}{Nd_i}\right] \qquad (2)$$

Where P_{ij} is the probability of candidate words w_i in domain J,$Nd_i = 2^{IDE(w_i)}$, N is the total number of the disciplinary domains.

The object of this study is peer reviews with three-level disciplinary domains, like NC. The following is the process to determine the multi-level aspects of NC, including DICA, DRCA and DRSA. DICA is the aspect that often appears and distributes evenly in every first-level domains. DRCA often appears in a certain first-level disciplinary domain and is evenly distributed in its sub-domains. DRSA is the aspect unevenly distributed in each second-level domains and often appears in a certain second-level domain. First, we count the number of peer reviews where the zero-level candidate aspects at NC's first-level domains and calculate the IDE, next select words with the top 80% cumulative percentage of total word frequency, then we get the words with entropy higher than median as the final DICA. Second, we count the number of peer reviews where NC's first-level candidate aspects at corresponding second-level domains and calculate the IDE, then calculate its termhood at each second-level domain, next remove DICA, according to the same filtering conditions, get the words that meet the conditions as DRCA. After filtering DICA and the corresponding DRCA, we obtain the top100 termhood words of each second-level domain as the final DRSA.

Aspects clustering. In this paper, we select the Affinity Propagation (AP) algorithm (Frey & Dueck, 2007) to cluster aspects, the purpose is to aggregate the same aspects of different expressions. We train word2vec[iv] model to represent word vector, then use cosine similarity to calculate the similarity between two aspects and choose the Silhouette Coefficient (SC) to evaluate the clustering result.

Results

The extraction result of candidate aspects

We respectively extract the candidate aspects from NC's every-level discipline peer reviews. As a result, we extract 5896 zero-level candidate aspects, 5 groups of first-level candidate aspects, and 71 groups of second-level candidate aspects.

The determination result of multi-level aspects

In NC peer reviews, we obtain 598 DICA, 5 groups of DRCA, and 71 groups of DRSA. Table2 is the partial result of the NC multi-level aspects, including NC's DICA, Biological sciences (BIO)'s DRCA and Computational biology and bioinformatics (CBB)'s DRSA.

Table 2. Multi-Level Aspects

Level	Category	Domain	Aspects
0	DICA	NC	Data\result\method\figure\analysis\change\experiment\effect\text\level\model\topic\example\...\discussion\
1	DRCA	BIO	Assay\target\domain\...\specificity
2	DRSA	CBB	Object\update\classifier\...\paradigm

The clustering result of zero-level discipline aspects

In AP clustering, the preference value refers to the reference degree of the point as the clustering center, and the damping factor is the coefficient used for convergence. We cluster NC's DICA. Our clustering requirement is to control the number of clusters between 10 and 50, so that clusters have both clustering effect and discrimination, we set preference from -50 to -25, and damping from 0.5 to 0.8. When preference = -40, damping = 0.65, the SC value was the largest, we regard it as the optimal clustering result. Table3 is part of the clustering results of NC's DICA. There are four clusters, which are "Result", "Impact", "Method", and "Figure". In the "Result" cluster, reviewers pay more attention to *result, conclusion,* and *finding*. In the "Impact" cluster, reviewers focus on *impact* and *lack*. Besides, *method*, *figure*, etc are also the focus of reviewers.

Table 3. The NC's DICA Clusters

Cluster	Aspects	# Member
Result	Result\conclusion\finding\...\claim	19
Impact	Impact\lack\contribution\...\focus	48
Method	Method\approach\technique\...\strategy	19
Figure	Figure\image \table\legend \...\panel	29

Conclusion

This paper proposes a method for building multi-level aspects of peer reviews for academic articles, which aims to comprehensively extract the multi-level aspects in peer reviews. The multi-level aspects reflect the key aspects that reviewers focus on, such as *result* and *method*, which can provide reference for inexperienced submitters to optimize their research design and writing.

Multilingualism of Ukrainian Humanities: how it is seen globally

Serhii Nazarovets[1] and Olesya Mryglod[2]

[1] *sergiy.nazarovets@gmail.com*
State Scientific and Technical Library of Ukraine, Antonovycha Str 180, 03680 Kyiv (Ukraine)

[2] *olesya@icmp.lviv.ua*
Institute for Condensed Matter Physics of the National Academy of Sciences of Ukraine, Svientsitskii Str 1,
79011 Lviv (Ukraine)

Introduction

Dissemination of knowledge in the Humanities occurs through the use of different languages and different types of documents. Many studies of recent years consider the issue of proper evaluation of scientific non-English achievements of Humanities (Pedersen, Grønvad, & Hvidtfeldt, 2020). Such a lively interest can be partially explained by many examples of misuse of metrics in order to assess the impact of research in Humanities. In recent years such popular initiatives as DORA, Leiden Manifesto, Metric Tide, Helsinki initiative attracted the attention of the scientific community to the problem of correct evaluation of non-English works. However, the other side of the coin, which is related to the importance of international evaluation of results in Humanities, is not always properly addressed to by researchers. The exclusive focus on the local level also leads to negative consequences: lack of independent review, decrease of the quality and relevance of scientific results.

The research policy of Ukraine, which became independent in 1991, inherited many Soviet remnants. For a long time scientists in Ukraine have been rewarded primarily for publications in national journals in their native language (Hladchenko, & Moed, 2021). The locally-nested character of research together with such formal stimulations create the preconditions for harmful self-isolation and "invisibility" of Ukrainian Humanities.

The aim of this work is to investigate the volume and language distribution of publications by Ukrainian researchers in Humanities indexed in Web of Science (WoS). Further, a number of other non-English-speaking countries of Eastern Europe with similar post-Soviet background is chosen for comparison.

Language is an important factor influencing the coverage of a country's scientific publications by Web of Science, especially in the Humanities (Mongeon & Paul-Hus, 2016) for non-English-speaking countries. However, this database – one of the most used for scientometric studies – can be considered as a prism through which national research output is seen globally. Therefore, despite all cautions, the data from Web of Science Core Collection are used in this work.

Method and Data

The metadata about publications by Ukrainian authors (at least one Ukrainian affiliation per paper) in Philosophy, History and Literature in 2010-2019 from WoS Core Collection were used: total number of records, language distribution, information about journals where English-language works were published. The comparative analysis was performed using the same data (same period) for few other non-English speaking Eastern European Slavic countries: Poland, Czech Republic and Slovakia. An example of search query: CU=Ukraine AND PY= (2019 OR 2018 OR 2017 OR 2016 OR 2015 OR 2014 OR 2013 OR 2012 OR 2011 OR 2010) AND SU=Philosophy. The date of data retrieval is 10.01.2021.

Results

Our results show that according to WoS, choosing different languages for publications is typical for scientists from the analyzed countries of Eastern Europe in the fields of Philosophy, History and Literature (see Fig. 1-3). The share of publications in other than national language is explicitly defined if it is significant: Russian language for Ukraine; Slovak language for Czech Republic; and Czech language for Slovakia.

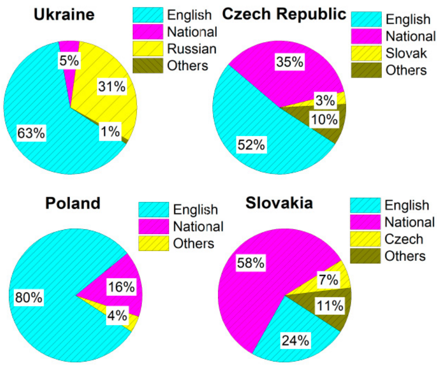

Figure 1. Language distributions of publications by authors from different countries: Philosophy (2010-2019).

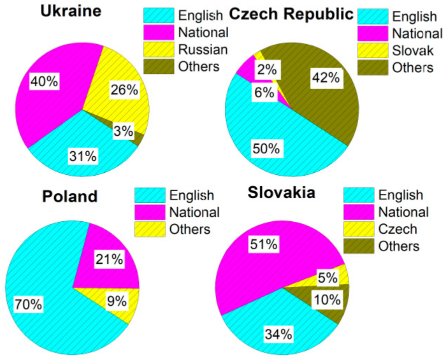

Figure 2. Language distributions of publications by authors from different countries: History (2010-2019).

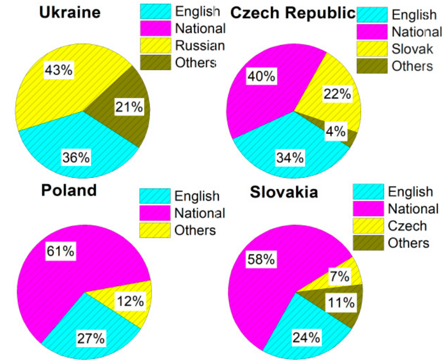

Figure 3. Language distributions of publications by authors from different countries: Literature (2010-2019).

Depending on the discipline and country, the ratio of English-language publications in other languages varies. For example, the shares of papers in the field of Philosophy written in English by Polish and Slovak authors during 2010-2019 are significantly different: 81% and 24%, correspondingly. At the same time, in the fields of History and Literature, scholars from all considered countries demonstrate similar behavior in the context of publication language choice.

In addition, our results shows that a significant share of English-language papers in Philosophy, History and Literature by authors from Eastern European countries are found in the journals published in the same country.

Conclusions

The results confirm the findings of previous studies: it is natural for Humanities to publish research outputs in various languages not being concentrated exclusively on English. This is quantitatively illustrated for Ukrainian, Polish, Slovak and Czech authors. Moreover, language particularities are observed for different countries. Due to historical circumstances, Russian language plays substantial role for Ukrainian Humanities, which is particularly notable and rather counterintuitive for the Literature. But only since 2017 Ukrainian becomes the official language of the educational process. E.g., Russian language is much less influential in Poland, where it was compulsory until 1989, see (Kulczycki, Rozkosz, & Drabek, 2019). Similarly, the mutual language influences are noticeable for scholar publications of Slovak and Czech Republics.

The majority of English-language articles in Humanities by researchers from the considered Eastern European countries and indexed in WoS correspond to the journals published in the country of authors. This practice needs to be studied more carefully, but there is an agreement with conclusions drawn in (Nazarovets, 2020).

Unfortunately, the lack of sufficiently large statistics does not allow to perform the temporal analysis of Ukrainian publication data presented in WoS. The potential changes in language spectrum in response to implementation of new rules would provide an answer to the question about the possible impact of research policy on the scholar publication strategy.

Our preliminary results suggest that natural multilingualism of Humanities has to be taken into account during the process of research evaluations, especially based on quantitative approaches and metrics.

Rigor and Transparency Index for Systematic Literature Reviews: a first stage approach

Gerson Pech[1] and Catarina Delgado[2]

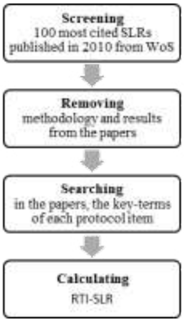
Introduction

Systematic literature reviews (SLRs) play a crucial role in science as they are responsible for systematizing the main results of the key questions of different research fields (Pech & Delgado, 2021). The quality of these works is related to the development of an appropriate review protocol, to the impartiality in papers' selection, and to the rigor in analyzing the data of the studies used. In this way, the AMSTAR**,** AMSTAR 2 (Shea et al., 2017), and PRISMA (Moher et al., 2009) guidelines have been applied in many SLRs as the main methodological supports for their development, and the evaluation of their quality. However, although some research has been carried out to assess the adherence level of the review studies to these two guidelines, none, so far, has carried out a large-scale longitudinal assessment covering different research areas. That is the issue addressed by this work. The objective of this study is to construct the basis of a tool able to, automatically, measuring the rigor and transparency level of SLRs. In fact, the development of a metric to assess the quality of reviews on a large scale based on the methodology would be important to understand their temporal evolution and their dependence in terms of different fields. This approach was used by Menke et al. (2020), not for SLRs, but to evaluate Medicine and Biology papers. The authors created an automated tool (sciscore.com) to assess the quality, based on rigor and transparency of the methodologies used in research of these fields. For this, they created the Rigor and Transparency Index (RTI) as a measurement of the method adherence used in these studies to the established guidelines. Considering the metric created by the authors, the higher the paper's RTI, the higher the guarantee that the study can be reproduced by other researchers. The same concept was applied in this paper, but for SLRs. This is a work in development, and in this first stage, we defined the RTI for Systematic Literature Review (RTI-SLR) using only the AMSTAR and PRISMA items related to the methodology and results' presentation. For each item, we generated lists of key-terms that were used to calculate the RTI-SLR in 100 selected articles.

Method

Our method consists of four steps, as shown in Figure 1.



Screening
100 most cited SLRs published in 2010 from WoS
Removing
methodology and results from the papers
Searching
in the papers, the key-terms of each protocol item
Calculating
RTI-SLR

Figure 1. The method used in this study

In the first step, we retrieved the 100 most cited articles containing the expressions "systematic literature review" OR "systematic review" in TITLE-ABS-KEY and published in 2010. We used the Web of Science database, as it is widely used in many research fields. The extraction was carried out on January 3, 2021. We used papers published in 2010 since the exposure time of these papers was at least 10 years. This made it possible to compare the number of citations of the paper with the RTI-SLR value. In the second step, we extracted the sections in which the methodology and results of the review study are presented. Here, we also used the results section, instead of only the methodology section, as used by Menke et al. (2020). The third step is designated to search the key-terms in the methodology and result sections. Table 1 shows the list of some key-terms classified in the eight methodological items defined in this work (hereafter, protocol-item). This search was done with the NVIVO 1.3, using the words' frequency function. In this way, we applied NVIVO to calculate the occurrence of the key-terms of each protocol-item in all the papers included in our database.

Table 1. Key-term of each protocol-item

Protocol-item	*Key-terms*
Eligibility criteria (EC)	“search strategy”; “inclusion criteria"; “exclusion criteria”
Duplicate study selection (DS)	“independently reviewed”; “independently by two researchers”; “reviewers independently”
Data collection process (DC)	“selection process”; “process of study selection”; “screening process”; “search process”; “review process”
Different databases (DD)	“Scopus”; “Web of Science”; “WoS”; “PubMed”; “Medline”; “Embase”; “Google Scholar”
Search terms (ST)	“string of search”; “search query”; “literature search”; “literature selection”
Flow chart of the process (FC)	“study flow”; “flow diagram”; “flow of articles”; “PRISMA”; “AMSTAR”
Status of the publications (SP)	“publication status”; “language”; “published in English”; “published from”; “published between”; “English-language”
Characteristics of the papers (CP)	“characteristics of studies”; “description of studies”

Finally, the last step calculates the RTI-SLR$_i$ for each paper i, using the following equation:

$$RTI\text{-}SLR_i = \sum_{\alpha=1}^{\alpha=8} Q(N_{i\alpha}) \quad (1)$$

where α defines the protocol-item, $N_{i\alpha}$ is the frequency which the key-terms of the protocol-item α were found in article i, and $Q(N_{i\alpha})$ refers to the quartile in which $N_{i\alpha}$ is found considering all the papers analyzed in this study. $Q(N_{i\alpha})$ is equal to 4, if $N_{i\alpha}$ is from the first quartile; 3, if it is from the second quartile, and so on.

Results

Figure 2 shows the WoS categories of the sample. We only represented categories with more than two papers. All the sample papers are from only one WoS Research Areas: Life Sciences & Biomedicine.

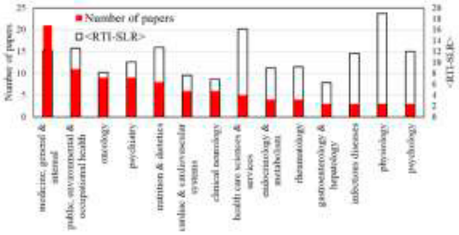


Figure 2. WoS categories of the papers. The red bars denote the number of papers. The open bars represent the mean RTI-SLR whose values are on the right axis.

In this sample, the journal that has more papers is The Lancet**.** Figure 2 also shows the average RTI-SLR value (<RTI-SLR>), indicated on the right vertical axis, for the sample papers belonging to each of the WoS categories. The value does not depend on the number of articles in the category; however, they vary from 6 (critical care medicine) to 19 (physiology) for this set shown in the figure, showing that in several areas the reproducibility of the research may be higher.

Conclusions and perspectives

This paper presented a method to assess the rigor and transparency of the methodologies that have been applied in the SLRs. The results showed that the key-terms used in the model have a close relationship with the process establish stated by the PRISMA and AMSTAR guidelines. Besides, our approach, specifically, the assigned of relevant protocol-items, and the selection of appropriate key-terms for each protocol-item may be a perspective of the first stage for the RTI-SLR development. This initial study suggests that, with further developments and analysis of this tool, it will be possible to extend this model to apply it on a large scale, to assess the rigor and transparency level of SLRs of different periods and fields. In this way, future works should address, mainly, the following improvements: (i) including other methodological items that must be evaluated; (ii) complete the list of key-terms for each protocol-item; (iii) elaborating the large-scale analysis longitudinally; (iv) measures the correlation between the mean RTI-SLR and the Journal Impact Factors; and (v) comparing the RTI-SLR scores with other research areas that usually develop SLRs, such as management and Physics.

Introduction

National language publishing and open access (OA) are claimed to facilitate dissemination of research knowledge beyond academia (Late et al, 2020; Zuccala, 2009), however their contribution to the impact of research remains a blind-spot.

Citation analysis based on Web of Science and Scopus databases provides only a partial picture of research impact (Nicholas et al., 2005), partly because they cover mainly English language articles (Kulczycki et al, 2020. Altmetrics aim to capture the wider outreach of research, and in this study, we focus on "use" in terms of a request for a particular source (cf. Kurtz & Bollen, 2010).

The most promising altmetric sources for user profiles, such as Mendeley, mainly cover research published in English language journals (Wouters & Costas, 2012; Haustein, 2014; Mohammadi et al., 2015; Hammarfelt, 2014). However, OA journal platforms, such as the Érudit platform (Cameron-Pesant, 2019), the Croatian open access platform Hrcâk (Stojanovski, Petrak, & Macan 2009) or the Journal.fi platform studied here offer the possibility to analyse the use of journals, which are published in languages other than English.

Research questions, data and methods

In this paper we study the diversity of users of OA articles on the Finnish Journal.fi platform. This platform hosts 98 OA journals (spring 2020) from all fields of arts and sciences publishing in different languages, mainly Finnish and English. Our main research questions are:

1. Who are the users of articles published on Journal.fi platform? In what role they are using articles from journal.fi platform and what is their geographical distribution?

2. Which kinds of publications are the different groups of users interested in? Do their interests differ according to the year and language of publication?

Federation of Finnish Learned Societies planned an open online survey to visitors of article abstracts and full-texts on the Journal.fi platform. 48 journals (50% of all journals) participated in the study, and the survey was active from 7 February until 31 March 2020.

The survey was organized by using a plugin created for the Open Journal Systems platform. Each visitor was presented in a pop-up window an invitation to join the survey, in which they were asked to indicate one role in which they read or search Journal.fi articles from a list of choices. Participants also permitted tracking cookies for storing data about the Journal.fi articles and abstracts they visited during the survey. Each visitor was identified with a unique hash key and the visitors' IP address was used to determine a geolocation. Information about the year and language of publication of articles was gathered from the Journal.fi platform.

Results

Total of 668 users participated in the survey. The two largest groups were students (40%) and researchers (36%), followed by private citizens (8%), other experts (7%) and teachers (5%). Other identified user roles include journalists, civil servants, entrepreneurs and politicians. Students (42%) are clearly the largest user group of national language (Finnish and Swedish) publications, and besides researchers (25%), also private citizens (12%) and other experts (11%) figure prominently among users. For the foreign language publications, researchers (46%) and students (38%) are more clearly the main user groups.

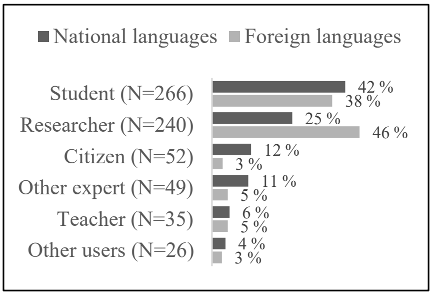

Figure 1. Share of 668 users of national and foreign language articles by self-reported role

The survey participants visited 1,546 articles a total of 2,018 times (counting only one visit by participant per article). As shown in Figure 2, article visits by students are less focused on the latest articles compared to other groups. The vast majority, 97%, of visits to national language articles are by users from Finland. The foreign (mainly English) language articles serve a much more international audience: 37% of the article visits are by Finnish users, 5% come from the Nordic countries and 58% the rest of the world.

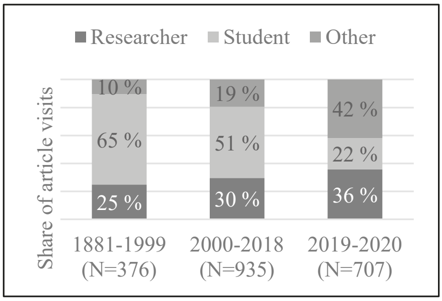

Figure 2. Share of 2,018 article visits by different user groups and year of publication.

Discussion and conclusions

Our study shows that OA publications in national languages are vital for reaching important users of research both within and beyond academia, including experts, citizens, teachers and students. In the specific context of Finland, these groups appear more prone to use research published in the national languages compared to English. These findings support recent claims for promoting multilingualism in scholarly communication (www.helsinki-initiative.org). Both OA and language diversity are needed to support the broader societal impact agendas of responsible research and innovation and open science.

The approach of using an online questionnaire, which targeted active users of the Journal.fi platform, was an effective method. However, the self-selection of participants may lead to the underrepresentation of certain groups. More detailed studies could look at the wider use of research from different academic disciplines. This study focused on the relatively small context of Finland, and similar approaches for studying other countries and regions would be beneficial for understanding the role of academic publishing in national languages more generally.

Exploring the Distribution Regularities of Referees' Comments in IMRaD Structure of Academic Articles

Chenglei Qin[1] and Chengzhi Zhang[2]

{[1] clqin, [2] zhangcz}@njust.edu.cn
Department of Information Management, Nanjing University of Science & Technology, Nanjing 210094 (China)

Introduction

Peer review is playing an essential role in scientific communication, which is closest to the natural state of the evaluated object (Narin, 1978). The peer review comments, as a carrier to record the process of peer review, objectively record the referees' suggestions, expert knowledge, and other valuable information. Most scientific articles' structural functions can be divided into IMRaD (Introduction, Materials & Methods, Results, and Discussion) structures. Exploring the distribution regularities of peer review comments among different structural functions can reveal the critical points of referees' focus and help students or early-career researchers deepen their understanding of peer review mechanisms. For a long time, limited by the traditional peer review mechanism, the peer review reports are not large-scale open access, scholars cannot unveil the mystery of peer review from the perspective of text content.

To further improve the fairness and transparency of the peer review process, improve the scientific quality, and speed up scientific dissemination, the open peer review mechanism came into being (Pöschl, 2012). Several influential journals, well-known publishing groups, and scientific research institutions began to adopt the open peer review mechanism (ASApbio, 2018; Madison Crystal, 2019). The open-access of many of peer review reports provides a data basis for mining and analyzing the peer review comments.

Based on the papers and peer review reports published in Atmospheric Chemistry and Physics (ACP, IF 5.6) from 2001 to 2016, this paper makes an exploration of the distribution of peer review comments in different structural functions of academic text to reveal the critical points of referees focus and provide reference for the writing of academic papers.

Methodology

Dataset

1,333 papers' section structural functions were recognized by the feature words of section type (Note that the feature words of section type can be found in Table 1 of Appendix, https://github.com/kakabular/peer-review/blob/main/Appendix_Table_1.pdf). The distribution of the dataset from 2001 to 2016 is shown in Figure 1.

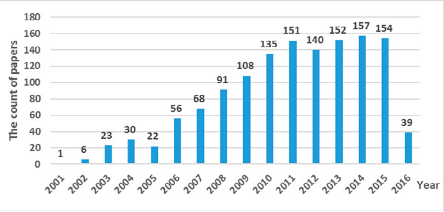

Figure 1. The distribution of papers from 2001 to 2016

The location information (such as page, line, table, figure, equation, etc.) of review comments can be extracted through the rules of the regular expression (The rules can be found in https://github.com/kakabular/peer-review).

According to the style of the ACP review reports, one paragraph generally comments on one problem. Therefore, we treat one paragraph as one comment sentence. The distribution of the number of peer review comments with location information is shown in Figure 2. The lowest coverage rate is 0.77.

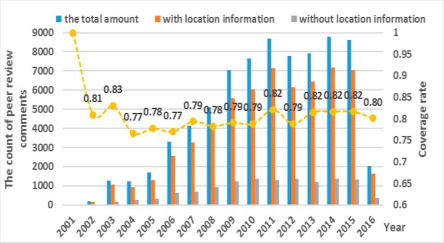

Figure 2. The distribution of peer review comments from 2001 to 2016.

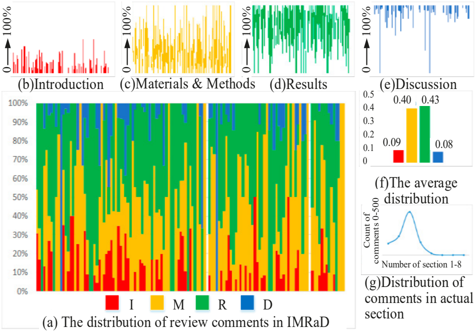
Method

This paper's research plan is as follows: First, we obtained research data from the ACP journal website. Because the original format of the manuscripts and the peer review reports are in PDF format, the PDF format files were converted into HTML files, and then the plain text is automatically extracted according to HTML source code. Second, use feature words of section type to recognize the academic articles' section structural function. And then, extract the location information in peer review comments according to the rules, maps the peer review comments to the original paper, obtains the corresponding structural function of the peer review comment. Finally, we analyze the peer review comments' distribution in academic articles' different structural functions (IMRaD) and actual sections.

Results

Taking the year of 2007 as an example, this section first analyses the distribution of peer review comments in the different structural functions of academic articles. Secondly, we analyse the average distribution of review comments in different years and the distribution of review comments in the actual sections.

Figure 3(a)- 3(e) shows the distribution of peer review comments in the IMRaD structure in 2007, which presents that in the majority of cases the proportion of peer review comments distributed in the Materials and Methods sections is significantly higher than in the Introductions and Discussion sections, reflecting deeper concern of the referees on materials, methods and experimental results (The abscissa represents each paper in 2007. The vertical axis represents the distribution percentage of review comments for each paper in IMRAD). Figure 3(f) shows the average distribution of the review opinions in the IMRaD structure that 40% and 43% of reviewer comments are directed at Materials & Methods and Results, which can verify the above findings. Figure 3(g) shows the distribution of the review comments in the actual sections, from which it can be seen that the number of review comments distributed in the opening and ending sections of the paper is significantly less than the sections in the middle part. Generally, scientific papers are organized according to the logical structure of IMRaD. So that we can get similar results.



(b)Introduction (c)Materials & Methods (d)Results (e)Discussion

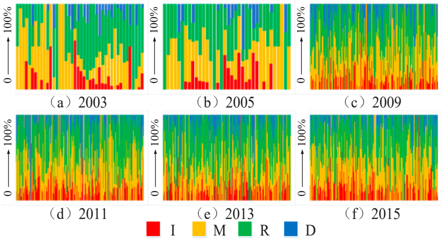
(a) The distribution of review comments in IMRaD

(f)The average distribution

(g)Distribution of comments in actual section

Figure 3. The distribution of peer review comments of data in 2007.

The distributions of peer review comments in other years (for example, in the year of 2003, 2005, 2009, 2011, 2013, 2015) are shown in Figure 4. We can find that referees pay more attention to the function of Materials & Methods and Results.



（a）2003 （b）2005 （c）2009

（d）2011 （e）2013 （f）2015

Figure 4. The distribution of peer review comments in other years

Conclusion

Based on ACP data from 2001 to 2016, this paper explores the distribution of peer review comments in different structural functions of academic articles and actual chapters. The results show that the reviewers pay more attention to Materials & Methods and Results. The proportion of reviewers' opinions in the middle sections of a paper is higher than that in the beginning and end of a paper. The findings are consistent with the general cognition: the scientific, reliable, and enough experimental methods are the premise of the research conclusion. This finding helps researchers understand the key points that referees focus on in reviewing processes, deepen their understanding of the review mechanism, and improve their writing skills. In scientific research, researchers should explore boldly and verify carefully to ensure the quality of science. Also, there are many shortcomings in this paper. For example, due to the significant differences in the writing style of the review experts, the rules cannot cover all the location information.

References to Literature in Patent Documents: A Case Study of Electromobility Research

Zhao Qu

zhaoqu@dzhw.eu
Department 2, German Centre for Higher Education Research and Science Studies (DZHW), Schützenstr. 6a,
Berlin 10117 (Germany)

Introduction

Electromobility (e-mobility) takes a systematic standpoint that reaches far beyond mere technical aspects and also requires complex social changes (Grauers et al., 2013). Specifically, it is associated with the shift to a broader, more diverse and global network of actors and stakeholders, which may help promote and introduce innovations to the market (Capgemini, 2012). The crucial point for fostering innovation is the transfer and recombination of knowledge from numerous actors, thereby blurring the boundaries between science and technology (Campbell et al., 2005).

This study is to explore the connections between science and technology through journal articles pertaining to e-mobility cited in patent literature. This special issue is a bridging effort to bring together scientific papers, patent citations and comparative analysis by shining a spotlight on measuring the progress in knowledge generation, diffusion and transfer

Data and methods

This study consists of two stages of analysis, including an overview on global trends in e-mobility research as well as a further discussion on partial articles that are cited as non-patent literature (NPL) references and the matched citing patents. We limit our analysis to 3,441 journal articles and 1,162 patent documents retrieved from Web of Science and Lens patent corpus (Figure1).

Figure 1. Dataset of e-mobility research and matched citing patents.

Three widely used indicators based on the existing literature, including the patent scope (Lerner, 1994), patent family size (Harhoff et al., 2003) and forward citations (Trajtenberg, 1990) are employed to capture the technological importance of the invention citing scholarly works and the possible impact on subsequent technological developments. NPL references are further linked to data on applicants and frequently transferred patents for the purpose of tracing technology transfer with a knowledge base provided by different types of collaboration.

Results and discussion

Global e-mobility studies have presented a growing trend both in counts and scientific collaborations since 2006, increasing both national and international links. The United States and China are the main sources of e-mobility research among 75 countries and territories identified by postal addresses of listed authors. Authors from 69 countries have engaged in an international collaboration, and when comparing the structure of institutional collaboration network, over 92 percent of total institutions have collaborated with others.

There is a generally upward trend in the number of citations received three years after publication except 2008. E-mobility studies cited in patent literature cover a smaller proportion by comparison to articles that do not match to NPL references, while the percentage of collaborative works is higher than that of all relevant publications during the same period. NPL references present a distribution pattern over time similar to that of the whole set. That is, the more publications a year or a country corresponds to, the higher the number of articles cited by patents is. However, the rank of countries by the percentage of articles cited by patents displays an entirely different picture (Table1).

The publication date of citing patents ranges from 2008 to 2018, and the coverage of patented technologies is comparatively broad, ranging from human necessities to emerging cross-sectional technologies. Patents citing e-mobility research are principally applied by companies in the United States, Singapore and Japan. Seventy-six percent of patents have cited scientific papers with a collaboration between academic institutions corresponding to 73 percent of applicants from companies and academia (Figure 2). Articles containing an academia-industry collaboration have been largely cited in company’s patent literature while the one published by companies is more likely to be cited by academic patents. Patents citing research conducted through an academia-industry collaboration have more forward citations, while patents with citations to the collaboration between authors from companies cover a broader scope of technologies (Table 2). More than half of citing patents have been assigned to new parties, and 75% of assignments are made from individuals to companies or universities. Eighty percent of patents assigned more than ten times have cited collaborative articles of academic institutions.

Conclusions

This study has provided an informative overview of e-mobility research and matched citing patent documents. Global research on e-mobility since 2006 has been conducted increasingly by a broader network of authors. In the light of evidence from patent citations, e-mobility research cited frequently by other articles are more likely to be cited by patents. Articles exploring the issues of EVs published by universities or research institutes, especially with the national collaboration, have received more patent citations. Mostly, academic institutions' collaborative articles have been cited by applicants from companies and academia. Studies conducted by an academia-industry collaboration have been widely cited in company's patents while the one with a business collaboration is more likely to be cited by academic patents. Patents citing single-author articles and international research collaborations seem to be more important indicated by broader patent scope, larger family size and more forward citations on average. More than half of citing patents have been assigned primarily from individuals to companies or universities, and most of frequently transferred patents have cited collaborative articles of academic institutions. Differences mentioned above need to be explored in a broader context, while the growing trend in scientific collaborations of NPL references and its influences on patents measured in each dimension should not be neglected.

The scientific productivity of German PhD graduates: A machine learning–based author name disambiguation and record linkage approach

Andreas Rehs[1]

[2] *andreasrehs@googlemail.com*
University of Kassel, International Center for Higher Education Research, Mönchebergstr. 17, 34109 Kassel (Germany)

Introduction

Although PhD students and graduates play an important role in scientific knowledge production and economic growth (Stephan, Sumell, Black, & Adams, 2004), we have little information on their publications and related bibliometric indicators. Therefore, there is a need for new data sources to identify PhD students' publications and a need to link them to other databases of interest. This especially holds for Germany where the problem of missing publication information on PhD graduates has repeatedly been pointed out (Konsortium Bundesbericht Wissenschaftlicher Nachwuchs, 2017, p. 35).

Data

The dataset we used to trace the publication record of German PhD graduates is built on two sources: the electronic catalog of the German National Library (DNB) and the Web of Science (WOS). The DNB is mandated to collect all German dissertations, and therefore its catalog lists the vast majority of PhD theses submitted at German universities. For every dissertation, the DNB stores some basic information, like the dissertation's year, the granting university and the author's name. Regarding our second dataset, we use a 2017 copy of the WOS as the basis to retrieve publication data.

Author name disambiguation

To resolve ambiguous author names in the WOS, we perform author name disambiguation on the basis of Rehs (2021). In this task, we consider all surname-initial combinations (in the following: blocks) that appear in the DNB dissertation database as worthwhile to disambiguate. There are 533,198 distinct blocks in the DNB; 153,213 appear more than once, which means there is more than one dissertation related to that block. In a 30-day processing period, the disambiguation algorithm processed 184,783 of the 533,198 blocks in the DNB and ended up with 10.6 million publications processed into about 1.96 million different authors. These processed homonyms cover about 51% of the 960,000 relevant dissertations in the DNB. We consider dissertations between 1975 and 2015 and those outside the disciplines: history, philosophy, theology, and arts and music as relevant. Concerning the complete WOS, our disambiguation approach processed 2.8% of the 6.5 million homonyms. Those homonyms account for 4.2% of the 178 million block-publication relationships in the WOS (Rehs, 2021).

Probabilistic record linkage of WOS data to German dissertation authors

In the next step, we want to connect entries in the DNB with those in our disambiguated WOS database. However, we lack unique identifiers in the two databases and need to apply record linkage. Record linkage is either deterministic or probabilistic. In deterministic linkage, records are matched if linkage fields agree, or unmatched if they disagree. Deterministic approaches are not robust to measurement error (e.g., related to misspellings) and missing data. Additionally, uncertainty in the merging procedure cannot be quantified. Instead, arbitrary thresholds determine the similarity sufficient for matches.

Probabilistic record linkage approaches can account for this uncertainty (Fellegi & Sunter, 1969). They estimate the probability that two given records refer to the same or different entities. In this process, each identifier, such as first names, is weighted by its performance in determining matches and non-matches between two databases. For the determination of weights, two probabilities are of interest: unmatched probability (u-probability) and matched probability (m-probability). The u-probability gives the probability that a variable between two datasets agrees by chance. For example, we use the address string to compare records between the DNB and the disambiguated WOS dataset that share the same homonym "Muller, M". If we assume ten unique and uniformly distributed addresses in the two databases, the u-probability would be 1/10, or 0.1. The m-probability describes the probability that a variable in matching pairs will agree. Again using the example of addresses and abstracting from peculiarities of the two datasets, the matched probability between two records may be exactly 1.

That means the address of a dissertation always agrees with the address stated on the corresponding publication. However, we don't know much about this probability and the related true matches. We can only estimate the m-probability using iterative methods, such as the expectation maximization algorithm (Dempster, Laird, & Rubin, 1977). Given that we would estimate 0.95 for the m-probability, the address variable weights would be calculated as described in Table 3. The described calculation can be repeated for all other possible variables between the two datasets. Finally, the total weight for matching and non-matching are determined by adding all variable weights. The posterior probability for matching is then derived from the total weight (Blakely & Salmond, 2002).

Table 1. Identifier weighting in probabilistic record linkage

Variable	**Outcome**	**Proportion of links**	**Proportion of non-links**	**Frequency ratio**	**Weight**
Address	***Match***	m= 0.95	u≈ 0.1	m/u≈ 9.5	ln(m/u)/ln(2) ≈ 3.25
Address	***Non-match***	1−m= 0.05	1-u≈ 0.9	(1-m)/(1-u) ≈ 0.05	ln((1-m)/(1-u))/ln(2) ≈ -4.17
First name	…				

Depiction based on (Blakely & Salmond, 2002).

In our approach, we use an extension of this framework (Enamorado & Fifield, 2019). This "fastlink" framework allows the incorporation of partial agreements and missing data, which relaxes the conditional independence condition of the Fellegi-Sunter model. The conditional independence condition requires the variables to be independent of each other, which is seldom the case with real-world data. In our case, a publication's address field and the author's first name, for instance, correlate in their submissions.

In the next step, we prepare the datasets and take into account that both datasets have peculiarities. While the DNB, as a dissertation database, usually captures a single event, our disambiguated WOS database covers a researcher's lifetime record of publications. Therefore, we aggregate all WOS publications belonging to a disambiguated author and build a synthetic author profile consisting of the minimum paper year, the mode value of the address, and the mode value of the first name.

In our further procedure, we consider only blocks with sufficient frequency. A minimum frequency is computationally needed to conduct reasonable probabilistic inference (Enamorado et al., 2020). We do so by setting the threshold to blocks with at least ten different dissertations and at least ten different disambiguated authors. In the last step we apply the fastlink framework to the the synthetic WOS author profiles and the DNB. We use the DNB university city vs. the mode value of the synthetic author profiles address, first name vs. first name and dissertation year vs. minimum value of paper year to link both datasets.

We apply deterministic linkage for blocks containing fewer observations than the mentioned thresholds. Here, we merge authors that match in the same variables. If there are fewer than three entries in both databases, we relax the matching to comparison of years and one other variable. Generally, we allow a margin of +/− 2 for year. For address and first name we allow fuzzy matching but allow variation of only one character in the Levinstein distance used.

Results

In our probabilistic approach, we were able to link 30,840 dissertation authors to corresponding author profiles. This number is based on all observations with higher than 0.8 posterior probability. The deterministic strategy yields 30,804 dissertations. Our dataset of 61,644 linked authors covers 5.4% of the relevant DNB dissertations and 0.03% of the disambiguated WOS author profiles.

Introduction

It has been stated that in 2020 many journals, especially biomedical and multidisciplinary ones, have accelerated their throughput, especially for COVID-19 related submissions (Callaway, 2020; Horbach; 2020). Horbach (2020) analysed the duration of the publication process, in number of days, for a sample of 529 journal articles, published in 14 different journals, including the *International Journal of Infectious Diseases* (IJID). For this investigation, he used a repository of coronavirus-related research articles established by the Centre for Science and Technology Studies (CWTS), more specifically the April 4, 2020 version. The main conclusions of his study are that medical journals have, since the outbreak of the pandemic, strongly accelerated their publication process for coronavirus-related articles. Concretely, he found that the time between submission and publication has decreased on average by 49%. The largest decrease in number of days between submission and publication of articles was due to a decrease in time required for peer review. For articles not related to COVID-19, no acceleration of the publication process was found.

For IJID he considered 32 articles published before October 1, 2019, and 32 dealing with COVID-19 published after January 1 (and before April) 2020. As a comparison, he further considered the ten most recently published articles (as of April 16, 2020) dealing with studies not related to COVID-19.

In this submission, we focus on IJID. This journal, the flagship journal of the International Society for Infectious Diseases, is a truly international journal to which many non-Western and non-Chinese authors contribute. Concretely, we only consider publications of article type (according to the WoS classification) and made a distinction between COVID-related articles and other ones. In 2020, 709 documents of article-type were published in this journal.

Research questions

1) Is there a noticeable increase in the speed with which articles are published in IJID?

2) If there is an increase, does it apply to all articles, or only to COVID-related ones?

3) If there is an increase is it due to the time between submission and acceptance, or the time between acceptance and online availability, or both?

Methods

COVID-related articles were determined based on the WoS query:

TS= (“SARS-CoV-2” OR COVID* OR “2019-nCoV”)

Other articles were considered not COVID-related. As we collected data manually we were able to check that this query indeed retrieved all COVID-related articles (and we again noticed problems with the WoS definition of reviews (Colebunders & Rousseau, 2015), see below). As the baseline, we consider all articles in volumes 90 and 91 (published in January and February 2020). Then we collected all COVID- and non-COVID articles submitted between January 23, 2020 (first submission of a COVID-related article in IJID) and June 30, 2020. For each of these articles, we noted the submission date, the acceptance date, and the date the articles became available online. The time in days between any two dates was determined (taking into account that 2020 was a leap year). The most recent articles, among those submitted before July 2020, were published in the February 2021 volume.

Results

Results for the time between submission and acceptance, here referred to as acceptance delay, are shown in Table 1 while the corresponding data for time between acceptance and online availability (availability delay) are shown in Table 2.

Although these data clearly show that the average acceptance delay is much smaller for COVID-related articles than for non-COVID-related ones, we see that also for non-COVID-related ones the delay was shortened compared to the baseline period. Availability delay is always very short for this journal and remained practically the same, yet slightly shorter for COVID-related articles than for the others. In this sample of IJID articles, the decrease in average acceptance delay for COVID-19 articles is 43% while for non-COVID-related articles it is 9%.

Table 1. Acceptance delay, time in days

	# art.	Mean delay	St.dev	Md.	Q1
Baseline	103	71.02	38.05	68	[3,34]
COVID	214	40.35	32.65	31	[1,19]
Non-COVID	161	64.92	39.06	55	[1,36]

Note: Md. stands for median and Q1 for first quarter

Table 2. Availability delay, time in days

	# art.	Mean delay	St.dev	Md.
Baseline	103	6.92	5.40	6
COVID	214	7.38	7.52	5
Non-COVID	161	7.55	8.37	6

Applying a Mann-Whitney test, as described e.g. in (Rousseau et al., 2018, p. 95) the null hypothesis of equality of distributions of acceptance delays was rejected for two cases: baseline versus COVID-related, and COVID versus non-COVID articles (z-scores larger than 7 in both cases). The z-score for the baseline versus the non-COVID case is 1.636. Hence we cannot reject the null hypothesis that these two distributions are the same. Yet, there is no reason to think that speeding up has occurred at the cost of non-COVID-related papers.

Discussion

Although we come essentially to the same conclusion as Horbach (2020) for IJID, our findings are based on a much larger dataset, covering a longer period.

The acceptance period involves three types of actors: the reviewers, the authors revising their manuscript, and the editor(s) handling the manuscript. For COVID-related papers, all three groups have a motif to speed up their actions and we can only assume that they actually did.

The reader may see in Table 1 that there is one non-COVID-related article that was accepted after one day. This article is published as a review, but considered an article by Clarivate Analytics. It is a discussion of a practical toolkit for developing Antimicrobial Stewardship Programs (ASPs) developed by the WHO (Pierce et al., 2020). Probably the main editor immediately accepted it.

We offer the following thoughts about the differences in time between the three groups of papers. Assume that COVID-related papers are treated with preference compared to non-COVID-related ones. Then borderline COVID papers may yet be accepted (because of their possible scientific interest) but need a longer time to be revised. This would lead to a higher average acceptance time than would otherwise be the case. Assume further that for non-COVID-related papers the opposite is the case, so that borderline papers are rejected. This would shorten the average acceptance time and hence brings the two acceptance times closer to one another. Regrettably, we have no information on rejection rates, which is another important parameter when studying journals and their publications. The first quarters, though, (Table 1) show that there are much more COVID papers, compared with the other two groups, that are accepted in a very short time.

Conclusion

IJID indeed accepted COVID-related submissions in the first half of 2020 faster than it did earlier papers. There is no indication that this happened at the cost of other submissions. On the contrary, also other articles were published faster, although not in a statistically significant way.

Speeding up the time between submission and online publication was mainly due to a decrease in acceptance times as this journal has already a very short availability time.

Acknowledgments

The author thanks Robert Colebunders (University of Antwerp) for suggesting this investigation.

Introduction

Due to the steady increase of scientific literature, one important question that arises is how to identify outstanding contributions in a continuously growing pool of scientific publications?
Over the years, several channels dedicated to signaling outstanding publications in the immense collection of research knowledge have evolved in the scientific community (Mugabushaka, Sadat, & Costa Dantas Faria, 2020). Up to date, the most common way to identify outstanding publications relies on bibliometric indicators, even though there is criticism to this approach (e.g., Aksnes, Langfeldt, & Wouters, 2019). Here we will focus on an alternative way to identify such publications, namely by exploring scientific expert judgements of two major science journals: *Nature* and *Science*.

In recent years, a number of scientific journals have added sections dedicated to provide better visibility for outstanding research from among the high number of publications. For example *Nature* and *Science* provide a weekly selection for especially outstanding contributions from among all of their own journals' publications (e.g., *Nature*'s "News & Views" or *Science*'s "This Week in Science") and from the pool outside of their own journal (e.g., *Nature*'s "Research Highlights" or *Science*'s "Editor's Choice"). These highlighted sections, so-called editorial recommendations, are usually curated by scientific editors and refer to scholarly articles that are judged as being highly influential and promising for future research developments. They carry a precious expert judgement of scientific quality and are readily available unlike current bibliometric evaluations. Thus, such featured publications provide valuable information for research monitoring.
Up to now, this type of scientific recognition has rarely been used or described in detail. In what follows, we will outline some main characteristics for two such example datasets collected from *Nature* and *Science*. We will focus on the journals of publication to which the editorial recommendations refer to, the main authorship countries, and a tentative exploration with respect to their research areas. This will increase our understanding of similarities or differences dependent on the highlighting journal and further describe important characteristics for this type of scientific recognition.

Methods

In order to compare editorial recommendations of different journals, they need to have the same regularity, scope, and target audience (Sadat & Mugabushaka, 2020). Thus, we focused on weekly occurring, outward directed editorial recommendations with a similar target audience: (a) *Nature*'s "Research Highlights" and (b) *Science*'s "Editor's Choice". These two weekly sections each highlight around seven publications per issue, coming from across a wide range of research areas, pointing to scientific journals outside their own, and are targeted to the scientific community. Datasets of editorial recommendations were collected from the information available on the journals' websites. The collection of Digital Object Identifiers (DOIs) for scholarly articles was in most cases automated. However, automated retrieval was always followed by a substantial effort in manual data cleaning and curation, since many references to DOIs were missing or unstructured.
For (a), we collected and cleaned a dataset with 5'345 editorial recommendations of scholarly publications for a period from January 2008 to November 2020. For (b), we collected and cleaned a dataset with 4'085 editorial recommendations of scholarly publications for a period from January 2009 to May 2020 (data available here: http://doi.org/10.5281/zenodo.4707580). To obtain additional information about the referenced publications, we retrieved meta data from CrossRef for each DOI regarding the journal (5'323 for [a] and 3'999 for [b]) and the country of authors from Scopus (4'302 for [a] and 2'981 for [b]). To gain a better picture of the dominant research areas in editorial recommendations, we present some preliminary analysis regarding the field information data provided by the journal (5'294 DOIs across 517 different fields for [a] and 4'083 DOIs across 875 fields for [b]). Due to their diversity, they were regrouped into the following most frequent categories based on subjective judgement: Astronomy, Biology, Chemistry, Ecology, Genetics, Geosciences, Materials, Medical research,

Microbiology, Neuroscience, Physics, Social Sciences, Technology, and Zoology.

Results

Which journals are most commonly referenced?

The main journals of editorial recommendations from *Nature* and *Science* are typical high impact journals (e.g., PNAS and Cell; see Figure 1). The highest share of *Nature*'s "Research Highlights" refers to publications in *Science*, whereas *Science*'s "Editor's Choice" fails to show the reverse pattern.

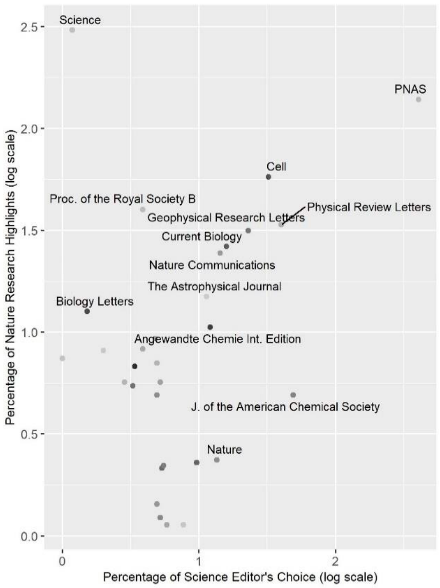

Figure 1. Percentage of referenced journals in editorial recommendations.

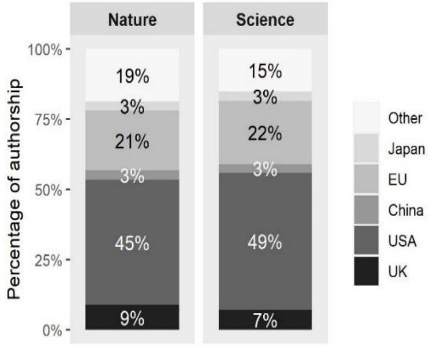

Figure 2. Percentage of authorship countries in editorial recommendations.

Which authorship countries are most common?

Geographical distribution of authorship was calculated as fractional percentage on a whole-normalized country-based level and was similarly distributed in both journals (see Figure 2). USA-based scientists author the main share of referenced publications in the editorial recommendations of *Nature* and *Science*, preceding EU-based ones and a group of scientists from countries other than the listed ones.

Which research areas are most common?

The distribution of editorial recommendations across research areas was similar in *Nature* and *Science*, apart from a few exceptions (see Table 1).

Table 1. Diverging research areas for editorial recommendations

Journal	Biology	Chemistry	Ecology	Zoology
Nature	9.5 %	4.5 %	14.2 %	6.7 %
Science	17.1 %	7.5 %	10.3 %	0.7 %

Outlook

The current poster aims at describing the main characteristics of editorial recommendations from two major science journals. We showed similarities and differences regarding the referenced publications, their authorship countries, and their main areas of research. Next steps of analysis entail the systematic comparison of editorial recommendations with concurrent measures of research impact like citation metrics and internet-based mentions. In sum, the current project provides a first description of outstanding publications highlighted in two major science journals, providing a promising new approach to evaluating research output.

Acknowledgments

We are grateful to Dr. Alexis-Michel MUGABUSHAKA for helpful comments and discussions about this work.

Introduction

Academic serials (especially peer-reviewed journals) play a very critical role in the scientific ecosystem and both integrity and independence are perceived as essential for good editorial governance (Rynes, 2006). For being responsible for articles selection (Bedeian et al., 2009; Feldman, 2008), elite board membership ensures the scientific quality of publications and "occupy key roles as opinion formers, gatekeepers and arbiters of disciplinary values" (Burgess and Shaw, 2010, p.630). So far, board elites have not been subject to a scrutiny proportional to their decision power (Burgess & Shaw, 2010) and an overall lack of transparency has been reported about the general editorial process despite of being actual gatekeepers (Miner, 2003; see also Bedeian et al., 2009; Horan et al., 1993).

In this work, we draw on the existing, but limited, body of knowledge available to examine empirically journal editorial boards (EB) in innovation studies field. We shed some light on demographics characteristics of editorial members. We believe this work may add some relevant information for those interested in science governance and social structures of research activities.

The Boards of "Innovation Studies"

Fagerberg et al. (2012) studied both the most productive journals in innovation as well as those using the most findings already published. For the 20 top-tier journals identified, we aim to present the demographic features of scholars behind. Scholars' names, affiliation country and gender were collected from official journal's editorial page. A total of 3,005 available seats were recorded occupied by 2,440 distinct persons from 30 countries.

The size of EBs

The mean size of Boards is 150 editors. Although *R D Manag* Board was found with only 19 editors, others have over 300 scholars: the likes of North-American outlets as *Acad Manage J* and *Acad Manage Rev* while *Manage Sci* stands out as the one with the largest team, 399 editors as presented in Figure 1.

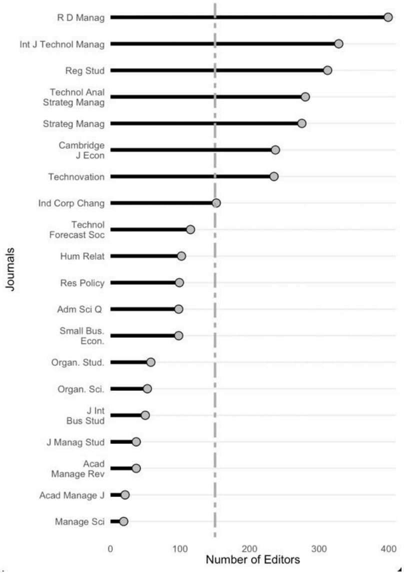

Figure 1: Editorial Board size per journal intercepted by the mean number of editors.

Geographies of editorship

Braun (2004) defined international journals as those with scholars from 5 countries in EB. Thus, all outlets from our study set are international ones, as their editors come from 8 to 30 different countries. Figure 2 shows a world representation of editors' frequency found in each country. Darker the colour, higher the frequency of editors.

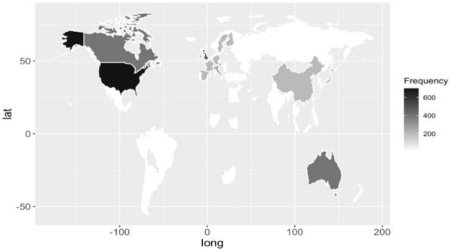

Figure 2. Geographical location of editorial members.

The US overwhelming dominance of membership is clear. García-Carpintero et al. (2010) reminded most science publishing houses are US-based. Europe and India host a significant number of editors. With exception of Australia, nations from the South represent a negligible role in this editorial process with very few editors involved.

Gender balance

With the purpose of understanding gender balance, we matched gender proportion in ten countries with higher numbers of editors as illustrated in Figure 3.

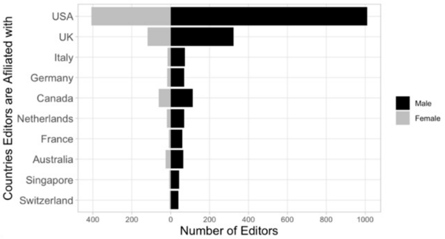

Figure 3: Number of editors affiliated to the top 10 countries, by gender.

US number of editors is by far different from the other countries with around 1,000 men and 400 women editors. However, US are not gender-balanced. Actually, all countries show a higher frequency of memberships held by men editors than women. Metz & Harzing (2009) pointed women's presence in academia is not long enough to reach levels of seniority which are associated with Board membership.

Conclusions

The present study is an attempt to understand the demographic structure of innovation EB members which showed to be diverse quantitative and qualitatively. Despite of being an eclectic topic, a low diversity for gender (male predominance) and country affiliation (high representation of US and UK editors) is perceived. A greater diversity is important for EB meet their missions (Jagsi et al., 2008) and a key driver in academia for knowledge development by applying different methodologies and paradigms (Robinson & Dechant, 1997).

Keyword Distance Ratio:
Evaluating Keyword Assignment with Word Embeddings

Brandon Sepulvado

sepulvado-brandon@norc.org
NORC at the University of Chicago, 4350 East West Highway, Bethesda, MD 20814 (USA)

Introduction

Despite the emergence of natural language processing (NLP) assisted search within certain new bibliometric databases (Wang et al., 2020), keywords remain a staple of information curation and retrieval within most major bibliometric sources, such as Web of Science, Scopus, and PubMed, and authors still choose keywords or phrases to summarize the information their documents contain. As such, keywords are an institutionalized component of the publication and literature search process, yet how does one empirically evaluate the keywords chosen for a document?

This text proposes the Keyword Distance Ratio (KDR) to respond to this question. Theoretically, keywords should, at the same time, be closely related to the content within a document while also remaining sufficiently distinct so as not to convey redundant information. The KDR is a document-level measure that relies upon the Relaxed Word Mover's Distance (RWMD; Kusner, Sun, Kolkin & Weinberger, 2015) to quantify these intuitions.

In investigating the utility of the KDR, this text compares article keywords submitted by authors to those chosen by Scopus in its index terms and then illustrates a dramatic difference in document summary based upon the keyword source.

Keyword Distance Ratio

Relaxed Word Mover's Distance

The KDR relies upon Word Mover's Distance (WMD; Kusner et al., 2015) in order to obtain distances between keywords and the documents they describe. For an intuitive understanding of WMD, imagine that a document is a cluster of points in n-dimensional space. The points represent the embeddings for words (i.e., keywords and those in the article), and a word's location is based upon the word's embedding vector. The current analyses use 300-dimension FastText embeddings (Mikolov, Chen, Corrado & Dean, 2013), which means that each word would be placed in a 300-dimension space. One plots the keywords and words in the document, and the distance then is a function of the effort it takes to move one set of points to the closest points in the other set. To reduce computational complexity, the RWMD relaxes a couple constraints imposed upon the WMD.

Keyword Distance Ratio

The KDR entails calculating two sets of RWMDs: (1) between each pair of keywords and (2) between each keyword and its corresponding document. The KDR then compares the sum of each type of distance, adjusting for the number of keywords listed. Let the KDR of document d be:

$$KDR_d = \frac{\sum_{j=1}^{n-1}\sum_{i>j} RWMD_{k_{i,d},k_{j,d}}}{\sum_{i=1}^{n} RWMD_{k_{i,d},a_d}} \cdot \frac{2}{(n-1)}$$

In this equation, the numerator sums all pairwise RWMDs between keywords k_i and k_j used to signify the content of scholarly document d; the denominator sums the pairwise RWMDs between keyword k_i and abstract a for the document d. This value however will increase automatically with each additional keyword because there are $\frac{n(n-1)}{2}$ possible comparisons in the numerator and only n comparisons in the denominator, where n is the number of keywords. As such, the second part of the KDR equation accounts for the number of keywords. To rephrase more intuitively, the KDR is the ratio of the sum of pairwise RWMDs for all keywords listed for a document to the sum of all the RWMDs between a document's keywords and its abstract; this value is then scaled to account for the number of keywords in a document.

Data

This text uses a small corpus of neuroethics articles to demonstrate the utility of the KDR for comparing author-provided keywords to Scopus-assigned keywords (i.e., index terms). The data used come from Scopus, which is an ideal bibliographic database because it has good journal coverage in both the humanities and health-related sciences and indexes more journals than other databases, such as the Web of Science (Falagas, Pitsouni, Malietzis & Pappas, 2008). A keyword-based query was used to obtain publication records from Scopus because this approach has proven successful for neuroethics (Leefmann, Levallois & Hildt, 2016). I searched Scopus for any articles published in English that contain "neuroethic*" in the title, abstract, and/or keyword fields. After excluding articles with missing abstracts and/or keywords, there are 727 publications. In calculating the distance from keywords to documents, this paper uses abstracts—rather than full article text—to represent a document.

Results

Table 1 presents the descriptive statistics on both sets of keywords. It is notable that, although the numerator and denominator are higher in the index terms KDR than in the author keywords KDR, the numerator is proportionally much higher in the index terms KDR. The mean and median KDRs are much lower for author keywords. Note that values below 1 indicate that a document's cumulative keyword-to-abstract distance is greater than the document's keyword-to-keyword cumulative RWMD; values greater than 1 indicate that a document's cumulative keyword-to-abstract distance is less than the document's cumulative keyword-to-keyword RWMD. In other words, KDR < 1 indicates that keywords are more similar to each other than to the abstract, and KDR > 1 indicates that keywords are less similar to each other than to the abstract. Table 1 suggests that authors tend to choose keywords that are more similar to each other while Scopus assigns index terms that maximize their differences.

Table 1. Descriptive statistics about the KDR and its main components for both author keywords and Scopus index terms

Value	Mean	Med.	SD	Min.	Max.
Author Keywords					
Numerator	20.3	13.5	21.4	1.06	184
Denominator	22.6	23.1	23.1	0.00	200
KDR	.881	.896	.0997	.381	1.16
Index Terms					
Numerator	406	243	562	.456	8107
Denominator	71.7	58.0	57.4	0.00	549
KDR	4.82	3.62	5.74	.0822	106

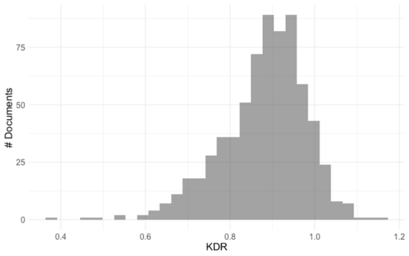

Figure 1. KDR distribution based upon author keywords

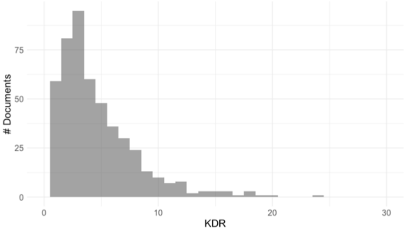
Aside from these descriptive statistics, it is instructive to visualize the distribution of these KDRs calculated from different types of keyword. Figure 1 presents the KDR distribution when calculated based upon author keywords, and Figure 2 presents the KDR distribution for index terms. The difference in the *x*-axes was to be expected from Table 1. However, the difference in distribution shape is striking. The author keyword KDR distribution is somewhat normally distributed around 1, while the index term KDR distribution is dramatically skewed to the right.



This figure includes Scopus index terms and excludes 125 observations for presentation purposes.

Figure 2. KDR distribution based upon Scopus index terms

Ongoing analyses (not included) examine the impact of potential limitations by increasing sample size and looking at less interdisciplinary fields/topics as well as other data sources (e.g., Web of Science). Future research should investigate specific mechanisms linking keyword selection practices to KDR distributions, how KDR differences are associated with perception of keyword accuracy and utility, alternative embeddings for calculating distances, and the use of full article text rather than abstracts.

Ranking Universities via Clustering

George Stoupas[1], Antonis Sidiropoulos[2], Dimitrios Katsaros[3] and Yannis Manolopoulos[1,4]

{grgstoupas,manolopo}@csd.auth.gr, asidirop@ihu.gr, dkatsar@uth.gr, yannis.manolopoulos@ouc.ac.cy

[1]Aristotle University of Thessaloniki, 54124 Thessaloniki (Greece)

[3]University of Thessaly, 38221 Volos (Greece)
[4]Open University of Cyprus, 2220 Nicosia (Cyprus)

Introduction

University rankings have been approached by academicians, politicians, journalists, and policy makers, even though it is surrounded with scepticism (Manolopoulos & Katsaros, 2017). University rankings are especially conspicuous for the top universities (Angelis, Bassiliades & Manolopoulos, 2019).

All university rankings basically agree on the order of the top-20 or top-30 universities, with major disagreements appearing thereafter. However, one could still wonder whether there is *really* a *serious* performance or prestige discrepancy between universities e.g., either in the range [400-500] or even in the ranges [2-5] or [6-15].

Problem description

Following the reasoning that there is small justification in providing absolute and rigid ranked lists of universities, but it is more meaningful to provide ranked sets, we will use clustering methodologies to achieve our goal. So, the aim of the present study is to use (and evaluate the appropriateness of) popular clustering algorithms to develop university rankings with the defining characteristic that competing universities are "organized" into sets where ranking/ordering is imposed only among the sets, whereas the elements within any set are considered unordered. This concept comprises a departure from existing methodologies where – at least for the first, say, 150 positions – there is a *strict* ranking/ ordering among universities, i.e., total order, whereas we seek for an approach developing partially ordered sets of universities (posets).

Dataset

We choose to work with the National Taiwan University Ranking (NTU) (http://nturanking.csti.tw), founded by the Higher Education Evaluation and Accreditation Council of Taiwan (HEEACT), because it is based exclusively on verifiable research performance indicators. NTU ranking is based on eight features categorized into three categories: *research productivity*, *research impact* and *research excellence* with weights 25%, 35% and 40%, respectively. We work with the top-500 universities of the NTU list.

Experimentation

We used the Weka software (Witten, Frank & Hall, 2011), which offers machine learning libraries, including many algorithms for clustering. For our experiments, we choose the most popular representative of each of three well-known families of clustering algorithms, namely:

- Expectation Maximization (EM) (model-based algorithm)
- DBSCAN (density-based algorithm)
- *k*-means (center-based algorithm)

Our experimental methodology was the following: First, we used the EM-algorithm with the default Weka values, and got 12 clusters. Second, we examined DBSCAN with its default Weka values, except that we set *minpoints*=1, so that we do not lose any outlier, plus we varied parameter *e* with step 0.01 to get the number of clusters. By using the Elbow method (Thorndike, 1953), we came up with 43 clusters. Using the previous findings, we performed a set of experiments on the 3 algorithms for 12 and 43 clusters. From Table 1 we see that DBSCAN does not provide any useful insight for the particular dataset, whereas EM and *k*-means give similar results in terms of the maximum cluster size and the number of singleton clusters.

Table 1. Statistics of the examined algorithms.

	#clusters	max cluster size	#singleton clusters
DBSCAN	12	488	10
	43	430	40
EM	12	90	1
	43	33	2
k-means	12	99	1
	43	23	1

To rank clusters, we assign to each cluster a value equal to the sum of the median values of each of the 8 features mentioned in the "Dataset section". Thus, we order the clusters from 1 (the highest quality) to 12 (or 43).

Table 2 shows the size of each cluster for each of the three algorithms, with EM and *k*-means clusterings bearing similarity in terms of clusters' cardinality.

Table 2. Size of the 12 clusters per algorithm.

	DBSCAN	EM	*k*-means
1	1	1	1
2	1	17	16
3	1	42	28
4	1	34	13
5	1	48	14
6	1	33	55
7	1	44	29
8	2	49	77
9	1	42	41
10	1	90	99
11	1	70	72
12	488	30	55

In Table 2, Harvard is always the (singleton) cluster #1. Cluster #2 of *k*-means and EM consists of: Berkeley, Cambridge, Columbia, Imperial College, Johns Hopkins, Michigan/Ann Arbor, MIT, Oxford, Pennsylvania, Stanford, Toronto, UCollege London, UCLA, UCSD, UCSF and Washington/Seattle. In addition, EM's cluster #2 includes Tsinghua. On the other hand, DBSCAN is much closer to the existing methodologies of university rankings.

Although NTU provides an ordered list, there are tie cases that can be considered as ranked clusters; thus, NTU rank can be viewed as a set of 406 clusters. Table 3 shows the Rand Index (RI) (Rand, 1971) for each pair of clustering algorithms as well as with respect to the NTU ranking for 12 (in parenthesis, for 43) clusters.

Table 3. Rand Index for 12 (43) clusters.

	EM	*k*-means	NTU
DBSCAN	0.147 (0.284)	0.167 (0.280)	0.048 (0.261)
EM	--	0.878 (0.973)	0.890 (0.971)
k-means	--	--	0.878 (0.973)

Oppositely, we view each cluster of the EM or *k*-means algorithm as a list of equal performing universities, ordered according to the position in the NTU list. Thus, we apply the Spearman rank correlation coefficient (ρ) for all pairs of algorithms in Table 3, getting Table 4.

Table 4. Spearman ρ for 12 (43) clusters.

	EM	*k*-means	NTU
DBSCAN	0.230 (0.509)	0.239 (0.500)	0.242 (0.503)
EM	--	0.905 (0.968)	0.960 (0.978)
k-means	--	--	0.896 (0.973)

It seems that *k*-means is the most appropriate clustering algorithm among the three to carry out our goal. Using this algorithm, we investigated the following question which might be crucial for university administrators: Is there any particular feature or set of features (among the eight ones examined) that affect the clustering the most, and which are the methodologies to discover it/them?

Weka has already built-in support for such kind of questions. In Table 5, we see that for the *k*-means, the *average number of citations in the last 11 years* (AveCit, cell in grey) is the most important and affects the ranking dramatically; the rest of the features present very similar rankings with the case when all the 8 features are used. For instance, the features HiCit (*number of citations in the last 11 years*) and CurCit (*number of citations in the last 2 years*) do not affect the ranking as their Spearman (Rand Index) value is close 1.

Table 5. Spearman *ρ* (Rand Index) for feature elimination in the *k*-means.

	8 features without HiCit	8 features without CurCit	8 features without AveCit
Full set of 8 features	0.9671 (0.9834)	0.9568 (0.9396)	0.5190 (0.8519)

Conclusions

We argue for the representation of university rankings in the form of ordered clusters. In the present work, we clustered universities from the NTU ranking with DBSCAN, EM and *k*-means, the last one being the most appropriate. Furthermore, looking at the clusters produced, with the exception of the top (singleton) cluster, the second position is occupied by 16 (17) universities, and based on the concepts developed here, these universities are performing equally well, and thus they can be ranked into the same position.

NSFC's reform and the new review mechanism

A Reform Plan on the Funding System was approved by the 8th NSFC Committee in 2018. According to the roadmap, in the next 5 to 10 years, three major tasks will be accomplished, namely identifying funding categories, improving evaluation mechanisms, and optimizing the layout of research areas. Improving the evaluation mechanism is a key step to guarantee the success of this reform. A category-specific, accurate, fair, and effective evaluation mechanism is desired to ensure that original ideas of the best scientific merit are timely supported. To achieve this task, the NSFC Committee set up a peer-review mechanism featuring Responsibility, Credit, and Contribution (RCC), based on the active participation of scientists to improve accuracy, fairness, and performance in supporting basic research. In 2019, the NSFC began to experiment with the RCC review mechanism in its review processes.

RCC's mission

Before the RCC, NSFC's review system just had one mission, namely selecting proposals to fund. However, the reform assigns RCC new missions, namely guiding the applicants to improve their proposals and funding the proposals that really belong to identified funding categories.

RCC's challenges

The new missions make the review system face at least two challenges.

The black box of peer review and review biases

Peer review is a fundamental procedure for the NSFC to decide who receive financial support for scientific research. The NSFC adopted a single-blind review system. Reviewers know applicants and their team members, but applicants don't know the names of the reviewers. The NSFC asked reviewers to provide scientific comments, rate the proposals and recommend which proposals deserve to be supported. Based on these rates and recommendations, the NSFC makes a shortlist for a panel discussion and select proposals to be funded. The panel discussion is confidential: whoever lets out any information about the discussion will be punished.

The scientific comments are reported to applicants by the NSFC after the review process is finished. However, they are often biased. Even if there are no prejudices, misunderstandings, and gaps in knowledge, it is hard to arrive at identical evaluations because human judgment can never be completely free from cognitive style, personal views, and social-cultural values. Due to different professional perspectives, review experts often have blind spots and different review focuses. Their views on a project are always disciplinary- and culture-based. So no one should be surprised that peer review is often biased and inefficient.

The selection process is a black box. Which proposals are selected for the panel discussion and how the panel discussion selects the proposals to fund from the biased scientific comments stay unknown. The NSFC doesn't make any efforts to judge whether comments are biased or not. Scientific comments, which are supposed to improve the applicants' research level, are often so confusing that applicants cannot receive any useful guidance.

Categories and the relation between scientific comments

In the reform plan, the NSFC is going to identify four funding categories based on the attributes of scientific problems: creative and timely ideas, research focusing on frontiers of science in unique ways, application-driven basic research, and transdisciplinary leading-edge research. According to the characteristics of these categories, the NSFC made concrete questions and indicators to ask reviewers to answer.

These four funding categories actually locate where the scientific problems are. The NSFC believes that clear identification of funding categories will not only help to improve the quality of applications but also make the evaluation process more efficient and fairer. However, in reality, most reviewers didn't follow the NSFC's instructions. For example, one applicant submitted a proposal in the category of transdisciplinary leading-edge research in 2020. The NSFC forwarded five reviewers' comments to him. Only one reviewer followed the NSFC's instruction and answered all questions that the NSFC wants reviewers to answer. Two of the reviewers asked why the scientific problems are not from one single discipline. One of the reviewers thought that very common concepts in other disciplines are just somethings fabricated in the mind of the applicant.

Under such circumstances, it will be very important for the review system to adopt a suitable method to select the proposals that have the proper characteristics. Normally the review system implements a majority and hierarchy rule. After scientific problems are classified by their characteristics, it is of the utmost importance that reviewers follow the attributions of scientific problems in their comments. Since review biases result from different professional perspectives, blind spots and different review focus, we may expect that combination of different review focuses from different professional perspectives according to their logic may reduce these problems. The relations between the comments of different reviewers must be taken into consideration to identify the scientific problems that have the specific attributions.

The solutions to these challenges: Responsibility+Credit+Contribution enhanced with open and "trust but verify with evidence"

Opening the black box of peer review is a solution to solve the challenges. Many scholars inclined to support openness in peer review, believe that open and transparent reviews lead to more constructive reviews and criticism would be more reasonable (Cosgrove & Flintoft, 2017). More importantly, responsible reviewers who contributed constructive comments should be able to claim credit, which will automatically improve the review process (Moussian, 2016).

Also reducing and correcting review biases is a way to solve the challenges. The NSFC should design its review procedure to make it possible for the reviewers on same proposals to reach an agreement so that the applicants can follow the scientific comments to improve their proposals and research levels. In the current review procedure, reviewers are prohibited to communicate with each other in the communication-based review stage, which also prevent the reviewers to reach an agreement.

Making peer review scientific is fundamental to solve all these challenges. Rennie (2016) described how the field of clinical science developed evidence-based lists of items to be included in review reporting and make sure journals, reviewers, authors, manuscript editors and copy editors uphold the standards. The NSFC should develop evidence-based lists of review items and ensure that all stake-holders uphold the standards. The NSFC only rely on the rate and recommendations from reviewers to select the proposals to fund. The rate and recommendation should be trusted, but must be verified by their evidence in the selection process.

Moreover, peer review must be thoroughly studied. Actually, outside China, a data-sharing infrastructure has been proposed to enable systematic research on peer review. To strengthen institutional cooperation with data sharing on different review formats, a group of science and technology scholars, publishing professionals and funders formed a collaboration called PEERE, funded by COST (the European Cooperation in Science and Technology). In 2017, a PEERE protocol for sharing data on the peer-review process was released, which carefully considers ethics, responsible management, data protection, and privacy (Squazzoni et al., 2020). This infrastructure intend to help open the black box of peer review without offending the reviewers, at the same time, make it possible to study and verify the peer review.

All in all, in the era of funding-oriented reforms based on the attributes of scientific issues, even though the 'Responsibility + Credit + Contribution (RCC)' peer-review system are making the great efforts to identify scientific problems as well as to guide the applicants to improve their proposals and research levels, the challenges need to be taken seriously. Solving this challenges requires the wisdom of all scientific and technological circles. We should not only create an infrastructure to facilitate the study of peer review, but also supervise the review process with "trust but verify" attitude to ensure the peer review scientific.

Broad shouldered - publication formats served by doctoral students

Jakob Tesch[1]

[1] *tesch@dzhw.eu*
German Centre for Higher Education Research and Science Studies (DZHW), Department Research System and Science Dynamics, Schützenstraße 6a, 10117 Berlin (Germany)

Purpose of the study

Studies of publication output from doctoral training on a national level covering all disciplines remain rarities. Larivière (2012) covers a Canadian province and Nettles and Millett (2006) as well as Enders and Bornmann (2001) selected disciplines only. This exploratory study takes a closer look at the variety of publication formats served during the PhD based on dissertations thus exploring the usefulness of this data source for studying formats and extent of doctoral publishing.

Data and Methods

This study uses a 5% random sample of German PhDs based on cleaned dissertation meta-data collected for the 2014 cohort (n = 1,381), which was downloaded from the German National Library (DNB) in 2019 (Tesch et al., 2021).

This study differentiates theses published by non-commercial- (NCPs) and commercial publishers (CPs, 18% of the sample). 54% of the sample are Electronic Theses and Dissertations (ETDs) the subset of the NCPs that are available in open access format (OA) and together with a few OA-CPs (3%) are thus fully accessible. The 41% of theses where Tables of Contents (TOC) but not the full text was available are termed "partially accessible theses." Only 2% of the sample were not accessible because the TOC was not available.

Identification of published work

Published work is a binary variable for presentation of results and is coded "yes" if the thesis contains references to at least one of the following publication formats authored by the PhDs: published-, in press- or accepted journal articles, published proceeding papers and contributions to edited volumes. Manual coding identified published work based on a coding scheme. Partially accessible thesis count as containing published work if the thesis contains a section entitled "own Publications" or similar or if publications related to the thesis title could be found using Google Scholar. 58 Thesis from Law were excluded because common search engines do not index publication formats typical for this discipline. Results report single disciplines if the Chi² test results shows the share of publishing PhDs to differ significantly from their official broader disciplinary grouping (e.g. Psychology in the case of Social Sciences).

Findings

Table 1 shows the different formats of the theses as well as the share containing published work in total and with at least one journal article authored by the PhD.

Table 1. Formats of German dissertations and published work (n=1,323)

	Publication format of the thesis		*Published Work*	*Journal Article*
Discipline	*Share ETDs in %*	*Share CPs in %*	*Share "yes" in %*	*Share with at least 1 in %*
Arts & Humanities	23%	69%	22%	13%
Social Sciences	37%	41%	39%	31%
Psychology	48%	8%	60%	40%
Natural Sciences	69%	5%	72%	66%
Mathematics	82%	0%	36%	27%
Medical Sciences	53%	1%	34%	29%
Agricultural- & Food Science	66%	3%	84%	81%
Engineering	51%	26%	59%	37%
Computer Science	94%	6%	94%	58%

Theses based on a series of papers are difficult to distinguish but they are unlikely to appear in CPs due to copyright issues. Yet in 16% of the CPs overall and 60% of the fully accessible CPs references to published work could be identified- most of them contributions to edited volumes.

The differences between the share of published work and PhDs with at least one journal article in Table 1 hint to the importance of publication formats other than journal articles in the discipline. For example, while coding identified published work for 94% of PhDs in Computer Science only 58% of these PhDs published at least one journal article.

The share of PhDs with at least one article is higher here than reported in Larivière (2012) for most disciplines which is plausible because here no restriction to WoS was made but it is lower in the

Medical Sciences. This may result from the peculiarities of the German system which does not know of a MD degree and the high share of students from Medicine graduating with a Dr. med (Konsortium Bundesbericht wissenschaftlicher Nachwuchs, 2017).

Number of publications in different publication formats

Theses containing published work differ in terms of number and type of this work. Figure 1 underlines the importance of proceedings in Engineering Sciences and even more so in Computer Sciences. The mean of journal articles in the Natural Sciences is close to three, a number often required for a thesis as a series of papers. Natural- and Medical Sciences are more homogenous in terms of relevant publication formats, which are articles and proceedings while all other disciplines address a broader range of formats.

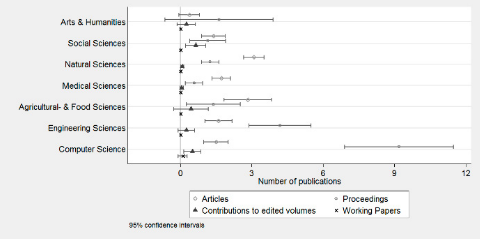

Figure 1. Number of publications in fully accessible PhD theses containing published work by discipline and publication format (n=528)

Discussion

The purpose of this study was to shed more light on the different publication formats served by PhDs during their studies. Based on dissertation metadata and full texts of dissertations this study finds results comparable to earlier studies in terms of the share of published work and PhDs with at least one journal article published or accepted prior to submission of the theses. Yet at the same time, this study highlights the high share of theses published in CPs in Social Sciences and Humanities and shows that these theses also contain published work by the PhDs. Regarding the number of publications in different formats Medical- and Natural Sciences are more homogenous as they focus on publishing in journals and proceedings. All other disciplines serve a broader range of different publication formats including edited volumes and working papers to a lesser extent.

The approach based on dissertations presented herein reports larger shares of PhDs with journal articles than for example Larivière (2012) while at the same time providing a more complete picture of the publication formats served. Nevertheless, this study may not fully cover publications if they are unrelated to the thesis or appear way before the PhD. Thus, future research should compare results for doctoral publishing based on matching to WoS with that on dissertations to assess the amount undercoverage for both approaches.

Conclusions

A large share of PhDs contributes significantly to research output in a disciplinary specific form. Dissertation metadata and full texts are a promising data source for studying research output (co-)authored by PhDs. However, given the low shares of ETDs in Humanities, Social Sciences and the high amount of manual work associated with coding, a combination of dissertation metadata and matching to WoS seems a promising avenue for investigating doctoral publishing in the future.

Acknowledgments

This research is part of the RISIS2 project funded by the European Union under Horizon2020 Research and Innovation Programme Grant Agreement n°824091. The author likes to thank Simrit Rattan for her valuable help with the manual coding.

Words Connecting Scientific Communities
The case of ‘argumentation’

Natalija Todorovic[1] and Benedetto Lepori[2]

{[1] todorn, [2] blepori}@usi.ch
Università della Svizzera Italiana, Via Buffi 13, 6900 Lugano (Switzerland)

Introduction

Science is a communicative social creation, whose main activities consist of sharing and transmission of scientific contents, with a goal of clarification and comprehension of concepts, values, and argumentations (Merton, 1996). The cognitive concepts that are being shared across communities might carry ambiguity, given that their interpretation might differ according to the context. Mc Mahan and Evans (2018) suggest that ambiguity acts as boundary object between different scientific communities, which drives communication and engagement, a consequence of what might be new interdisciplinary community. Ambiguity can be an important strategy used by scientists that helps accepting the same message by different communities, even if the interpretation is different (Ceccarelli, 2001). The ambiguous words thus become a connector of two otherwise separate communities, possibly enabling interdisciplinarity.

Rafols and Meyer suggested that interdisciplinarity is characterized by two dimensions: disciplinary diversity and network coherence. Diversity, that comes from differences in cognitive rooting, is measured as “heterogeneity of a bibliometric set from predefined categories”, while coherence represents increasing interconnectedness in the social structure.

In this study, we look at the communities using the keyword ‘argumentation’ to see whether and how the two mechanisms suggested by Rafols and Meyer (2010) together enable interdisciplinary research. We are interested in understanding the interdisciplinarity enabled by ambiguous language.

Argumentation studies are an area of inquiry often seen as having an important interdisciplinary appeal (Reed & Koszowy, 2011; Van Eemeren et al., 2014). There is an increasing usage of term “argumentation” in scientific literature with subdisciplines having different disciplinary rooting (ranging from philosophy to informatics), different approaches, and, possibly, different understanding of core concepts, argumentation being one of them. Nevertheless, we think that the term that is common across different disciplines drives communication and facilitate coordination among them.

Despite claims in literature that there is increasing integration of argumentation studies filed, we know little about its structure and we specifically miss: a) the extent of integration between different areas or subcommunities, b) the extent of diversity in the community and how concepts and terms are shared and interpreted across sub-communities. To tackle these gaps, we rely on the concept of interdisciplinarity and on the insights from science studies. Even so authors suggest the argumentation becomes interdisciplinary field (Keith & Rehg, 2008; Reed & Koszowy, 2011; van Eemeren et al., 2013; Walton, Reed, & Macagno, 2008), their work seems to be based on perceptions and we did not encounter a systematic analysis based on empirics. What also seems to be missing in literature is rooting of interdisciplinarity through integration and diversity. With this study we are aiming at closing these gaps.

Data Collection

The data was retrieved from Scopus database using two recursive queries. We first queried for the term ‘argumentation’ in abstract, title and/or keywords of the publications (in August 2020), focusing on results published from 2000 until 2019, published in English. After consulting experts from the field we performed additional querying to include results with ‘argument scheme’, ‘argument mining’, ‘argument interchange’, ‘argumentative discourse’, ‘argumentative dialogue’ and ‘argumentative strategies’ in title, abstract or keywords. After cleaning the data our final data set consists of 11178 publications.

Methods

We applied scientometric techniques, text mining and map visualization offered by VOSviewer software (van Eck & Waltman, 2010). The goal is to identify the main topics around which the communities formed using co-occurrence map analysis. Through analysis of scientific map, we reveal the structure of scientific community, that combined with expert knowledge from the community completes comprehensive picture of broad interdisciplinary community in question (Chandra, 2018). To execute topic mapping, we used VOSviewer’s natural language processing functionality. First, we crated thesaurus to cancel general ,“noise” and ambiguous terms (ex. Tree, note, goal) and to replace all plural forms of terms with their singular form. We chose to include in our analysis only terms that appeared more than 7 times.

The relatedness of items on map is determined on the number of documents in which they appear together (van Eck & Waltman, 2007).

Results

The world 'argumentation' is used in almost all subject categories, although it has the most weight in social sciences (27%), computer science (23%), and arts and humanities (18%). This wide usage of the term is reflected in journals and other sources of publications, as well.

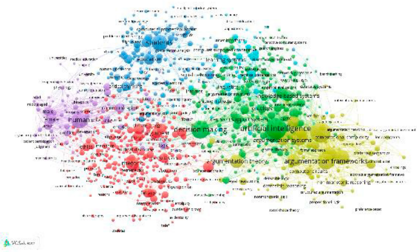

Figure 1. Keywords co-occurrence map

We examined the keywords in each cluster and named the clusters as following: *a) discourse analysis, b) interpersonal communication, c) argumentation in science and education, d) computer science, e) argumentation frameworks, f) natural language processing*. The first three clusters belong to social sciences and humanities, while the latter three are computer science. Some terms (like 'decision making', 'argumentation theory', etc.) are acting as point of connection representing the idea that language is not a simple collection of words, and that logical structure is important for transmitting a message and achieving the conclusion as a core of argumentation studies (Willard, 2003).

Conclusion

Starting from one word shared across communities we can analyse not only a single intellectual tradition it comes from, but also its declensions in other contexts. To do so we must understand both cognitive, social, and institutional structures of community and how these mutually connect. Starting from term 'argumentation' we discovered that it is used in some strictly disciplinary areas like science studies, that use this word as a complement for their subject of study. In some areas, such as rhetoric, 'argumentation' is primary object of inquiry. Other areas, like artificial intelligence, apply models and logic from argumentation studies in IT contexts. Thus, argumentation studies have relatively small and partially interdisciplinary core, with large, applied periphery. These findings might take us to further reflect on how scientific fields are structured.

Introduction

It is common practice for universities to collect research publications in publicly accessible databases. As they need a repository of all publications for reporting, the university collections also provide detailed information about the organizational units (e.g., departments). One example of such a repository is the so-called Research Collection (RC) hosted by the library of ETH Zurich. We link the RC with citation statistics from "Web of Science" (WoS) and "Scopus" to be able to prepare detailed bibliometric reports, e.g., for the ETH's controlling department. It is outlined below how this can be achieved and why this is a sensible approach for higher education institution.

Function and strategy of the RC

The RC serves as a single point of access for ETH Zurich staff to document, publish, and archive the scientific results of their research. Thus, it fulfils multiple functions as a publication directory, an open access repository, and a research data repository (Hirschmann, 2018): The RC contains publications authored by ETH staff and serves as a publication platform for *all* types of research results. This implies that staff can also publish research data using the RC. It further serves as a source to produce lists of publication for the academic Annual Reports and the website of the ETH Zurich. It is also an instrument to implement the ETH Zurich's Open Access Policy, because it gives university staff the opportunity to publish scientific papers beyond traditional publication platforms.

Linking the RC to Publication Databases

Many organizational units at the ETH Zurich are interested in providing evidence of and documenting publication achievements, but also in performing bibliometric analyses of their publication success. For example, one common request, e.g., by the ETH controlling department, is to compile a list of all publications in the last five years for a specific university department and to supplement it with current citation numbers. Occasionally, such a request is only the starting point for more in-depth queries for bibliometric evaluations, e.g., in the form of a field normalization.

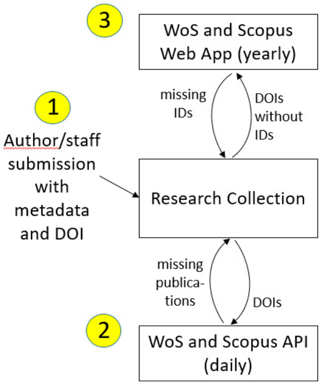
Commercial publication and citation databases, such as the WoS and Scopus, do not provide enough detail to validly assign publications to smaller organizational units within an institution. Thus, relying on these databases alone to process such a request is insufficient. This is where resources such as the RC provide valuable additional information. While the RC itself does not contain any citation information about the publications covered by the system, it remains the only central source that maps scientific outputs of all organizational units of the ETH Zurich. As such, it can serve as a link between publication outputs and citation statistics of the WoS and Scopus. To process requests like those described above, the RC are matched with the information of the WoS and Scopus.

Matching the RC with WoS and Scopus

We rely on licenced data provided to the ETH Zurich by the WoS and Scopus. For the WoS, the Core Collection Citation Indexes are used. We consider articles, conference proceeding, reviews, and letters for our analysis presented below.

To establish a connection between publications in the RC and the WoS and Scopus databases, the publication IDs (Accession Numbers (ANs)) are required. Next, the ANs need to be assigned to the publications by the database providers. In the WoS the ANs are commonly called the UT code (field tag UT in the underlying export-spreadsheet); in Scopus EID. In order to extract detailed information about the citation data for the ETH departments, each item's metadata in the RC needs to be supplemented with the ANs of the WoS and Scopus.

Researchers and administrative staff at the ETH submit the metadata of their publications (sometimes also a post-print) to the RC (Hirschmann, 2018). The RC also imports publication metadata using the APIs of the WoS and Scopus. The imports use the publishers' DOIs and ANs for matching the items and to avoid duplicate entries. Metadata imports may contain missing publication items or missing metadata fields.



3
WoS and Scopus Web App (yearly)
missing IDs
DOIs without IDs
1
Author/staff submission with metadata and DOI
Research Collection
missing publica-tions
DOIs
2
WoS and Scopus API (daily)

Figure 1. Simplified illustration of data imports to the RC. The data in the RC are provided by authors/ETH staff, WoS, and Scopus in 3 steps.

(1) Metadata that were manually entered by the authors or the ETH are supplemented with the ANs from the WoS and Scopus. This is done daily by matching items using their DOIs. (2) In the same process also the metadata of missing publications are added to the RC. If the DOI of an ETH publication cannot be found in the RC, the metadata are imported from the WoS and Scopus APIs.[1] (3) Processes (1) and (2) provide ANs for only 87.8% (WoS) and 63.1% (Scopus) of the publications (articles, reviews, letters, and conference proceedings) in the RC. Thus, missing WoS and Scopus IDs will be imported once a year. This solution ensures completion of the ANs for over 90% of the publications in the RC (WoS: 95.1%, Scopus: 91.6%). The proportion of papers that do not match include those papers for which no AN/DOI has been deposited and, thus, could not be found in the WoS or Scopus. The reason for the lack of DOI or AN in the RC needs to be further explored. Table 1 summarises the success of the matching procedures.

Table 1. ETH Zurich publications (2013-2019) identified in the RC by AN and DOI.

	***N* of ETH publica-tions**	***N* of ETH publica-tions in RC with AN**	***N* of ETH publica-tions in RC with DOI**	***N* of ETH publica-tions in RC with AN or DOI**
WoS	45,339	39,798 (87.8%)	40,153 (88.6%)	43,105 (95.1%)
Scopus	51,855	32,714 (63.1%)	46,755 (90.2%)	47,524 (91.6%)
	***N* of ETH journal articles**	***N* of ETH journal articles with WoS AN**		
RC	38,157	37,505 (98.2%)		

Final remarks

The RC paints a detailed picture of all organizational units' scientific outputs (publications) at the ETH Zurich. The benefit of the RC is that the WoS IDs of most publications are known for the organizational units at the ETH Zurich, so it is possible to determine citations for each of these units by using the WoS Web App. In addition, the completeness of the metadata is continuously checked and missing publications are added by employing a daily automated matching procedure on the basis of the WoS ANs and DOIs. DOIs can also be used for matching RC metadata with publication databases in a way that ANs are available for over 90% of ETH publications in the RC.

Our approach uses the WoS and Scopus for metadata enrichment. Using other commercial citation databases, such as Dimensions, would likely produce similar results. Future work will reveal how successful these databases are in enhancing the RC metadata. Any HEI institution that wishes to perform citation analyses for individual departments or other institutional subunits can apply the approach presented here, given that they have access to the WoS or Scopus and that an internal repository is available that contains nearly-complete information, such as DOIs or ANs.

[1] Because of limitations in the WoS and Scopus search for metadata retrieval, only items that are correctly attributed to the ETH Zurich by our search queries in WoS and Scopus are included.

Measuring "Science Teaching" in Higher Education - An Empirical Study Of Teaching Content

Carolin Vollenberg[1], Julian Koch[2], Christopher Still[3] and André Coners[4]

{[1] vollenberg.carolin, [2] koch.julian, [4] coners.andre}@fh-swf.de

[3]christopher.still@stud.fh-swf.de

Introduction

Scientific work is the basis of an academic education and implies the systematic analysis of a specific problem to gain assured knowledge (Ellis, 2004). Within scientometrics, however, the form, application, and expression of the mediating mode of "scientific practice" in teaching has not been adequately explored. This paper aims to present a method and analysis of teaching content on the area of "scientific work" in higher education. In this paper, we analyze module handbook data with a novel approach to show what benefits can be generated with this unique database. The resulting research questions are as follows:

1.) Are there discernible differences between universities and universities of applied sciences in relation to the teaching of "scientific work "?

2.) Which of the study programs has the largest proportion of "scientific work" in teaching?

3.) Is "scientific work" taught as an independent teaching unit or as part of the content in other teaching modules?

Methodology

As already mentioned, this work analyses and measures the textual content from module handbooks of universities and universities of applied sciences (hereafter referred to as "U" and "UAS"). This makes it possible to make statements about the extent to which and the form in which scientific work is taught in German university teaching. To be able to carry out the intended research in a meaningful way, a list of search operators first had to be compiled (Han, Kamber, & Pei, 2011). To create such a list, interviews were conducted with five experts in the field of teaching "scientific work" (Creswell & Creswell, 2017). This resulted in a list of suitable word combinations for identifying "scientific work" within the module handbook data. The first step in our entire research process (cf. Figure 1) is to compile the data sources of the U's and UAS's in Germany. For this purpose, we select the three mass study programmes Business Administration (B. A.), Computer Information Systems (C. I.) and Business Information Systems (B. I.). In the following step, the identified websites of the degree programmes are searched for relevant module handbooks with the help of a crawler, downloaded, transformed, extracted, and stored in a database. After the entire crawling process, the transformation process begins by converting the database into a structured text format. This is a necessary step for the subsequent text pre-processing (Feldman & Sanger, 2007). Using a text mining application, we then perform noise reduction in the form of tokenisation, lower case, stop word removal, stemming and lemmatisation (Allahyari et al., 2017). The database then contains structured data, e.g., the name of the U or UAS, the degree program, the module name and description, the specified SWS (semester hours per week) and ECTS (European Credit Transfer System) points per module. This structuring of all module handbooks subsequently enables us to carry out a variety of measurements and analyses, e.g., for comparison between U's and UAS's, between institution types (U's and UAS's), degree programs or module offerings.

Text Mining of Module handbooks
Measurement of "Scientific Work" in Higher education

Figure 1. Research process

With the help of text-mining algorithms, the module descriptions are searched for the given search operators of the teaching area "scientific work". To answer our research questions, a comparative analysis follows, both at the level of the higher education institutions (hereafter referred to as "HEI") - U's and UAS's - and at the level of the degree programs. We compare whether "scientific work" is anchored as an independent teaching unit or module, or whether it is found as part of the content of an external module, which then also includes other content. Furthermore, the two types of HEI's are compared at degree program level according to the average number of "scientific work"-related content per teaching module. In addition, the proportion of modules with "scientific work"-related content is compared in the chronological semester position of the degree programs.

Results and Discussion

Within the scope of our study, we first measured the number of degree programs with an independent teaching module "scientific work". The proportion of degree programs with an independent module at UAS in Germany is 33.66% on average. This is significantly higher than at the U with a share of 5.94%. Most degree programs (cf. 60.40%) at both types of HEI's do not offer an independent module on "scientific work" at all. The results at the level of the HEI's (U's and UAS's) can also be confirmed at the level of the study programs.

The proportion of individual degree programs at UAS's with a stand-alone module is significantly higher compared to U's. C. I. (7.27%) at U's has the highest proportion of stand-alone modules compared to B. A. (3.96%) and B. I. (6.52%) programs. In comparison, C. I. (20.91 %) has the lowest proportion compared to B. A. (40.59 %) and B. I. (41.30 %) at UAS's. Secondly, we measured the average number of "scientific work" related contents in the teaching modules that are not named as a separate module and thus also cover other content. Figure 2 shows the average number of teaching modules that at least also contain "scientific work" related content, separated by the individual degree programs for the two types of HEI's. This shows that the average number of "scientific work"-related content in the modules is higher at the U's than at the UAS's.

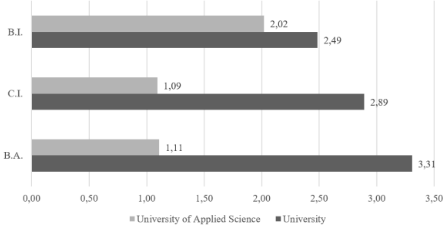

Figure 2. Average number of teaching modules with "scientific work"-related content

In addition, we show the distribution of the proportion of modules with "scientific work"-related content over the period of the (mostly seven-semester) degree programs, differentiated by U's and UAS's (cf. Figure 3). Here it becomes clear that the UAS's place the emphasis on teaching "scientific work"-related content at the beginning of the degree program, while the U's integrate the teaching of "scientific work" into the degree programs without significantly recognizable periods of preference.

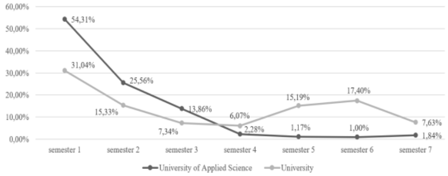

Figure 3. Semester location of modules with "scientific work"-related content

In summary, our analyses show that at UAS's the emphasis is on teaching "scientific work" in stand-alone modules and content of scientific work, especially in the first semesters of the degree programs. In contrast, at U's "scientific work" is not taught independently, but only as a part integrated within thematically different teaching modules.

This contribution to the question of how and to what extent "scientific work" is taught in academic higher education shows that our unique dataset offers enormous opportunities to analyze the content in academic higher education from the perspective of teaching. The paper shows that this approach also has the potential to generate valuable quantifiable results on teaching development, comprehensible thematic characteristics of teaching content, and measurable study trajectories in the future.

Introduction

The discourse around open access (OA) in scholarly publishing is an ever-present attraction among institutions, governments and government agencies, publishers and journal vendors, journal indexing services and funders who are increasingly demanding OA scholarship, especially regarding government-funded research. Researchers are particularly interested in the discourse mainly because they are central to knowledge production and sharing through research publications, among other research outputs. Funded researchers, who are the eventual authors of the research publications, are particularly under pressure to publish their research findings in OA platforms. Consequently, many institutions and/or governments have put in place mechanisms to mandate OA for federally funded research (see Kimbrough & Gasaway, 2016; Larivière & Sugimoto, 2018; Bryan & Ozcan, 2020). According to Larivière & Sugimoto (2018) 50 funders and 700 research institutions worldwide, had mandated some form of OA for their funded research by September 2018. Although Kenya does not have an OA policy or registered mandate in the Registry of Open Access Repository Mandates and Policies (ROARMAP) (Chilimo et al., 2018; Waithaka & Onyancha, 2021), the country is listed as one of the countries that have witnessed an increase in the number of OA publications in the recent past. However, the reasons and factors that could be influencing the publication trends and patterns are unknown. Using the Unified Theory of Acceptance and Use of Technology (UTAUT) as a theoretical lens, this study sought to examine the extent to which the UTAUT variables influence the adoption and use of open access scholarly publishing (OASP) in selected universities in Kenya.

Research Methodology

The study adopted a quantitative research approach, with the survey being the research design. The target population comprised 3009 teaching staff from three universities that were selected from the Nairobi County and its vicinity; that is the University of Nairobi [UoN] (n = 1472), Jomo Kenyatta University of Agriculture and Technology [JKUAT] (n = 643) and Kenyatta University [KU] (n = 894). The sample size of 341 was drawn using the sample size determination formula and table proposed by Krejecie and Morgan (1970), at 95% confidence level and .05% confidence interval (margin error). A self-administered questionnaire consisting of several items representing UTAUT variables was used to collect data. Out of the 284 questionnaires distributed, 341 were returned but only 281 were found to be usable in the study. The study used path regression analysis using intention to use and the actual use of OASP as outcome variables regressed against six influencers: (i) attitude; (ii) performance expectancy; (iii) effort expectancy; (iv) social influence; (v) Internet skills or efficacy; and (vi) facilitating conditions, and four demographic factors used as moderating factors: (i) age; (ii) experience; (iii) gender; and (iv) rank. The path regression analysis uses multiple regression equations that specify explanatory variables and the dependent variable at every stage.

Results and discussion

The model estimation yielded a value of adjusted R^2 as 0.994, an indication that there was variation of 99.4% on the dependent variable. The model worked well in attitude or perception, performance expectancy, effort expectancy, social (peer) influence, facilitating conditions and Internet skills or efficacy and intentions to use OA scholarly publishing. In addition, the adjusted multiple coefficient of determination of 0.993 implied a high joint impact of the explanatory variables. Figure 1 provides a summary of the findings based on the regression modelling of the factors influencing OASP in the universities investigated in the study. the model shows that facilitating conditions and efficacy (Internet skills) significantly influence the adoption of OA scholarly publishing while attitude, performance expectancy and social influence significantly influence intention to use OASP in the selected public universities in Kenya. Facilitating conditions emerge as main predictor variable that greatly influence the actual use of OASP among the researchers with the highest beta value of B = 0.521, p < 0.05, with the Internet skills/efficacy recording a value of B = 0.323, p < 0.05. Attitude (B = -0.045, p > 0.05) and social influence (B = 0.120, p > 0.05) have insignificant influence on researchers' OASP adoption while performance expectancy and effort expectance had no influence at all on the same. On the other hand, attitude (B = 0.238, p < 0.05), performance expectancy (B = 0.227, p < 0.05) and social influence (B = 0.125, p < 0.05) significantly influenced researchers' intention to use OASP while effort expectancy and efficacy insignificantly influenced the same. In terms of the effect of demographic variables as moderators of independent variables, age, experience and gender had significant moderating effect on the independent variables. Each moderating variable had varied effects on the independent variables in the latter's influence on intent to use and actual use of OASP. Gender had the most moderating effect, if the results of its significant coefficients are anything to go by. The rank or position of the researchers did not produce any significant beta coefficients, thereby signalling its insignificant moderating effect on all the independent variables. A number of scholars have observed similar patterns in different countries (e.g. Dulle, Minishi-Majanja & Cloete, 2010; Singeh, Abrizah, & Karim, 2013; Bashorun et al., 2016).

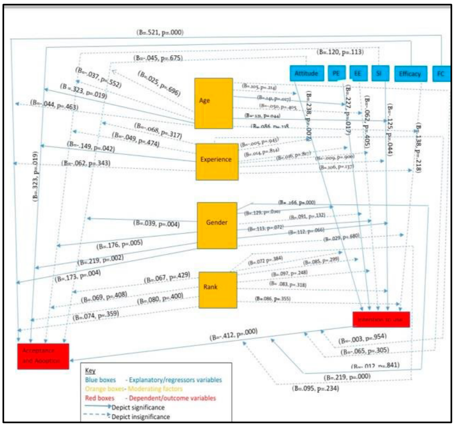

Figure 1: Theoretical model for adoption and use of OASP

Conclusions

The study concludes that the UTAUT variables significantly influence adoption and use of OASP by researchers in universities in Kenya. However, the extent to which each variable influences the adoption and use of OASP varies. The facilitating conditions (e.g., management/financial support; strong and dependable information technology infrastructure; content availability; strong mandates; training capacity; computer and networking skills; advocacy; Internet proficiency and the existence of OA channels and outlets) play a greater role than the other variables in influencing the researchers' intent and actual use of OASP. The Internet proficiency and self-efficacy featured as the second most important influencers or predictors of the adoption and use of OASP. While some independent variables such as facilitating conditions and efficacy have a direct and significant influence on the adoption and use of OASP, the attitude, performance expectancy and social influence significantly influence the intent to use OASP, which in turn significantly influences the adoption of OASP.

Introduction

In the globalized world, external knowledge obtained are facilitated by rising connectivity through organization based and individual based colaboration (Lorenzen & Mudambi, 2013). Individual based knowledge obtained e.g. talent mobility rely on the ability of individuals to overcome geographical distance to exchange and integrate knowledge. Internet have enabled real-time collaboration with skilled located at different location, enhancing the process of leveraging knowledge through direct interactions and personal contacts (Awate & Mudambi, 2018). In this paper, we evaluate the patterns and extent of inventor mobility as the various innovation teams in countries.

Methodology

Patents granted in United States Patent and Trademark Office (USPTO) since 2010 to 2019 and classified as Pharmaceuticals in the World Intellectual Property Organisation technology classification (WIPO, 2009) are collected in this study to analysis patterns of innovation team in countries.

Innovation team in patents are classified as follows:

- Domestic-Team Patent (DTP): All inventors' countries are the same as the assignee's country in a patent.
- Global-Team Patent (GTP): At least one inventor's country is the same as the assignee's country and at least one inventor's country is different from the assignee's country in a patent.
- Foreign-Team Patent (FTP): All inventors' countries are different from the assignee's country in a patent.

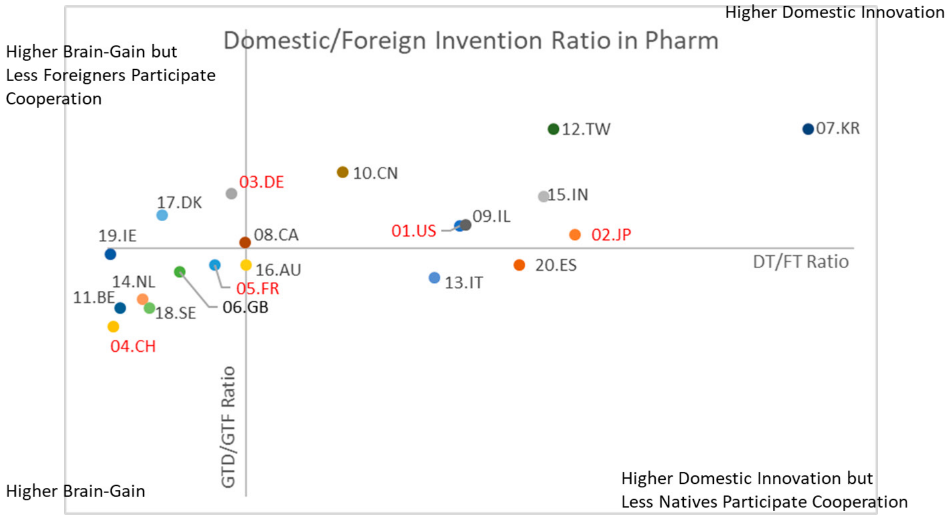
Result

Top twenty patent count of assignee countries with proportions of innovation team patents are listed in Table 1.

Table 1. Innovation-Team Patents of Top 20 Countries in Pharm.

	Patent Count			
	Total	DTP	FTP	GTP
US (UNITED STATES)	40373	84.2%	4.5%	11.3%
JP (JAPAN)	4625	89.5%	3.6%	7.0%
DE (GERMANY)	3519	65.8%	9.9%	24.4%
CH (SWITZERLAND)	2668	17.5%	50.6%	31.9%
FR (FRANCE)	2539	69.2%	12.0%	18.9%
GB (UNITED KINGDOM)	2346	60.9%	15.7%	23.4%
KR (SOUTH KOREA)	1655	93.1%	2.5%	4.5%
CA (CANADA)	1582	61.6%	8.3%	30.1%
IL (ISRAEL)	1217	83.6%	4.4%	12.1%
CN (CHINA)	1216	83.1%	6.6%	10.3%
BE (BELGIUM)	1134	30.7%	44.3%	25.0%
TW (TAIWAN)	1079	79.8%	3.3%	16.9%
IT (ITALY)	1045	78.9%	4.5%	16.7%
NL (NETHERLANDS)	872	52.8%	28.0%	19.3%
IN (INDIA)	863	86.8%	3.7%	9.5%
AU (AUSTRALIA)	826	73.2%	9.8%	16.9%
DK (DENMARK)	819	55.7%	18.9%	25.4%
SE (SWEDEN)	816	55.1%	24.5%	20.3%
IE (IRELAND)	631	13.8%	74.6%	11.6%
ES (SPAIN)	485	81.9%	3.7%	14.4%

*Red: Top 3 Countries in each type of Innovation-Team Patents



*DT: Domestic Team patents; DT: Foreign Team patents; GTD: Domestic inventors in Global Team patents; GTF: Foreign inventors in Global Team patents

Figure 1. Domestic/Foreign Invention Ratio in Pharmaceutical.

Innovation team in pharmaceutical of most countries are DTPs, especially Japan, South Korea, and India get more than 86% pharmaceutical patents all invented by domestic inventors. Ireland, Switzerland, and Belgium are get higher FTP proportion, it means that their pharmaceutical development higher depend on foreign inventors. Switzerland, Canada, and Denmark are with higher proportion of GTP, they more depend on international collaboration in pharmaceutical development.

We posited the pattern of innovation Team in countries as Figure 1, where x axis is the ratio of Domestic Team Patents to Foreign Team Patents and y axis as the ratio of Domestic Inventors of Global Team Patents to Foreign Inventors of Global Team Patents. Countries in the first quadrant are Higher Domestic Innovation; countries in the second quadrant are higher brain-gain but less foreigners participate cooperation; countries in the third quadrant are higher brain-gain; countries in the fourth quadrant are higher domestic innovation but less natives participate cooperation.

Conclusion

There are less study to analysis innovation team in countries according to brain gain and brain drain in inventors. We apply a pilot study to classify the patterns of innovation team of pharmaceutical in countries. In the result we find that Switzerland highly depends on foreign inventors to develop pharmaceutical and also with lower native in international collaboration. South Korea is another extreme country depending on highly domestic inventors in pharmaceutical innovation. The following study will focus on the effect from patents of these various innovation team on native innovation performance, and the findings would be the specific loss of brain drain.

Using Full-text Content of Academic Articles to Classify Research Methods in Library and Information Science

Ruping Wang[1], Liang Tian[2] and Chengzhi Zhang[3]

{[1]wangrp, [2] tianl, [3] zhangcz}@njust.edu.cn

Nanjing University of Science and Technology, Department of Information Management, 200 Xiaolingwei Street, Nanjing 210094 (China)

Introduction

The methodology is a key factor to connect research problems and results. Most of the existing studies have constructed many schemas of research methods in Library and Information Science (LIS). For example, Luo & McKinney (2015) divided the research methodology into the research design, research model, and research theory. Chu & Ke (2017) summarized the research methods of Library Information Science into 16 categories including 'Experiment', 'Bibliometrics', 'Questionnaire', etc.

Identifying the research methods used in academic papers is the basis for analysing usage behaviour and scenarios of different research methods. The research methods of papers usually need to be manually annotated, which is time-consuming and costing a lot. This paper uses a supervised multi-label classification method to identify the research methods in LIS based on the full-text content of academic articles.

Methodology

Dataset

This paper collects research articles from three kinds of journals in LIS field, namely Journal of the Association for Information Science and Technology (JASIST), Library & Information Science Research (LISR), and Journal of Documentation (JOD). After filtering, 5,273 research papers from 1990 to 2019 are obtained for the experimental dataset. Among them, 1,977 papers from 2001 to 2010 were annotated with the research methods by Chu et al. (Chu & Ke, 2017). This annotated corpus is used as training data in this paper. The number of articles using some research methods is very small, leading to data imbalance, and some methods are similar. Hence, we combine 'Bibliometrics' and 'Webometrics' into 'Metrics', and combine the less used research methods as 'Other'. There were finally 8 methods: 'Experiment', 'Theoretical Research Method', 'Questionnaire', 'Content Analysis', 'Metrics', 'Interview', 'Transaction Log Analysis' and 'Other'. Table 1 shows the distribution of different research methods in the training data.

Table 1. The number of articles using different research methods in training set (2001-2010)

No.	Method	Papers' Number
1	Experiment	553
2	Theoretical Research Method	377
3	Questionnaire	366
4	Content Analysis	339
5	Metrics	377
6	Interview	256
7	Transaction Log Analysis	120
8	Other	270

The full-text content of the article is divided into sentences and stop-words are filtered according to a stop-list. Then, the full-text content is represented as a vector after feature selecting by Chi-Square and feature weight computing by TF-IDF.

Classification model of Research methods

Problem transformation and algorithm adaptation (Tsoumakas & Katakis, 2007) are two common kinds of multi-label classification strategies. The strategy of problem transformation includes Binary Relevance, Classifier Chain, Label Powerset, and Random k-label sets. Algorithm adaptation is a way to perform multi-label classification by directly improving or modifying the existing classification algorithm. We use these two multi-label classification strategies to classify the research methods of academic articles in LIS. For problem transformation, we use Naïve Bayes, SVM, and XGBoost as the basic classification algorithms. For algorithm adaptation, we used KNN as the basic classifier. We generate a total of 13 combined classification algorithms, namely BR-NB, BR-SVM, BR-XGB, CC-NB, CC-SVM, CC-XGB, LP-NB, LP-SVM, LP-XGB, RAKEL-NB, RAKEL-SVM, RAKEL-XGB, and MLKNN. We train these combinatorial algorithms respectively and then evaluate each algorithm. We use the optimal algorithm to train the final classifier and then predict the remaining unlabelled articles.

To evaluate and select the optimal classification model, we divide the annotated data into training set, validation set, and test set. The training set accounts for 80% of the total annotated corpus, the validation set and the test set account for 10% respectively. This paper trains each algorithm on the training set and optimize each algorithm on validation set.

In multi-label classification, sample-based evaluation and label-based evaluation are two common evaluation methods(Madjarov et al., 2012). This paper adopts the label-based evaluation method. P, R, and F1 are used as the evaluation indicators. According to the results of the 13 combined classification models, the Classifier Chain based upon XGBoost (CC-XGB) performs the best with the highest F1 value at 80.77%.

Experiments and Results Analysis

Classification result of research methods in LIS

We use CC-XGB to train the final model upon all the annotated articles to predict the remaining 3,296 unlabelled articles. Table 2 shows the prediction results of different methods. We can see that many papers use 'Experiment', 'Theoretical Research Method', 'Questionnaire', 'Content Analysis', 'Metrics' and 'Interview'. 'Transaction Log Analysis' and 'Other' are used less.

Table 2. Distribution of different research methods on all articles (1990-2019)

No.	Method	Papers' Number
1	Experiment	960
2	Theoretical Research Method	1,260
3	Questionnaire	911
4	Content Analysis	734
5	Metrics	1,078
6	Interview	1,080
7	Transaction Log Analysis	167
8	Other	612

Using 1,977 papers that have been manually annotated with research methods and 3,296 papers that have been automatically classified by CC-XGB, we analyse the frequency of different research methods in 1990-1999, 2000-2009, and 2010-2019. The number of papers in each period affects the use of research methods. Hence, we analyse the relative frequency of different research methods in the three periods. Figure 1 shows the result.

We can see that the relative usage frequency of 'Metrics', 'Questionnaire', 'Interview', 'Content analysis' and 'Other' is increasing year by year. The usage of 'Experiment' and 'Transaction Log Analysis' is increasing and then decreasing; the usage of 'Theoretical Research Method' is decreasing gradually. These changes reflect that researchers pay more attention to experiments and data in the process of research.

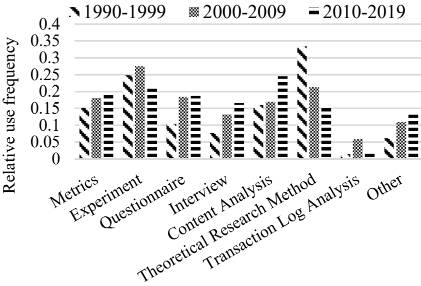

Figure 1. The relative frequency of different research methods in each period.

Conclusion and Future Work

Using LIS field as a case, this paper uses the full-text content of academic articles to classify the research methods. As a preliminary work, we use two multi-label classification strategies to combine with multiple basic classifiers. Finally, the Classifier Chain with XGBoost as the underlying classifier (CC-XGB) has the best performance. The results show that 'Metrics', 'Interview' and 'Theoretical Research Method' occupy a high proportion, and the use of 'Theoretical Research Method' decreased over time.

In the future, we will try to further improve the classification effect. Also, we will make an in-depth analysis of different methods, explore the usage situation and the evolution of different methods.

Algorithm Entities Usage in Chinese Academic Articles from The Domain of Information Science

Yuzhuo Wang[1], Heng Zhang[2] and Chengzhi Zhang[3]

{[1]wangyz, [2] zh_heng, [3]zhangcz}@njust.edu.cn
Department of Information Management, Nanjing University of Science and Technology, Nanjing (China)

Introduction

With the emergence of the fourth paradigm for science, the demand for big data-related algorithms is increasing. As one of the three key elements of artificial intelligence (algorithms, computing power, and data), algorithms have made great contributions to both social science and natural science fields.

An algorithm is any well-defined computational procedure that takes a set of values as input and produces some value as output (Cormen et al., 2009). Academic papers are excellent resources for scholars to learn algorithms. However, manually finding algorithms from massive articles is time-consuming and high-cost. Scholars need automatic methods to extract algorithms. Previous work used rule-based, statistical machine learning, and deep learning methods to extract method entities from academic papers (Hou et al., 2020). However, these studies did not further filter and analyze the extracted entities.

In this article, a deep learning model with a manual filtering method is proposed to find algorithm entities and carry out further exploration. Taking Chinese academic papers in the information science (IS) domain as an example, we plan to explore: *1. How to extract algorithm entities with an automatic method? 2. What is the distribution of algorithms in Chinese IS academic papers?*

We define algorithm entities as nouns or noun phrases representing the name of algorithms or models that are algorithms in nature. Although we only study Chinese IS academic articles, it can be an example to demonstrate that our method is available and can be extended to other disciplines.

Method

We collected the full-text content of papers and then built corpus to train extraction models. Algorithm entities were extracted and reviewed to explore the distribution of algorithm entities in IS papers.

Data collection. The full-text content of 1,367 articles published in the *Journal of the China Society for Scientific and Technical Information* (*JCSSTI*) from 2009 to 2018 was downloaded. *JCSSTI* is the top journal in the field of IS in China. It is believed that articles in this journal are of high quality and algorithms in the articles are representative.

Corpus construction. The papers in PDF format were converted into XML format manually. After that, 200 papers in XML format were selected randomly. Two postgraduates annotated algorithm entities in the 200 papers independently and corrected the inconsistent results. The interrater reliability between the two coders was measured by Cohen's kappa and achieved 0.78. Finally, we got a training corpus that includes 200 articles, 687 algorithm sentences, and 1,130 algorithm entities.

Candidate entities extraction. We chose the commonly used Bi-LSTM+CRF as the extraction model. The training corpus is divided into training and testing set at the ratio of 8:2. After using FastText (https://fasttext.cc/) to train word-vector, training data was inputted to the Bi-LSTM+CRF model. The trained model was then utilized to extract candidate entities from 1,367 articles.

Reviewing algorithm entities. A Ph.D. candidate reviewed all the candidate entities and picked out algorithm entities based on their own experience, authors' descriptions, external knowledge, and experts' explanation. Considering an algorithm could be mentioned with different names, including full name, abbreviation, and aliases, we compiled a dictionary where different names representing the same algorithm were organized into a set.

Analyzing algorithm entities in IS papers.

(1) Classifying algorithms. Algorithms entities were classified into three types: *single, functional and composite*. A s*ingle algorithm* is an explicit algorithm not showing the category and function in the name, such as the *Support vector machine* (SVM). A *functional algorithm* indicates a specific function or type in the name, such as the *Classification algorithm*. A *composite algorithm* contains the actual task solved by the algorithm in the name, such as the *Literature recommendation algorithm based on user interest topics*. In general, A s*ingle algorithm* (SVM) belongs to a f*unctional algorithm* (Classification algorithm), and a *single algorithm* and a *functional algorithm* can belong to the *composite algorithms* (Author name recognition algorithm). The category of the nested algorithm is judged based on the root of the algorithm. For example, the *author name recognition algorithm based on SVM* is marked as *composite* because it is essentially the *author name recognition algorithm.*

(2) Influence of algorithms. The number of papers is the commonly used indicator of influence. We use the same method in Wang's work (Wang & Zhang, 2020) to calculate the influence of the algorithm entity in IS field. For an algorithm *j*,

$$Influence(j) = (\sum_{i=2009}^{2018} \left(\frac{N_{ij}}{N_j}\right))/T_j \qquad (1)$$

Where i represents the year, ranging between 2009 and 2018. N_i is the number of articles published in year i, N_{ij} is the number of articles that mentioned algorithm j in year i. T_j is the duration from the year when algorithm j first appeared in papers to 2018.

Results

Recognition result of algorithm entities

We obtained 5,036 candidate entities from 3,318 sentences in the training corpus, and 30,002 candidate entities from 18,316 sentences in the raw corpus. The performance of the Bi-LSTM+CRF model is precision (67.26%), recall (72.82%), and F1-value (69.93%). After manual filtering, we got the algorithm dictionary containing 2,122 algorithm entities with 4,460 names. All the algorithm entities were classified into 962 *Single algorithms*, 775 *Functional algorithms,* 385 *Composite algorithms*.

Algorithm entities distributed in different year

Figure 1 shows the number (Bar) and proportion (Line) of papers mentioning algorithm entities each year. From 2009 to 2018, about 80% of articles mentioned algorithms. With time going by, the proportion increased from 2009, peaked in 2011, fluctuated from 2011 to 2015, and stabilized at 80% after 2016. It means that algorithms have always been important in the IS academic papers in China.

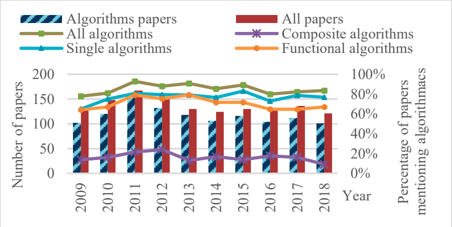

Figure 1. The number and percentage of papers mentioning algorithms

For the three types of algorithm entities, S*ingle algorithms* have always been the algorithm mentioned in the largest number of articles, and its proportion is also the most stable. The percentage of articles mentioning the other two kinds of algorithms decreased significantly after 2012. It indicates that in the IS journal articles, more and more articles begin to directly mention and use the existing single algorithm entities, rather than the descriptive algorithm entities about the purpose and function.

Single algorithms with high influence in IS papers

Considering single algorithms were mentioned most in the articles, we further analyze the influence of every single algorithm based on formula (1). The ten most influential single algorithms are listed in Table 1. Among the ten algorithms, SVM, K-Means and Decision trees are classic machine learning algorithms, the Neural network and Long short-term memory (LSTM) are the deep learning algorithms. It shows that the Chinese IS papers still pay attention to the machine learning task when mentioning algorithm entities. Additionally, the popular algorithms in the computer field also have a strong influence in the IS field in China.

Table 1. Top-10 influential single algorithms

Rank	Algorithm	Rank	Algorithm
1	TF*IDF	6	Neural network
2	Vector space model	7	LSTM
3	SVM	8	K-means
4	Cosine similarity	9	Latent dirichlet allocation
5	Mutual information	10	Decision trees

Conclusion

Taking the algorithms mentioned in Chinese academic articles in IS field as the research object, we propose a method combining deep learning and manual review to extract and evaluate algorithm entities from academic papers. Our research shows that algorithms play an essential role in IS papers in China. The influence of the *single algorithm* is the highest and the most stable. Among the algorithms, classical machine learning algorithms and emerging deep learning algorithms are more influential.

The limitation of this work is we only use a deep-learning model on data from one field. In the future, we will try to combine more deep learning models and improve their performance to reduce the workforce. In addition, the co-occurrence of algorithm entities will be explored to understand the relationship between algorithms. Moreover, the evolution of IS in china can also be analyzed based on the trend of algorithm influence.

Introduction

The main research questions to be answered in this paper include how can breakthrough innovations be identified using ERTs? Are there different patterns of citation curves between ERTs and their knowledge base? Can the combination of citation curves patterns of ERT and their knowledge base improve the assessing the ERTs' breakthrough potential?

Literature review

Many scholars have conducted studies from different point of views to identify and predict breakthrough innovation. The main commonly used quantitative methods for detecting groundbreaking research frontiers are citation analysis methods (Dahlin & Behrens, 2005; Schoenmakers & Duysters, 2010; Small, 2016), topic mutation analysis(Kleinberg, 2003; Yoon & Kim, 2011), sleeping beauty literature analysis (Van Raan & Winnink, 2018), technical evolution methods and analyses based on machine learning models (Xu & Wang, 2019).

In general, this article aims to identify ERTs that have the potential to become breakthrough innovations with the method of citation curve fitting analysis and the characteristics of citation diffusion. By extracting the patterns and characteristics of citation curves of different ERTs, we expect to supplement and enrich the identification and prediction methods of breakthrough innovation. The breakthrough innovation mentioned in this paper refers to the technological innovation with the characteristics of dynamic, discontinuity and novelty.

Methodology

Theoretical base

This paper aims to evaluate the breakthrough potential of ERTs through analyzing the features of development trend and the correlation between the citation curve of ERTs and their knowledge base. Based on the analysis, we can finally achieve the breakthrough prediction. According to this purpose, we first list four theory bases of using citation curves to track the development patterns of ERTs, and discusses the feasibility of using citation curves to achieve breakthrough prediction from these four theory bases.

Procedural steps

There are three main steps in this article to achieve breakthrough innovation predictions for ERTs. First, we identify ERTs in a field, and then perform fitting analysis on the citation curves of these topics and their knowledge base. Finally, through comparative analysis of different citation curve patterns, we assess the breakthrough potential of different ERTs. The following is the analysis process in this article.
The content of method model in this paper includes identifying features and connotations, as well as the measurement characteristics and methods (Table 1).

Table 1. Method models for breakthrough identification of ERTs

Identify features	Measurement characteristics
ERTs	High novelty and rapid growth
basic knowledge	The knowledge base continues to develop
Knowledge transition	Multiple layers of citation curves
Continuous growth	Keep high citations and continue growing in recent period, the highest citation peak appears late

Empirical analysis

Data acquisition and analysis

The study of stem cells—a type of biological cell capable of self-renewal and multidirectional differentiation—is an important topic in biomedical research. The literature on stem cells research was selected as testbed to demonstrate the approach proposed in this paper. The data for this study were collected on October 20, 2018.

Comparison of Citation Curve Features

We then constructed the citation curves of the knowledge base in the form of time slices from 2001 to 2017 as the "citation curve of knowledge base". The citation curve of the ERTs in this study is from 2001 to 2017, but the publication of the knowledge base is from 1990 to 2015. Therefore, there are two piece of curve differences, which will not affect the analysis. The knowledge base crosses a relatively long time-span, to better understand and comparatively analyze the development pattern of the knowledge base and ERTs, we divide the knowledge base into EKB (1990-2000) and late knowledge base (LKB) (2001-2015).

Comparison of development pattern of knowledge base and ERTs in different time periods

Taking topic 2276 as an example (Figure 1), its citation curves of the EKB show a fluctuating trend. The curve reaches its local peaks in 2005, 2010, 2013, and 2015 respectively, and their peak value are not much different (Figure 1). The citation curve of the LKB has roughly experienced three transitions (leaping), in 2011, 2013 and 2015 respectively, and the highest peak of the citation curve appeared in 2017 in the 2015 papers' curve. The recent citation curve shows an uprising trend, and the citations value is higher than before. There is a possibility of another curve transitions. These characters indicate that the LKB of the ERT is in developing. The citation curve of ERTs has roughly undergone three transitions, in 2006, 2011 and 2013 respectively, and the highest peak of the citation curve appeared in 2017 in the 2015 papers' curve. The recent citation curve shows an uprising trend, and the popularity is higher than before. These characters indicate that this ERT is in development.

Discussion and conclusions

Based on the citation diffusion characteristics, combining the citation curve analysis of both knowledge base and ERTs, we can better analyze the development model of ERTs and assess their breakthrough potential, to provide reference and support for making science and technology planning. Therefore, the use of citation curves to identify breakthroughs in ERTs can further improve the theory and methodology of breakthrough identification. The professional evaluation of empirical results by experts and the current research status in the stem cell field prove that citation curve analysis combining knowledge base and ERTs can more efficiently assess the breakthrough potential of ERTs.

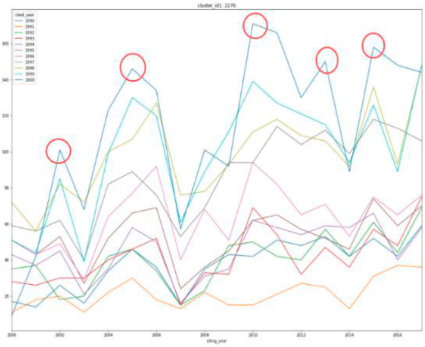

Figure 1. Citation curve of the EKB (# 2276)

Analysis of selected journals in Excellence Action Plan for China STM Journals Based on Bibliometrics

Yang Rui[1] and Wang Baoji[2]

[1] *664681261@qq.com*

[2] *wbj@cau.edu.cn*
Information Research Center, CAU Library, China Agricultural University, Beijing (China)

Introduction

Excellence Action Plan for China STM Journals was launched in 2019. The project is by far the largest project in China which aims to promote the high-quality development of Chinese scientific journals. Compared with the previous scientific journals funded projects in China, Excellence Action Plan for China STM Journals has the following new characteristics:

1). The number of the funded journals is the largest in a single funding cycle with 280 journals.

2). The amount of funding is the largest in a single funding cycle. The total funding is expected to exceed 160 million dollars.

3). The project is actually a systematic integration and reconstruction of the previous scientific journals funded projects.

4). The project has dynamic management and relatively more scientific evaluation.

Excellence Action Plan for China STM Journals has 7 sub-projects, including 4 journal sub-projects, 1 sub-project of the pilot for clustering journals, 1 sub-project of the international digital publishing service platform, 1 sub-project of selecting and breeding high-level talents for running journals. We focus on the analysis of 4 journal sub-projects.

The 4 journal sub-projects include leading journals (22), key journals (29), echelon journals (199) and new high start journals (30). Leading journals, key journals and new high start journals are all English journals. 199 echelon journals include 99 English journals, 68 Chinese basic research journals, 27 Chinese engineering and technology journals, and 5 Chinese popular science journals. These journal sub-projects are arranged like a pyramid. Specifically, leading journals are at the top of the pyramid which are the most promising to become world-class journals by some measures and they were selected by subject areas; key journals and leading journals form a competitive situation; the project positions echelon journals as a backup force; new high start journals should found new English scientific journals of the traditional predominant, emerging multi-disciplinary, strategic frontier or key generic technologies fields.

At present, the evaluation of journals in different languages is an urgent problem to be solved, especially for non-native English speaking countries. Dahler-Larsen proposes the PLOTE-index which could measure the percentage of citations flowing from the non-English publications of the researchers. This study analyzes the bibliometric characteristics of the selected journals based on new indicators being explored in China.

Method

The analysis of the academic impact of the selected journals is mainly based on *Annual Report for Chinese Academic Journal Impact Factors 2019* and *Annual Report for World Academic Journal Impact Factors 2019* which were both issued by China National Knowledge Infrastructure (CNKI).

Annual Report for Chinese Academic Journal Impact Factors 2019 proposes the Academic Journal Clout Index (CI), a comprehensive evaluation indicator that reflects the academic impact of journals. This indicator combines total cites and impact factors, and the Journal Mass Index (JMI) is used to modify this indicator. *Annual Report for Chinese Academic Journal Impact Factors 2019* quarters the Chinese journals of each discipline in descending order of CI.

Annual Report for World Academic Journal Impact Factors 2019 proposes World Academic Journal Clout Index (WAJCI) which could be got by dividing the CI by the median CI. *Annual Report for World Academic Journal Impact Factors 2019* also quarters the journals in the world in descending order of WAJCI. Multi-disciplinary journals are counted according to its highest quartile.

Results

Table 1 shows the international and domestic academic impact of the selected journals. According to *Annual Report for Chinese Academic Journal Impact Factors 2019*, 14 leading journals are ranked Q1, which means that 63.64% of leading journals have high academic impact in China.

According to *Annual Report for World Academic Journal Impact Factors 2019*, 15 journals are ranked Q1, which means that 68.18% of leading journals have high international academic impact. It is found that high international academic impact is not a necessary condition for selected, and the selection of leading journals is more focused on English journals with high international academic impact.

Table 1. The international and domestic academic impact of the selected journals.

Report	Quartile	Leading journals	Key journals	Echelon journals			
				Summary	English journals	Chinese basic research journals	Chinese engineering and technology journals
Annual Report for Chinese Academic Journal Impact Factors 2019	Q1	63.64% （14/22）	24.14% （7/29）	72.36% （144/199）	53.54% （53/99）	95.59% （65/68）	96.30% （26/27）
	Q2	13.64% （3/22）	27.59% （8/29）	9.05% （18/199）	14.14% （14/99）	4.41% （3/68）	3.70% （1/27）
	Q3	9.10% （2/22）	24.14% （7/29）	4.52% （9/199）	9.10% （9/99）	-	-
	Q4	-	10.34% （3/29）	4.02% （8/199）	8.08% （8/99）	-	-
	No data available	13.64% （3/22）	13.79% （4/29）	10.05% （20/199）	15.15% （15/99）	-	-
Annual Report for World Academic Journal Impact Factors 2019	Q1	68.18% （15/22）	41.38% （12/29）	16.08% （32/199）	12.12% （12/99）	20.59% （14/68）	22.22% （6/27）
	Q2	31.82% （7/22）	51.72% （15/29）	33.67% （67/199）	40.40% （40/99）	33.82% （23/68）	14.81% （4/27）
	No data available	-	6.90% （2/29）	50.25% （100/199）	47.47% （47/99）	45.59% （31/68）	62.96% （17/27）

Note: Five Chinese popular science journals are not academic journals, so these journals are not listed in Table 1.

According to *Annual Report for Chinese Academic Journal Impact Factors 2019*, 7 key journals are ranked Q1, which means that 24.14% of key journals have high academic impact in China. Under the same calculation conditions, the domestic academic impact of key journals is lower than that of leading journals.

According to *Annual Report for World Academic Journal Impact Factors 2019*, of the 29 selected key journals, 27 journals have available data which are all ranked Q1 or Q2. Whereas, under the same calculation conditions, the international academic impact of key journals is lower than that of leading journals. And the selection of key journals is more focused on English journals with higher international academic impact.

According to *Annual Report for Chinese Academic Journal Impact Factors 2019*, 144 of the 199 echelon journals are ranked Q1, which means that 72.36% of the journals have high domestic academic impact. From the overall data, the domestic academic impact of echelon journals is higher than that of leading and key journals, mainly because half of the echelon journals are Chinese journals, and the proportion of these Chinese journals ranked Q1 is as high as 95%.

According to *Annual Report for World Academic Journal Impact Factors 2019*, 32 of the 199 echelon journals are ranked Q1, and 16.08% of the journals have high international academic impact. From the overall data, the international academic impact of echelon journals is much lower than that of leading and key journals, and there is a big difference between the international academic impact of echelon journals and that of world-class journals. However, the proportion of English journals of echelon journals ranked Q1 is 12.12%, which is lower than that of Chinese journals (20%), indicating that some Chinese journals have already accumulated definite international academic impact.

Conclusion and Discussion

Leading journals and key journals are selected by priority construction areas; are more focused on English journals with high international academic impact. Echelon journals give consideration to both Chinese and English scientific journals; do not have overall high international academic impact, while the Chinese journals among them have high domestic academic impact.

So far, the project has brought many positive effects, the most important one is that it points out the macro planning for the development of Chinese scientific journals. However, we should also note the limitations of this project. For example, although 280 journals have been funded, the coverage is still very limited in terms of the number of scientific journals in China as a whole.

Does knowledge of Library and information science field transform to technology?

Xiao Yang [1], Lingzi Feng [2] and Junpeng Yuan [3]

{[1] yangxiao, [2] fenglingzi , [3] yuanjp}@mail.las.ac.cn
National Science Library, Chinese Academy of Sciences (China)

University of Chinese Academy of Sciences (China)

Introduction

Scientific research is the source and driving force of technological innovation. (Bush, 1945). The transformation from science to technology is more common in hard disciplines (Lo, 2010; Sung et al., 2015), while soft disciplines are not the main source of knowledge for technological innovation. Some scholars have investigated the impact of citing humanities and Social Sciences papers on patents (de Moya-Anegon et al., 2020), and demonstrate the technological and economical viability of Library Science (Halevi, 2012).Therefore, this paper studies the relationship between the papers in LIS and the its citing patents, in hopes of understanding the characteristics of the knowledge transformed from LIS to technology, so as to explore the new advantages of the development of LIS from the perspective of technological innovation.

Data

This study focuses on the papers in the field LIS. Firstly, we selected the Web of Science (WoS) platform and "Information Science & Library Science" in the JCR classification system, which included 87 journals. Then, we matched 417 papers that are cited by patents in The Lens (covering 22 journals in LIS), and found 1,437 patents cited these papers. In order to better reveal the situation of these LIS papers cited by patents, we choose the subset of papers included in WoS as the analysis object. By using the paper identifier such as DOI to match the papers in WoS, 357 papers to be analyzed are matched. Finally, we matched the patents which cited these 357 papers in The Lens again, and 1090 patents were obtained.
All data were acquired on December 11st, 2020.

Analysis of the linkages between scientific publications and patents in the field of LIS

Journal distribution

The journal distribution of LIS papers cited by patents are shown in Table 1. These 357 papers cover 22 journals (25.3%) in this field, among which Information & Management has the most number of papers cited by patents. Through the Spearman correlation test, it is found that the correlation coefficient is 0.657 and the significance is 0.01, indicating a significant positive correlation. That is, the higher the impact factor of the journal, the higher the number of the patent citation.

Table 1. The journal distribution of LIS papers cited by patents (top10)

Journal	*Num. of articles*	*Cited by Patent*	*Journal Impact Factor*
Telecommunications Policy	28	246	1.7638
Information & Management	60	151	3.729
Electronic Library	20	109	0.6796
Information Systems Research	37	86	2.8306
Online Information Review	26	75	1.6188
Scientometrics	36	64	2.4082
Social Science Computer Review	17	61	2.5378
Library Hi Tech	9	35	0.958
Library & Information Science Research	8	17	1.3394
Information Society	5	14	1.8036

Table 2. Annual Time lag between LIS paper and its citing patent. (recent ten years)

Pub. year (Patent)	*Time lag*		
	Max.	*Min.*	*Average*
Average	18.5	3	9.8
2020	32	3	15.8
2019	33	0	14.8
2018	32	4	16.0
2017	28	2	15.6
2016	27	1	14.5
2015	27	3	13.5
2014	29	2	13.7
2013	34	0	12.6
2012	32	1	12.8
2011	27	2	13.8
2010	25	2	10.5

Analysis on time lag of patent-paper

In order to accurately calculate the time lag of LIS papers cited by patents and its citing patent, we count the time lag between the publication year of each patent and the publication year of one or more LIS papers cited by this patent and observed the time lag between patents and LIS papers every year. As shown in Table 2, the average time lag is 9.8 years. According to the average annual time lag of this study, the time lag has become longer and longer from 1989 to now. By 2020, the average annual time lag has reached 15.8 years, which is 6 years longer than the overall average time lag.

Analysis on the topic flow from paper to patent

In order to sort out the flow of scientific knowledge in LIS to technology, we used LDA model to determine the topic of the LIS paper, including: Library and public services(1), literature citation and author cooperation(2), decision support and user communication(3), network service and reference consultation(4), website production and web design(5), knowledge organization and strategic planning(6), project management and organization(7), financial marketing and economic mechanism(8) and others(0). According to the International Patent Classification (IPC) the topics(categories) of patent are: physics(G), electricity(H), human life needs(A), operation and transportation(B), and chemical metallurgy(C). Then we used Sankey diagram to present the paper-patent topic flow (Figure 1).

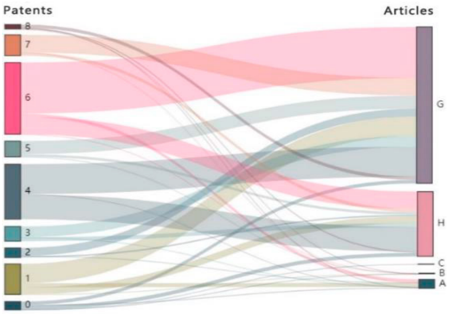

Figure 1. Sankey diagram of paper-patent topic flow.

Quality relationship of paper-patent

In order to further reveal the correlation between LIS papers' impact and its citing patents' quality, we also present this relationship through Sankey diagram (Figure 2). The column on the left side is the cited frequency of papers (cited by papers), and the column on the right side is the cited frequency of patents (cited by patents). Since the data of cited frequency is relatively dense, we divided the data into few sections based on the size of number. As can be seen from Figure 2, no matter the impact of the LIS papers is big or small, they are cited by different quality patents.

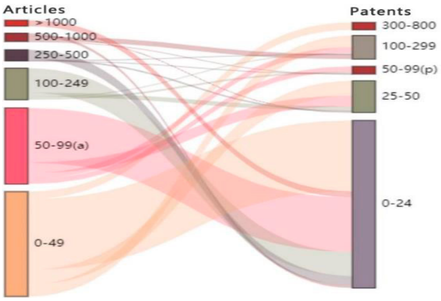

Figure 2. Sankey diagram of paper-patent quality flow.

Conclusion

As a comprehensive interdisciplinary soft discipline, the Library and information science (LIS) does cited by patents, and we could explore new growth points by analyzing the situation and characteristics of the conversion of scientific knowledge in this field to technology.

Acknowledgments

Thank Ruhao Zhang for his support in data analysis. This work is supported by LIS Outstanding Talents Introducing Program, Bureau of Development and Planning of CAS [2018] No. 12.

Artificial Intelligence in Pharmaceuticals: Bibliometric and Collaboration Network Analysis of Patents

Yang Xin

yang_xin@fudan.edu.cn
Fudan University, Fudan University Library, Intellectual Property Information Service Centre, No. 300 Guonian Road, 200433 Shanghai (China)

Introduction

Artificial Intelligence (AI) includes four categories: systems that think humanly (the cognitive modeling approach), systems that act humanly (the Turing Test approach); systems that think rationally (the "laws of thought" approach), and systems that act rationally (the rational agent approach) (Russell & Norvig, 2010). With the thriving development of AI techniques, more than 340,000 AI-related inventions have been filed applications up to early 2018 (WIPO, 2019). Through the bibliometric analysis of patent literature, it can objectively and quantitatively investigate the stage of technical improvement, predict the technological and economic development trend. Thus, both bibliometric and Social Network Analysis (SNA) are conducted to achieve a holistic view of the AI-pharmaceutical field. The study is intended to provide references for future strategy planning, development, and technological marketization.

Method and Data

The patent data is retrieved from Derwent Innovation Index database (DII). The patent retrieval strategy is composed of two portions: (1) search terms related to AI (Topic "artificial intelligen*" or "depth learning*" or "deep learning*" or "natural language processing*" or "speech recognition*" or "computer vision*" or "gesture control*" or "smart robot*" OR "Video recognition*" OR "Voice translation*" OR "Image Recognition*" OR "machine intelligen*" or "Machine learning*"); (2) Derwent Manual Codes related to pharmaceuticals (B01* to B15*). The date of retrieval is December 16, 2019. As a result, 1282 raw records are achieved and downloaded from DII. Then, the patent family records are displayed as a single patent, and duplicates are manually cleaned. Finally, 3610 items of single patent information are obtained.

Results

Patent activity trend

The application year of patents can reflect inventive performance. Figure 1 exhibits the annual patent application count in the AI-pharmaceutical domain. It is observed that the number curve of patent applications could be divided into two stages, which presents diverse growth patterns. The first phase is from 1972 to 2010, when the number of patent applications had endured four decades of slow development stages, with the annual quantity less than 100. The second phase is during the interval from 2011 to 2017, when the count of patent applications has shown a sharp increase, with an average growth rate of 42.5%. This intense rise is attributed to the dramatic promotion of artificial intelligence, in particular, deep learning sprang up as an emerging field of machine learning, which tremendously boosts the development in visual object recognition, drug discovery, and many other domains (LeCun, Bengio & Hinton, 2015). After 2017, the decline in quantity is caused by the 18 months lag period of patent applications. Therefore, the number of AI-pharmaceutical-related patents in both 2018 and 2019 is inadequate, for reference only.

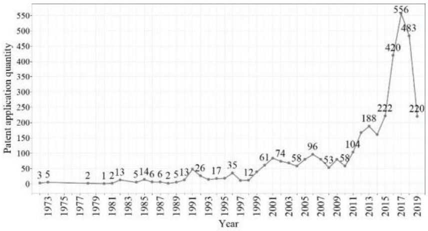

Figure 1. Annual amount of AI- pharmaceutical-related patent applications

Geographical distribution

The information of patent geographical coverage can provide an insight into the industry activity and market competition. The main geographical layout of AI-pharmaceutical-related patents are displayed in Figure 2. The earliest priority country refers to the country or region where the patent application is first filed, suggesting the origin of inventions and national innovation activity. The target country stands for any country or region where the patent right is subsequently protected, indicating the competitive market.

The countries or regions of first fillings are the United States of America (US) with 2248 number of records, followed by China (CN, 364 records), Japan (JP, 233 records), European (EP, 152 records), and Republic of Korea (KR, 116 records). The patent quantity of the US is more than 6 times larger than the second productive country (China), reflecting its technology predominance in the AI-pharmaceutical field. For the top 10 earliest priority countries or regions, apart from the developing country China (rank 2nd), the rest are all developed countries or regions.

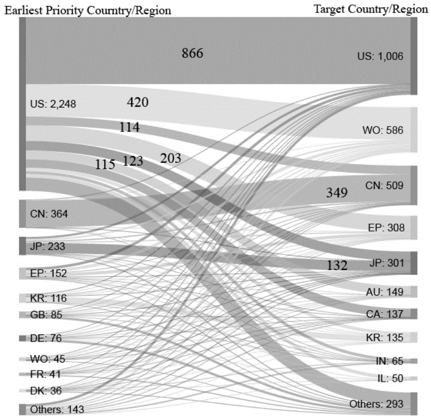

Figure 2. Main geographical distribution of the AI-pharmaceutical-related patents

Patents cooperation network

The collaboration networks, established by assignees of co-owner patents, have been proven to evaluate what positions organizations occupy in a special technology field (Li, Garces & Daim, 2019). The collaborative network is composed of 1233 nodes and 450 links (Figure 3).

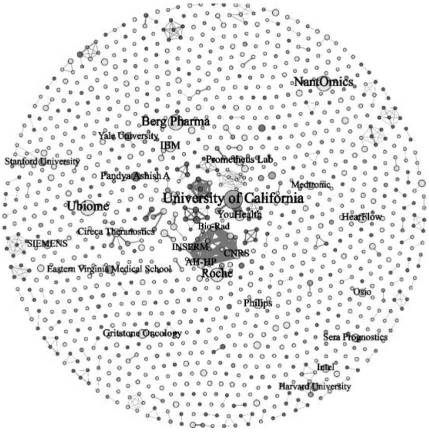

Figure 3. Assignees cooperative network of AI-pharmaceutical patents

The average density of the network is merely 0.001. The low density of collaborative network suggests that there is a weakly cooperative relation among assignees, due to plenty of unconnected nodes (67% of all assignees). Approximately 12% of patents are co-owned by assignees from at least two organizations. This also implies that the co-owner relationships of AI-pharmaceutical-related patents are not highly cooperative.

The patents engaged by companies account for around 73 percent of the total. Companies and academic institutions are the friskiest assignees in the applications of AI-pharmaceutical-related patents. The co-owned patents mostly exist between enterprise and academic institutions, while the co-ownership patents among enterprises are marginal. The cooperative relationships between enterprise and enterprise are basically concentrated upon inter-group and parent-subsidiary.

Conclusions

The quantity of AI-pharmaceutical-related patents has entered a sharp growth period since 2011. The United State of America is both the dominant nation of technological innovation and the significant AI-pharmaceutical market, followed by China. Additionally, the US pays higher attention to overseas patent layouts than other countries or regions. The low-density value of the assignee cooperation network indicates the insufficiency of inter-organizational collaboration. In the AI-pharmaceutical field, companies and academic institutions are the friskiest innovation subjects. The academic-enterprise collaboration should be enhanced to accelerate technology transform, and it's beneficial to consider the geographical factor.

Who Shares Scholarly Output on Facebook?

Houqiang Yu[1], Wei Zhang[2], Yue Wang[3] and Tingting Xiao[4]

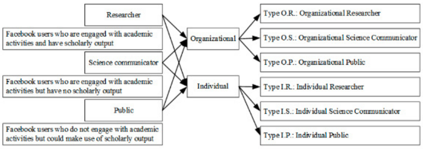
Introduction

Scholarly outputs are increasingly shared on Facebook (Bowman, 2015). Therefore, Facebook becomes one important altmetrics data source. We use *scientific Facebook user* to refer to Facebook user who mention scholarly output in their posts. This study has revealed scientific Facebook users' productivity distribution based on a large dataset. Moreover, the study has selected different samples of scientific Facebook users and investigated their identity distribution. The research questions are:(1) What is the productivity distribution of scientific Facebook users? (2) What are the identities of scientific Facebook users?

Data and Method

Data are collected from Altmetric database. Facebook mentions of scholarly output from September 1st, 2017 to August, 31st, 2020 were retrieved. In total, there were 1,506,036 Facebook posts with 1,613,993 mentions of scholarly outputs.

The study used simple random sampling and stratified sampling strategy to extract the data. In total, five samples were obtained, consisting of 2,160 records, including 500 random records (sample 1) and 1,660 stratified records (sample2 to sample 5). Qualitative coding analysis was adopted on these data to reveal the identity of scientific Facebook users. As shown in Figure 1, there are six basic types of identities. These basic types are further divided into 30 specific types of identities. While the basic types of identities are obtained in a top-down way, the specific types of identities are summarized in a bottom-up manner.



Researcher
Facebook users who are engaged with academic activities and have scholarly output
Science communicator
Facebook users who are engaged with academic activities but have no scholarly output
Public
Facebook users who do not engage with academic activities but could make use of scholarly output
Organizational
Individual
Type O.R.: Organizational Researcher
Type O.S.: Organizational Science Communicator
Type O.P.: Organizational Public
Type I.R.: Individual Researcher
Type I.S.: Individual Science Communicator
Type I.P.: Individual Public

Figure 1. Six basic types of scientific Facebook user

Results

Productivity distribution of scientific Facebook users

Number of mentioned scholarly outputs is used to measure scientific Facebook user's productivity. As shown in Table 1, scientific Facebook users are further divided into 20 levels of activeness according to their productivity with each level having around 5% of total scientific Facebook posts.

Table 1. Scientific Facebook users of different levels of activeness

A.	*Range*	*P.U.*	*A.*	*Range*	*P.U.*
A1	[1,8]	67.9%	A11	(222,294]	0.5%
A2	(8,18]	11.1%	A12	(294,387]	0.4%
A3	(18,29]	6.0%	A13	(387,488]	0.3%
A4	(29,43]	4.0%	A14	(488,629]	0.2%
A5	(43,60]	2.7%	A15	(629,858]	0.2%
A6	(60,82]	2.0%	A16	(858,1310]	0.1%
A7	(82,108]	1.4%	A17	(1310,1981]	0.1%
A8	(108,139]	1.2%	A18	(1981,3288]	0.1%
A9	(139,175]	0.9%	A19	(3288,5648]	0.04%
A1	(175,222]	0.7%	A20	(5648,14466]	0.01%

**A.* is activeness of scientific Facebook users, *P.U.* is percentage of users.

Identities distribution based on the random sampling strategy

Based on the random sampling strategy, the coding result is shown in Figure 2. Organizational users are dominant in scientific Facebook users, taking up 82.5%. Public users (type O.P. and I.P., 54.7%) are the majority, followed by researcher users (type O.R. and I.R., 32.1%) and science communicator users (type O.S. and I.S., 13.2%). To be more specific, organizational public users (type O.P.) plays a leading role in scientific Facebook users.

Zoom into Figure 2, Figure 3 is obtained. Among organizational public users (type O.P.), business organization has taken up 25.7%. It's followed by social organization (18.5%) and government organization (2.3%). Among organizational researcher users (type O.R.), higher education institutions (O.R.1) and academic associations (O.R.2) are two major types, taking up 10% and 7% respectively. Among organizational science communicator users (type O.S.), scholarly journals (O.S.3) and scientific websites (type O.S.6) have relatively higher percentage, that is 3.4% and 2.8% respectively. For individual users, university faculties (I.R.1) and non-academic personal media (I.P.2) are leading types of user, taking up 5.1% and 4.7% respectively.

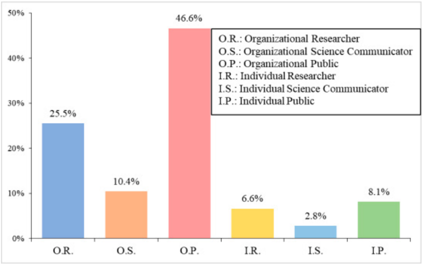


Figure 2. Identities distribution of scientific Facebook users based on general sample

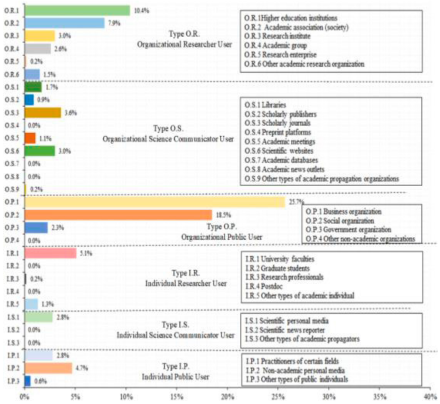

Figure 3. Specific identities distribution of each basic user type

Identities distribution based on the stratified sampling strategy

Identities distribution of different stratified sample users has presented different pattern, as shown in Table 2. For example, type O.S. percentage is decreasing rapidly from sample 2 to sample 5. In sample 2, the percentage of type O.S. user is astonishingly as high as 63%, but in sample 5, the percentage is as low as 8.8%. It suggests that the productivity of scientific Facebook users will have great impact on their identities distribution.

Table 2. Identities distribution of users across samples of different level of activeness

Code	***Sample 2 (A16-A20)***	***Sample 3 (A11-A15)***	***Sample 4 (A6-A10)***	***Sample 5 (A1-A5)***
O.R.	16.1%	26.0%	27.5%	23.1%
O.S.	63.2%	49.1%	27.0%	8.8%
O.P.	1.9%	10.2%	25.5%	49.5%
I.R.	9.7%	5.5%	6.8%	7.5%
I.S.	8.4%	7.9%	8.3%	2.9%
I.P.	0.6%	1.3%	5.0%	8.4%

Conclusion

Productivity distribution is highly skewed towards the lowly productive scientific Facebook users. Identities of scientific Facebook users are very diversified in types. They can be classified into six basic types and 30 specific types. Organizational scientific Facebook users are prevailing taking up more than 80% of total users. Public users (Ptg= 55%) have surpassed researcher users (Ptg= 32%) and are the major type of scientific Facebook users.

Scientific Facebook user's level of activeness has strong connection with their identities. There is clear increasing pattern as regards percentage of public users with the decreasing level of activeness. These findings are based on larger sample and more specific codings compared with previous studies (Mohammadi, Barahmand & Thelwall, 2020). By not considering the filed factor in sampling strategy, the study has revealed the overall situation of Facebook users, but it can also be regarded as a major limitation because disciplinary difference exists.

Where, how and why are scientific products mentioned in policy documents?

Houqiang Yu[1], Biegzat Murat[2], Jiatong Li[3] and Longfei Li[4]

[1] yuhouq@yeah.net, {[2] nulibiegzat, [4] nust_llf}@163.com, [3]1065047683@qq.com

Introduction

Policy document mention is considered to be useful for measuring the societal impact of scholarly output. Major altmetric databases such as Altmetric and PlumX have collected policy document mentions for several years. Policy document is defined in a broad sense that a range of document types such as government guidelines, reports, white papers, recommendations and independent policies are all included. In this study, publications that are unrelated to policy (such as doctoral thesis, conference proceedings and conference reports, etc.), or just marginal part of the policy document (such as brief, appendices and lists, etc.) are not considered as policy documents and will not be further analyzed.

Previous studies have investigated the coverage (Bornmann, Haunschild, & Marx, 2016) and data quality (Yu et al., 2020) of policy document mentions, as well as the predicting factors of whether scientific products get mentioned by policy document (Kale et al., 2017). However, it is not clear how policy document mentions can be interpreted. This study is aimed to answer three research questions. (1) Where are scientific products mentioned in the policy documents? (2) How are scientific products mentioned? (3) Why are scientific products mentioned?

Methodology

Policy document mention data were retrieved from Altmetric database on August 19th, 2020. In total, there were 2.22 million mentions from 187 institutions. Considering the difference between institutions, we first randomly selected 40 institutions (as shown in Table 1) and then randomly selected 10 records from each institution. The sample dataset consists of 400 records.

The analysis was conducted with the following steps. (1) Click the URL of policy document in the record and download the file. (2) Search for the mentioned scientific product. Title, part of the title, source, author's first name, DOI, publication link, or publication date was used to help locate the mentioned scientific product. (3) Check in what format the policy document has mentioned the scientific product. (4) Examine in which part the mention appears in the policy document. (5) Investigate what part of the scientific product is mentioned. (6) Determine the motivation of mentions combing all available context information.

The coding table was established with collaboration of four coders. 200 records were coded by three coders. The overall consistency rate is 85%. The other 200 records were coded by one coder.

Table 1. The list of policy document source institutions.

N.	Policy document source institution
1	UNESCO
2	The Publications Office of the European Union
3	International Union for Conservation of Nature
4	World Bank
5	World Meteorological Organization (WMO)
6	United Nations Environment Programme (UNEP)
7	Flemish Government Policy Documents
8	European Food Safety Authority
9	Intergovernmental Panel on Climate Change
10	Analysis & Policy Observatory (APO)

*Only 10 out of 40 institutions are presented here due to the space limitation

Results

Where are the mentions located?

Given the various types of policy documents, there is no fixed structure. However, based on the functional structure, locations of mentioning the scientific product can be summarized in Table 2.

Table 2. Location of mentioning scientific product in the policy document

Code	%	Code	%
1. Abstract	0.4%	7. Column	3.1%
2. Review	19.5%	8. Acknowledgment	0.4%
3. Methodology	3.4%	9. Appendix	3.1%
4. Expounding	53.4%	10. No mention	8.8%
5. Results	4.6%	11. Others	1.1%
6. Summary	2.3%	Total	100%

How are scientific products mentioned?

In total there are four forms in which scientific product could be mentioned in the policy document as shown in Table 3. Code *4. Non-standard reference* t only mention elements like title, DOI, or author of the scientific product.

Mentioned elements of scientific product are summarized in Table 4. Fragment entities (code 2.3) such as a number, or a chart are mentioned the most frequently. Sentences in conclusions (code 1.4) are also frequently used (23.7%).

Table 3. Different citing forms of scientific product in the policy document.

Code	%
1. Reference list	87.8%
2. Footnotes or endnotes	5.0%
3. Complementary material	5.0%
4. Non-standard reference	2.3%
Total	100%

Table 4. Mentioned elements of scientific product in the policy document.

Code	%
1. Sentences	30.9%
1.1. Title	0.8%
1.2. Abstract	1.1%
1.3. Method	4.2%
1.4. Conclusion	23.7%
1.5. Discussion	1.1%
2. Entities	35.5%
2.1. Opinion	5.7%
2.2. Concept	2.7%
2.3. Fragment	26.3%
2.4. Instrument	0.8%
3. Topics	21.4%
3.1. Theme	6.1%
3.2. Summary	7.3%
3.3. General	5.7%
3.4. Parallel reference	2.3%
4. Pure link	12.2%
Total	100%

Why are the scientific products mentioned?

Four major categories and twelve specific categories of motivations are identified, as shown in Table 5. It is highlighted that persuasive references (code 2) are dominant and have taken up 52% of total mentions. It means that scientific products are often used as evidence for justifying the argument proposed by the policy document.

Table 5. Motivation of mentioning scientific product in the policy document.

Code	%
1. Acknowledgeable reference	21.4%
1.1. Indicate the source of mentioned entities	10.7%
1.2. Indicate the source of mentioned examples	3.4%
1.3. Indicate the source of mentioned methodology	2.7%
1.4. Indicate the source of mentioned concept	2.3%
1.5. Indicate the source of mentioned topic	2.3%
2. Persuasive reference	51.5%
2.1. Support the argument by using examples	13.7%
2.2. Support the argument by listing relevant work	37.8%
3. Constructive reference	6.5%
3.1. Basis for reasoning	2.7%
3.2. Material of meta-analysis	3.8%
4. Informative reference	9.9%
4.1. Provide background information	6.1%
4.2. Provide complementary material	2.7%
4.3. Help to locate relevant studies	1.1%
5. Unable to judge	10.7%
5.1. Indirect reference	1.9%
5.2. Pure reference	8.8%
Total	100%

Conclusions

Main conclusions are drawn as follows. (1) Policy documents have seen most of the mentions of scientific product in the expounding parts (percentage = 53%) where core ideas are expressed, unlike scholarly articles where citations are mostly located in the literature review or introduction part. (2) Policy documents have mostly (percentage = 88%) followed academic citation style when mentioning scientific product, although it is not mandated. Meanwhile, there are other types of non-standard citing forms. (3) Among all types of mentioned elements of scientific product, fragment entities have been mentioned the most frequently, while conclusions of the scientific product are almost equally heavily mentioned. This indicates that policy documents are likely to mention the scientific product in a confirmative way, and could potentially be biased. (4) Over half of the mentions (percentage = 52%) are aimed to make the argument proposed by the policy document more persuasive. This indicates that policy document mentions of scientific product are indeed reflecting their societal impact because they are relevant in helping make decisions.

Compared with scholarly citations, policy document mention is likely to directly make use of the findings of the scientific product to inform practical guidance. To our observation, the policy document mention is separate from the academic discussion, therefore, no controversial, flattery, or critical mentions were involved. In this sense, policy document mention is more neutral.

Introduction

Launched by Digital Science in January 2018, *Dimensions* is a partly free scholarly database with the characteristic of linking and contextualizing different research information objects. As a young data provider, whether *Dimensions* is a reliable or even favorable data source has caused some attention in recent years. Thelwall et al. (2018) explored the coverage of Scopus journal articles in *Dimensions* and comparability between average citation counts in two databases; Herzog et al. (2020) assessed the coverage of publications from *Dimensions* in comparison with other data sources. Less attention so far has been given to examining the coverage and accuracy of funding and the funded publications in *Dimensions*, and this gap in literature leads to our study. In this poster, we present the following preliminary results:

1) the completeness of funding data in *Dimensions*, compared to the related funder's official website;

2) a comparison between *Dimensions'* collection of funded publication data and those provided by the Web of Science (WoS).

Data

National Natural Science Foundation of China (NSFC), as the largest funding agency for basic research in China, is selected as the primary object for comparison due to its unique position in the Chinese scientific funding system. The number of funded projects provided by the statistics report on the NSFC official website[1] is used as a baseline for assessing the coverage of *Dimensions'* grants data. Further, the seven major types of funded projects from 8 scientific departments (2001-2018) in the NSFC are selected for comparison in the current study. A unified 8-digit NSFC grant number that contains unique information to distinguish project type, application year and scientific department is used to match the project data. In total, 358,287 and 404,976 funded projects applied during 2001-2018 were obtained from *Dimensions* on Oct. 2019 and Jan. 2021, respectively. As for the baseline, 407,076 funded projects from NSFC are used for comparison.

In terms of funded publications, the grant number of funded projects completed during 2001-2018 and publicized in the NSFC official platform[2] is used to retrieve the related publication data from both *Dimensions* and WoS. The total amount of funded publications obtained are 2,068,242 (*Dimensions*) and 2,414,222 (WoS) respectively.

Results

Funded projects

As seen in Figure 1, the number of NSFC-funded projects retrieved from *Dimensions* respectively in Oct. 2019 and Jan. 2021 are in general identical, with the only exception of the year 2006. The funded project data for 2006 obtained in 2019 has a striking deficiency in *Dimensions*, compared to that from NSFC's website. However, the data for 2006 was improved largely in *Dimensions* by Jan. 2021, in spite of a small degree of incompleteness. Although part of the data for 2018 has not been updated timely in *Dimensions*, it seems the coverage of data in *Dimensions* is continuously improving.

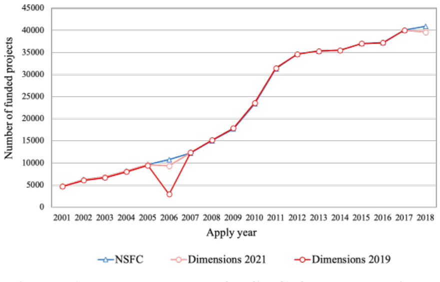

Figure 1. The number of NSFC-funded projects

To provide a more refined analysis, we calculate the coverage ratio of projects in *Dimensions* for seven different funding types and eight scientific departments in NSFC. In particular, the number of projects in *Dimensions* (Jan. 2021) is divided by the number of projects obtained from the NSFC report. As illustrated by Figure 2, the number of projects of GP, YS, EYS, LDR and DYS types are in general consistent with the number obtained from the NSFC

[1] www.nsfc.gov.cn/publish/portal0/tab505/

[2] http://output.nsfc.gov.cn

except for 2006. Notably, the coverage of KP projects in the *Dimensions* is only 56% in 2006. Further, different degrees of deficiency for JP projects can also be observed in most years. The varying degrees of missing data for all types of projects in 2018 might be due to Dimensions' update issue.

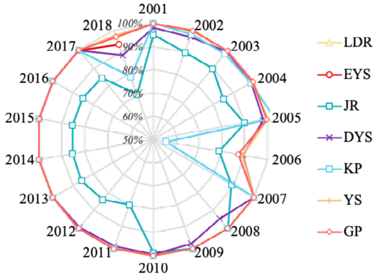

Figure 2. Coverage of 7 types of funded projects

Note: LDR= Fund for Less Developed Regions, EYS= Excellent Young Scientists Fund, JR= Joint Research Fund for Overseas Chinese Scholars and Scholars in Hong Kong and Macao, DYS= National Science Fund for Distinguished Young Scholars, KP= Key Program, YS= Young Scientists Fund, GP= General Program

Similarly, Figure 3 indicates the exceptional low coverage for projects in all departments in 2006 and 2018. In terms of different departments, the numbers of projects in CS, LS, ES, MS and HS are basically identical with that from the NSFC report, while the numbers in M&PS, E&MS and IS deviate from the official records in NSFC.

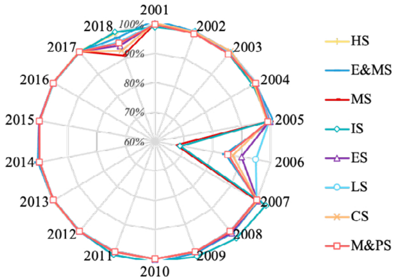

Figure 3. Coverage of funded projects in 8 scientific departments

Note: HS= Health Sciences, E&MS= Engineering and Materials Sciences, MS= Management Sciences, IS= Information Sciences, ES= Earth Sciences, LS= Life Sciences, CS= Chemical Sciences, M&PS= Mathematical and Physical Sciences

Funded publications

From Figure 4, a significant increasing trend can be observed in both the total and the average number of publications indexed in two databases. For the average number of publications, *Dimensions* took a leading position before 2008 but was overtaken by WoS since 2009. In addition, the remarkable contrast of the average number of publications in 2009 between two databases might indicate a certain level of publication data deficiency in *Dimensions*. The relatively low number of publications in 2014 in both databases is mainly attributed to the low number of funded projects in that year.

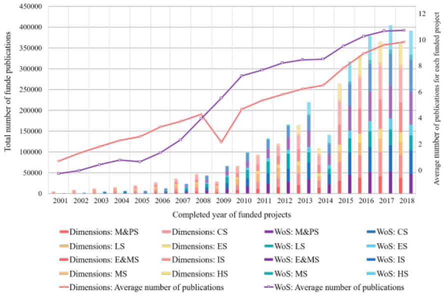

Figure 4. The total and average number of publications for funded projects

Discussion and Conclusions

In general, *Dimensions* provides accessible and relatively reliable data on funding (at least for NSFC-funded projects). However, the data coverage may vary with different years and project types, and a delay of data updates is observed for recent years. For the funded publications, data retrieved from *Dimensions* and WoS shows clear divergence. Since the completeness and accuracy of funding information derived from publications in bibliographic databases are often questioned by scholars (Álvarez-Bornstein et al., 2017), whether *Dimensions* provides satisfactory or complementary information remains to be further explored.

In subsequent research, both the funded projects and publications in different databases will be matched precisely based on the grant number of projects and DOI, respectively, for a refined analysis on the data accuracy of *Dimensions*. Furthermore, other official sources of funded projects and publications, such as the US National Science Foundation (NSF), will be included to examine the data integrity of *Dimensions* from a more comprehensive perspective.

The effect of international academic mobility on international cooperation: from the perspective of overseas institutions

Zhang Ying[1,2], Liu Xiaomin[1,2] and Sun Yuan[3]

{zhangying, liuxm}@mail.las.ac.cn, yuan@nii.ac.jp

[2] Department of Library, Information and Archives Management, School of Economics and Management, UCAS, Beijing (China)
[3] National Institute of Informatics, Tokyo (Japan)

Introduction

This study explores how the mobility of researchers among international institutions affects their international collaboration. We took 254 researchers who returned to China from overseas as the samples, then established panel data through personal homepages and Scopus database. Finally, we utilized two-way fixed effect model (FE model) and random effect model (RE model) to analyze the relationship between mobility and international collaboration.

Data & Methods

In the study, we took researchers who returned to Chinese Academy of Sciences between 2011 and 2015 as samples. After excluding those without complete information, there were 254 researchers included. 48.4% of them earned the PhD overseas, then worked abroad for at least 3 years as postdoctor or formal staff. The rest got PhD in China, and they worked at least 5 years overseas after that.

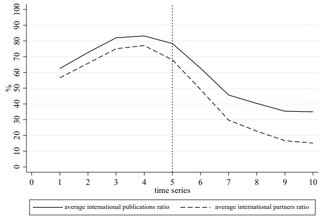
We established panel data with a time series of 10 years, including data 5 years before and 5 years after their return. Personal data (age, gender, discipline, education and work experience) were from personal homepages; publication data were collected through Scopus based on the author unique identifier. The variables and their descriptions are shown in Table 1. A publication was defined as an international publication if its authors' institutions belong to different countries. An author was regarded as an international partner if whose institution do not belong to the same country with our target researchers (the 254 samples).

As for the analysis model, the hausman-test showed that the FE model was more appropriate than RE model. In order to simultaneously control the individual effect of researchers and time effect, we constructed two-way FE model. But in order to reveal the effects of the time-invariant variables, we still further ran a RE model. Finally, we conducted the test of robustness by dividing the samples into two parts according to whether they have overseas degrees, which proved that our results were stable and reliable. (The robustness test results are not shown because of poster's space limit).

Table 1. Descriptions of variables

Variables	Descriptions
Dependent variables	
international publications ratio$_{it}$	ratio of international publications to total publications published by researcher i in year t
international partners ratio$_{it}$	ratio of international partners to total partners of researcher i in year t
Explanatory variables	
length of time spent overseas$_{it}$	number of years spent in overseas institutions by researcher i until year t
number of overseas institutions$_{it}$	number of institutions experienced by researcher i until year t
postdoctor$_i$	1 if researcher i had overseas postdoctoral experience; 0 otherwise
formal position$_i$	1 if researcher i had overseas formal working position; 0 otherwise
Control variables	
age$_{it}$	age of researcher i in year t
gender$_i$	1 if male; 0 otherwise
discipline_1$_i$	1 if the discipline is fundamental frontier interdisciplinary sciences; 0 otherwise
discipline_2$_i$	1 if the discipline is resources ecology and environment sciences; 0 otherwise
discipline_3$_i$	1 if the discipline is life and health sciences; 0 otherwise
discipline_4$_i$	1 if the discipline is advanced materials sciences; 0 otherwise
discipline_5$_i$	1 if the discipline is optoelectronics and space sciences; 0 otherwise
America$_i$	1 if researcher i visited America; 0 otherwise
Germany$_i$	1 if researcher i visited Germany; 0 otherwise
Japan$_i$	1 if researcher i visited Japan; 0 otherwise
Britain$_i$	1 if researcher i visited Britain; 0 otherwise
other countries$_i$	1 if researcher i visited other countries; 0 otherwise

Results & Discussion



When "time series"=5, the researchers returned to China

Figure 1. Average international cooperation in the 5 years before and 5 years after returning

From the results of descriptive analysis, researchers' average ratios of international publications and partners had shown a similar trend. In the period of 5 years before the return, both of them had increased steadily from about 60% to about 80%. But during the 5 years after their return, they had dropped sharply to about 35% and 15% respectively.

Table 2. Results of two-way FE panel regression

Variables	international publications ratio	international partners ratio
length of time spent overseas$_{it}$	0.131***	0.140***
	(0.015)	(0.013)
number of overseas institutions$_{it}$	-0.103***	-0.102***
	(0.026)	(0.023)
age$_{it}$	-0.083***	-0.101***
	(0.009)	(0.008)
_cons	2.608***	3.113***
	(0.298)	(0.268)
N	2540	2540
r2	0.214	0.351

Standard errors in parentheses=
"*p < 0.05, ** p < 0.01, *** p < 0.001"
Note: All variables were taken into account in the model, but here we only presented the results of time-varying variables. And because our data included the 5 years before researchers' return, the length of overseas time varied over time before the return, so did the number of overseas institutions.

When other variables were controlled, length of overseas time and number of overseas institutions had opposite effects on international cooperation. An extra year in overseas boosted about 14% in both ratios of international publications and partners. However, the two ratios both decreased by about 10% for each additional overseas institution experience. Meanwhile, as the age increased by a year, international publications and partners ratios decreased by 8.3% and 10.1% respectively.

The results of RE model have confirmed our previous results of time length, institution number and age. Moreover, when other variables were controlled, postdoctoral experience could boost the two ratios by about 9%. But formal position did not show significant effect on them. As the research fields, only discipline_5 showed significantly better than discipline_1 in international cooperation. However, both the gender and countries visited had no significant effects. As for the negative impact of the number of overseas institutions, an additional robustness test was carried out. We controlled for the researchers' productivity and international network, then the results cleared that the negative impact of the number of overseas institutions on international cooperation still remained significant.

Table 3. Results of RE panel regression

Variables	international publications ratio	international partners ratio
length of time spent overseas$_{it}$	0.023***	0.029***
	(0.005)	(0.005)
number of overseas institutions$_{it}$	-0.055***	-0.066***
	(0.015)	(0.014)
postdoctor$_{i}$	0.082*	0.090**
	(0.036)	(0.033)
formal position$_{i}$	0.043	0.043
	(0.025)	(0.023)
age$_{it}$	-0.030***	-0.030***
	(0.005)	(0.005)
discipline_5$_{i}$	0.113**	0.075*
	(0.039)	(0.036)
_cons	1.380***	1.321***
	(0.161)	(0.148)
N	2540	2540

Standard errors in parentheses=
"*p < 0.05, ** p < 0.01, *** p < 0.001"
Note: To avoid collinearity of disciplines, we chose discipline_1 as reference variable. Due to space limit, Table 3 only showed the results of explanatory variables and some control variables which had significant influence.

Conclusion

To build better international cooperative relations, increasing the length of time spent abroad is desirable; however, frequent movement between different institutions is discouraged. As for the type of work, post-doctoral work is beneficial to international cooperation, but the effect of formal work is not significant. In addition, people tend to cooperate with people who are younger, regardless of their gender. And it makes no difference which country you choose to stay in.

This study provides evidence from China on the impact of international mobility on cooperation and can provide reference for researchers to make overseas work plan. Next, we will further improve this study by heckman two-stage method to solve the endogeneity problem caused by sample bias.

Research on international patent technology layout in high-speed railway field

Rongying Zhao[1], Ruru Chang[2], Xiaoyu Wang[3] and Zhaoyang Zhang[4]

Introduction

The development and mastery of railway technology provide a solid foundation for economic and social development. The patent layout is for targeted improvement of patent layout strategy. Therefore, itis particularly important to fully understand technological development and market competitive advantages from the overall impact of high-speed rail on the regional city economy. We observe the trend of patent distribution from three perspectives: vertical, horizontal and depth. Based on the comprehensive analysis of the patent technology layout in the field of high-speed rail, this paper further analyses the patent layout of the main competitors. A scientific patent measurement is proposed to accurately identify market gaps and major competitors. At the same time, by examining the development of technology competitiveness through patenting as undertaken to provide useful insights.

Data and Method

The 12,060 patents in this paper are obtained from the Derwent Innovations Index (DII) by subject search. One is technology classification, subject related to high-speed rail technology can be roughly divided into five categories as shown in Table 1. The other is special appellation in various countries, such as Train a Grande Vitesse (French), Alta Velocidad Española and talgo (Spanish), Korea Train Express (Korea), Acela Express (American), Inter City Expressand and Transrapid and Eurostar (German and European), ETR (Italian), High-Speed Line (Belgium), LRC (Canada), Shinkansen (Japan), Pendolino (British), ICN (Swiss), Sokol (Russian), Intercity Express and CRH and THSR (China) (Dang, 2016; Fumihiro Hasegawa et al., 2018).

Patent layout refers to the overall layout behaviour of the company's own patent situation. Patent layout, not only must always pay attention to the quantity, but also monopolize the technology market through patent portfolios, prevent competitors from attacking their own technical weaknesses, and avoid falling into infringement disputes. The layout content includes the total number of patent applications, the fields involved in the patent application, the region to which the patent application is applied, and the useful life of the patent application. It can be summarized as follows: the time, place, type and quantity of patents in general.

Table 1. The categories of high-speed rail technology patent terms

Categories	Terms	Results
High-speed train/train	bullet train; high-speed train; high-speed rail*; express railway	9,082
EMU	train-set; motor train set; rail motor car*; multiple-unit train	377
High-speed railway	rapid transit railway	244
Express train	Express train	93
Maglev train	maglev train; Magnetically Levitated Train; magnetic suspension train; JR-Maglev	982

Results and Discussion

Vertical analysis: the changes of patent applications

The global high-speed rail technology patent application trend can show the development history of high-speed rail technology to a certain extent. The patent application date is closer to the invention time of the patent. In this paper, the application date is used as the time basis for data statistics.

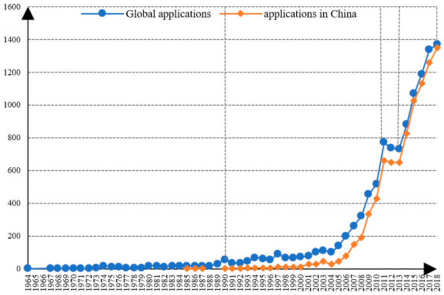

Figure 1. The annual change trend of patent applications for high-speed rail

It can be roughly divided into four stages: the initial period (1964-1990), the rising period (1991-2010), and the adjustment period (2011-2013), the rapid development period (2014 to present).

With the rapid development of computer technology, high-speed rail technology will face more changes and progress. At the same time, according to the development of high-speed rail technology, the closer global trade cooperation will promote the optimization and innovation of high-speed rail technology.

Horizontal analysis: patent sources and geographical distribution

By analysing the country of the patent applicant, the main technology source country in this technical field can be identified, and the patent layout of the high-speed rail patent market can be clarified, See Figure 2.

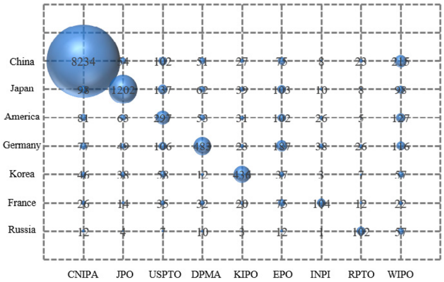

Figure 2. Patent sources and geographical distribution in the high-speed rail field

Most of countries are focusing more on the patent layout in their own countries. Especially for China, its domestic layout is much larger than its international layout. In overseas markets, China pays more attention to the United States and Europe.

In addition, other countries also pay more attention to the Chinese market and actively carry out patent layout. China is the third largest target country for Japan, the US and Germany besides themselves, and the second largest target country for South Korea and Russia's overseas deployment. The international distribution is much higher than that of most countries in Japan. It can be seen that Japan attaches great importance to the overseas patent technology market.

Depth analysis: major global patent technology companies

In order to more specifically understand the future development direction, it is necessary to further analyse the main patentees. Patent quantity and patent quality are two factors to measure competitive advantage. Patent quantity refers to patents held by patentees (enterprises) and patent quality is an index related to patent citation. We use average patent citation rate as a measure of patent quality. Taking the patent applications as the abscissa and the patents citation as the ordinate, and the larger the bubble, the larger the total number of patents cited, See Fig. 3.

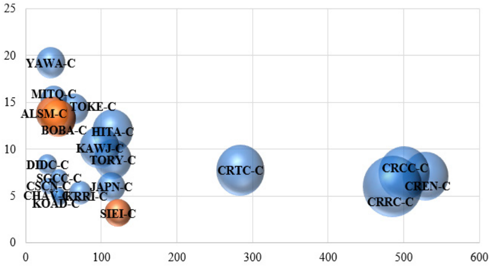

Figure 3. Bubble chart of top 20 enterprises in high-speed rail field

The Nippon Steel & Sumitomo Metal Corporation has highest average patents citation rate (19.21%). Most of these 20 enterprises are Asian enterprises, including seven Chinese enterprises, one Sino foreign joint venture and seven Japanese enterprises. As a big high-speed rail country, China has shown strong momentum in patent applications in the field of high-speed rail, and the number of patent applications is far ahead. However, in terms of patent quality, Chinese enterprises still need to improve.

Conclusions

This paper makes a macro analysis of the patented technology in the high-speed rail field from three dimensions: vertical, horizontal and depth. It is expected that patent applications in the high-speed rail field will continue to maintain a rapid growth trend in the future. Then, the awareness of international protection of patented technology needs to be improved from country to country, especially in China. Finally, patent quality can't be ignored, while enterprises keep the advantage of high patent output. Both countries and enterprises should reduce redundant patent applications and strengthen technological innovation to improve patent quality.

A Bipartite Author-algorithm Network for Exploring Versatile Scholars

Yi Zhao[1], Yuzhuo Wang[2] and Chengzhi Zhang[3]

{[1]yizhao93, [2]wangyz, [3]zhangcz}@njust.edu.cn
Nanjing University of Science and Technology, 200 Xiaolingwei Street, Nanjing 210094 (China)

Introduction

The need for particular skills is one of the factors that motivate scholars to find collaborators. However, it's difficult to know directly what fine-grained skills (e.g., algorithm) a scholar masters, but this kind of information is deeply embedded in scholars' publications, especially in the artificial intelligence domain. For example, if a researcher wants to use alternating directions dual decomposition (AD^3) algorithm to address a natural language processing (NLP) problem, he/she may want to know the following information: Which researchers are studying the AD^3 algorithm, and with whom could the researcher collaborate? Even researchers who study AD^3 prefer to publish solo-authored publications; code sharing is ubiquitous in the computer science field, and we can also reproduce their algorithm via the codes they provided in their paper. Therefore, it is essential to build a connection between the authors and the algorithms, and the network can help researchers find suitable collaborators who master particular algorithms. In this paper, we briefly 1) construct a bipartite author-algorithm network and 2) explore the scholars with the most diverse skills (i.e., *versatile scholars*) in the NLP domain, versatile scholars are those who mentioned a variety of algorithms in their papers.

Methodology

Dataset

Our dataset consists of two parts: algorithm entities and author information. For the algorithm entities, we used the in-house dataset annotated by Wang and Zhang (2020). To obtain author information, we first downloaded and parsed the paper title, author name, paper ID, publication year from the dataset (https://github.com/lingo-iitgn/NLPExplorer), which was built using the data provided in the ACL Anthology (https://www.aclweb.org/anthology/). Then, we extracted authors' affiliations, affiliation locations from each paper manually. Finally, we integrated the two parts through paper IDs provided by the ACL Anthology. Moreover, the ACL Anthology volunteer team has used multiple approaches to address name ambiguities (Mohammad, 2020).

Method

Bipartite network is a graph on a node set which represents two different types of entities and relational ties occur only between nodes of different types. A bipartite network is represented as follows:

$$\mathrm{G} = (\mathrm{U}, \mathrm{V}, \mathrm{E}) \qquad (1)$$

Where U and V are two types of nodes in network G. U and V denote the authors and algorithms respectively. E is the set of edges in G.

The indicator of *effective partners* (EPs) was used to explore most versatile scholars (Bersier et al. 2002). In formulae:

$$H_j = -\sum_{i=1}^{s} \frac{a_{ij}}{a_{\cdot j}} log_2 \frac{a_{ij}}{a_{\cdot j}} \qquad (2)$$

$$EPs_j = \begin{cases} 2^{H_j} \\ 0, if\ a_{\cdot j} = 0 \end{cases} \qquad (3)$$

Where a_{ij} is the number of co-occurrences between author j and algorithm i, $a_{\cdot j}$ is the total number of co-occurrences between author j and all algorithms. Eps_j is the effective number of algorithms mentioned by author j.

Results

Statistics of Dataset

Table 1. presents the basic statistical description of our dataset. 891 types of algorithm entities are extracted from ACL papers, and 5,619 authors published ACL papers between 1979 and 2015.

Table 1. Statistics of the dataset

	author	affiliation	country	algorithm
total	12,142	12,711	12,711	59,277
unique	5,619	1,034	65	891

The bipartite network of authors and algorithm entities in the NLP domain

We choose eight as the threshold of the minimum number of author-algorithm co-occurrences to generate better visualization. Fig.1 displays the bipartite network. The author node is red, and the algorithm node is blue. A link between the author and the algorithm exists if the author has published a paper that mentioned the algorithm. The thickness of the link represents the number of papers an author published that mentioned an algorithm. The size of the node denotes the number of papers an author published (red) or the number of papers published that mentioned an algorithm (blue).

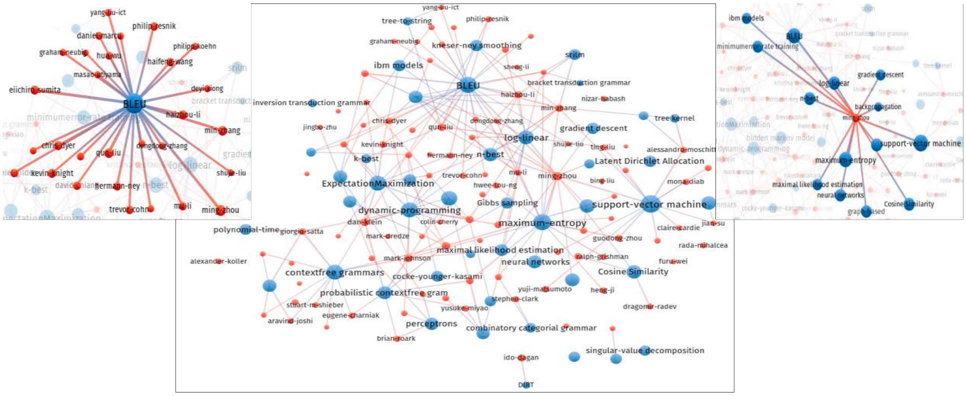

Figure 1. Bipartite network of authors and algorithm entities (tool: VOSviewer)

As Fig.1 shows, support vector machine, BLEU and maximum entropy are widely mentioned by authors. In addition, almost all the blue nodes are much larger than the red nodes. 4.52 types of algorithms are mentioned per paper, whereas the average number of publications per author is 2.14. BLEU is widely used for the evaluation of the results of machine translation, it was mentioned by 29 authors (Fig.1, upper left). For Ming Zhou, a famous NLP scholar, 117 types of algorithms are extracted from his papers (Only those with frequency over 8 are shown in Fig.1, upper right). According to our statistics, BLEU (proposed by Papineni, etc.) and maximum-entropy (proposed by Jaynes) are his two most mentioned algorithms, spanning 17 and 15 papers, respectively, and it may suggest that he is adept at using these two algorithms. Additionally, machine translation is perhaps one of his research interests.

The most versatile scholars in the NLP domain

We calculated the EPs and explored who is the most versatile scholar in the NLP domain, as shown in Table 2.

Table 2. The top-5 versatile scholars

Author	EPs	Affiliation	Location
Christopher Manning	83.34	Stanford University	USA
Ming Zhou	77.76	Microsoft Research Asia	China
Noah Smith	76.96	University of Washington	USA
Daniel Klein	75.54	University of California at Berkeley	USA
Chris Dyer	65.03	Carnegie Mellon University	USA

Eps provides interesting rankings for authors who have mentioned or even used a variety of algorithms in their papers. Most of the top-5 versatile scholars are influential scholars in the NLP domain: ACL Fellows (i.e., Christopher Manning, Noah Smith), ACL president (i.e., Ming Zhou). Four of the five authors are affiliated with elite universities in the USA, while Ming Zhou is affiliated with an excellent firm that is located in China. It may indicate that in terms of algorithm usage, American scholars still dominate the NLP community.

Conclusion

This paper is intended to build a bipartite author-algorithm network to facilitate the development of applications, such as finding collaborators, exploring scholar's algorithm usage. The author-algorithm network displays that each author has mentioned what types of algorithms in their papers. Moreover, we found that 4 of the 5 versatile scholars are from the US. Given that whether the algorithm is truly used by the author has not been considered, more types of models should be used to classify the algorithm citation functions. The validity of the author-algorithm network to facilitate the scientific collaboration will be demonstrated in the future.

Citation Time Entity Recognition Based on Deep Learning

Yufei Zhu[1], Si Shen[2] and Dongbo Wang[3]

{[1] zhuyufei, [2] shensi}@njust.edu.cn
Nanjing University of Science and Technology (China)

[3] db.wang@njau.edu.cn

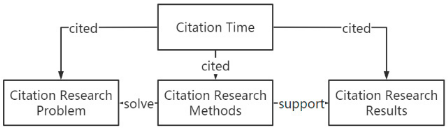
Introduction

With the increasing enrichment of academic resources, some scholars have been beginning to study how to improve the utilization rate of academic resources, such as mining the content of academic full text. Academic full text contains a lot of important academic resource information. Extracting the key points in academic full text by means of entity annotation and recognition can facilitate further analysis and research of text content. For example, building an academic resources network by the creation of knowledge mapping technology. These work make the visualization of academic information, the integration of academic resources, easy to retrieve and query, and improve the efficiency of academic resources.

Some scholars have proposed the concepts of publication year, date entity when constructing the ontology of scientific papers, but most of them explore the time association between papers from the perspective of papers, rather than focusing on the content of academic full text. This paper analyses the citation content in the academic full text at the median level, and the concept of citation time entity is proposed. Citation time is the time when the citation is published in the academic full text. The citation time has been listed in the references of the journal, but only the author, institution and literature name are listed together with it. If the citation time is annotated and extracted in the full text, the cited content can be annotated and extracted at the same time. The cited contents include the research problems, research methods and results of citations. When the citation time is marked and associated with the quoted content, we can build a dynamic topic model and other technologies by considering the time factor to analyse the research trends, research topics, citation authors' writing trends, and the changes of tools and models used in the research in recent years, so as to further tap the resources in the academic full text. The logical framework of association between citation time and cited content in academic full text is shown in Figure 1.



Citation Time
cited
cited
cited
Citation Research Problem

Citation Research Methods
support
Citation Research Results

Figure 1. The citation time is associated to the quoted content.

In this paper, scientific literature published in JASIST journals in recent three years is selected for the citation entity tagging experiment by using the method of sequence tagging of CRF and BERT models. The experiment of named entity recognition of citation time is carried out from academic full text.

Data Sets and Methods

This paper selects 502 papers published in JASIST journals from 2017 to 2020, and finds examples of citation time in the literature, and then unifies the labelling specification. The entity introduction and examples are shown in Table 1.

Table 1. Introduction of citation time entity.

Name	Introduction	Example 1	Example 2
Citation time	The publication time of citations in academic full text.	In **2003** {ref[#asi 22654-bib-0024]} , Jansen and Spin.	By **1994** the confusion within the field had already.

After that, we selected 15 taggers to annotate the citation time entities on the BRAT platform, and the results are shown in Table 2. In this experiment, a total of 3876 citations were annotated, of which 3873 were 1 in length, that is, most of the citations were in a single year, such as 2016, 2017, etc.

Table 2. Statistics of entity annotation.

No.	Introduction	Count
1	Paper	502
2	Citation time entity	3876
3	Average citation time entity	7.72
4	Citation time entity of length 1	3873
5	Citation time entities with length greater than 1	3

We find that there are few types of citation time entities, that is, most of them are specific years in the past 20 years. The frequency statistics of each year is shown in Figure 2.

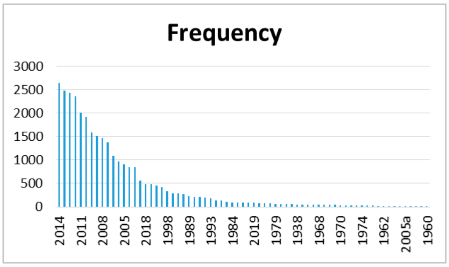

Figure 2. Statistics of citation time frequency distribution.

Conditional random fields (CRF) was first proposed for sequence data analysis, and has been successfully applied to named entity recognition in natural language processing. In this paper, CRF + + is used to recognize the named entity of citation time.

BERT is a very powerful model in NLP field, and can be used to solve the problem of sequence annotation. In this paper, we use BERT to do named entity recognition experiments on citation time entities.

SCIBERT is a BERT model trained in scientific writing. It has its own vocabulary (SCIVACAB), which is most suitable for training corpus.

Results

When we using the CRF + +, the hyper parameter is set to 10.0, and the threshold of training feature is set to 10. In the training of BERT model, a training model with 12 layers, 768 hidden units and 12 self attention heads are selected. The crossing data set is set up to be trained for 6 times by the BERT model. Finally, the data set is trained by SCIBERT once.

The evaluation effect of the model is shown in Table 3.

Table 3. Evaluation of model effect.

Model	Accuracy	Precision	Recall	F1
CRF	0.9981	0.8652	0.9555	0.9082
BERT-1	0.9996	0.9861	0.9775	0.9818
BERT-2	0.9997	0.9889	0.9816	0.9853
BERT-3	0.9997	0.9909	0.9788	0.9848
BERT-4	0.9998	0.9883	0.9922	0.9902
BERT-5	0.9997	0.9925	0.9771	0.9847
BERT-6	0.9996	0.9768	0.9880	0.9824
SCIBERT	0.9996	0.9739	0.9713	0.9726
MIN	0.9981	0.8652	0.9555	0.9082
MAX	0.9998	0.9909	0.9922	0.9902

From the experimental results, it can be seen that the effect of the three models for named entity recognition is good, and the evaluation effect of BERT model is the best, which can achieve the accuracy of 0.9998. The evaluation effect of CRF is the worst, its evaluation values are all the lowest among the four indexes in this experiments. The evaluation effect of SCIBERT is between two other models, but there is little different from BERT. The citation time entities in the content of academic papers are easy to train because they are relatively standardized, most of them are the specific years with length of 1, and there are few categories of citation time entities. It can be seen that citation time is suitable for automatic and semi-automatic entity annotation on large-scale corpus.

Conclusion

This paper puts forward the concept of citation time entity, which is often associated with citation problems, citation research methods, citation results and other content. We can use time topic model and other technologies to analyse the changes of academic content in recent years, such as research trends, research topics, tools and models used in research, so as to fully tap the resources in academic full text. This paper also marks the citation time of 502 scientific papers published in JASIST in recent four years. We found that the citation time format of academic papers is very standardized, most of them are individual years. Then we use the CRF and BERT models to do named entity recognition experiments on annotated corpus, and evaluate the experimental results. The experimental results show that the effect of citation time on entity recognition is better, and it is concluded that citation time is very suitable for automatic and semi-automatic entity annotation in large-scale corpus. In the future research, we can do further research on the reference resolution of citation time, or on the topic evolution of time factors by integrating citation research problems, citation research methods and citation authors.
