The two-scholar model shows that increasing the funding beyond a certain threshold has a counter-intuitive effect of decreasing the funding efficiency. This is because increasing funding leads the lower quality scholar to also apply, which incurs a cost, but does not entail additional benefits.

Efficiency in the n scholar unlimited grant model

Without considering the distribution of scholars' quality, there are 6 free parameters. Following the previous sections, we set $k = 1$, $c_0 = 1$, and $l = 1$.

We use a non-random, fixed-interval uniform distribution $q_{min} \le q_i \le q_{max}$ for some exploration work, the quality of scholar i is always $q_{min} + \frac{i-1}{q_{max}-q_{min}}$. Subsequently, we use a beta distribution to be more flexible while being compatible with the analytical solution in (Lai, 2021). We use the notation $q_i \sim \mathrm{Beta}(\alpha, \beta)$ to indicate that q_i follows a beta distribution.

We first attempt to reproduce the three phases that we observed in the two-scholar model. We set the number of scholars in the model to $n = 2,6,20,50$ and the number of grants to $m = 1$. We also assume that the scholars' qualities follow a fixed-interval uniform distribution with a minimum of 0.3 and maximum of 0.7, making the $n = 2$ case identical to the two-scholar model. We simulate the model and compute the efficiency. Fig. 4 shows that this model indeed reproduces a similar pattern as the two-scholar model. While the patterns are similar, we can see that the exact Nash equilibria are not reached in the simulations so that the patterns are not exactly the same. The efficiency decreases when we increase the scholars since the competition is higher and the total available resource remains unchanged.

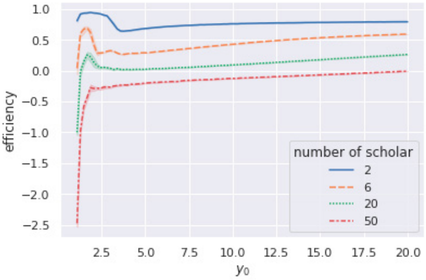

Figure 4. The efficiency of the n scholar unlimited grant model as a function of the amount of funding y_0, with $n = 2,6,20,50$, scholars' qualities follow uniform distribution.

We now explore the model further with $n = 100$ scholars, with beta distributed qualities. Fig. 5 shows the plot of the efficiency as a function of y_0 for $q_i \sim \mathrm{Beta}(2,2)$. The results show that having a higher k (more accurate assessment of scholars' quality) is clearly beneficial, while having a negative l does not necessarily improve the efficiency. The results also depend on the distribution of scholars' qualities. Fig. 6 shows results with $q_i \sim Beta(10,2)$, which means the qualities of scholars are in general higher. Interestingly, the efficiency is not higher than when using $q_i \sim Beta(2{,}2)$,g . This suggests that having more high-quality scholars does not necessarily imply a higher efficiency since the competition is also tougher.

In every simulation, there is a steep increase in efficiency when y_0 is small. It is because better scholars are easier to have higher payoffs when choosing to apply and they are more likely to apply, thus discouraging lower-quality scholars to apply. For some parameter settings, there is a peak in the efficiency curve, similar to the three phases we observed in the two-scholars model, but this does not happen for all parameter settings.

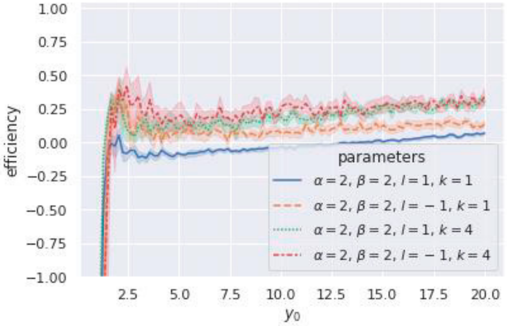

Figure 5. The efficiency of the $n = 100$ scholar unlimited grant model as a function of the amount of funding y_0, scholars' qualities follow the beta distribution with $\alpha = 2$ and $\beta = 2$.

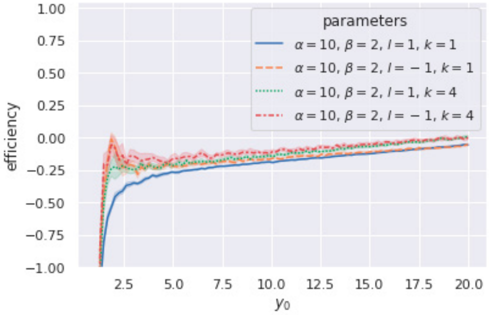

Figure 6. The efficiency of the $n = 100$ scholar unlimited grant model as a function of the amount of funding y_0, scholars' qualities follow the beta distribution with $\alpha = 10$ and $\beta = 2$.

Efficiency in the n *scholar one grant per scholar model*

Similar to the unlimited grant model, excluding the parameters about the quality distribution, there are 6 free parameters. We take $k = 1$, $c_0 = 1$, $l = 1$ as the starting case. Fig. 7 shows the efficiency curve with $n = 2{,}6{,}20{,}50$ and $m = 1$. We can observe the 3-phase feature for $n = 2$, while for larger n ($n = 20$, $n = 50$) the peak disappears. While it is possible that this is the nature of the model, insufficient steps in the simulations may also cause this observation since the algorithm here needs more time steps to converge to equilibria comparing to the algorithm used in the unlimited grant model. Due to the limitation of computational power, we leave this for future studies.

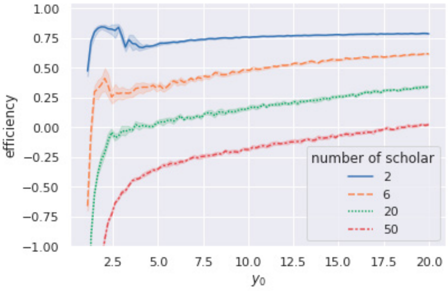

Figure 7. The efficiency of the $n = 2,6,20,50$ scholar one grant per scholar model as a function of the amount of funding y_0, scholars' qualities follow uniform distribution.

To investigate how different parameter settings in the model affect the efficiency, we run simulations with $n = 100$ scholars and beta distributed scholars' qualities. Unlike the unlimited grant model, the number of funding m is a meaningful variable in this model which is not degenerate with y_0. However, in our exploratory simulations, we don't observe any effects of increasing m besides having a higher overall efficiency, which is similar to the effect of increasing y_0. We therefore fix $m = 20$ such that at most 20 scholars receive funding. Fig. 8 shows the efficiency curves with $l = 1 \ or - 1, k = 1 \ or \ 4, \alpha = 2 \ and \ \beta = 2$. Fig. 9 shows a similar result but with $\alpha = 10$. Despite the rapid increase in the efficiency when y_0 is small, there is no 3-phase we observed in some of the earlier plots. We again observe that increasing k seems to increase the efficiency while the effect of varying l is less clear. In contrast to the result in the unlimited grant model, where $\alpha = 2$ simulations are having a much higher efficiencies than that in the unlimited grant model, the efficiencies for $\alpha = 2$ and $\alpha = 10$ are closer in this model.

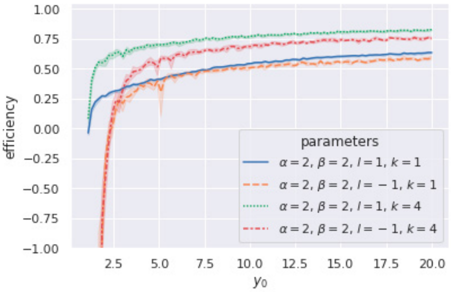

Figure 8. The efficiency of the $n = 100$ scholar one grant per scholar model as a function of the amount of funding y_0, scholars' qualities follow the beta distribution with $\alpha = 2$ and $\beta = 2$.

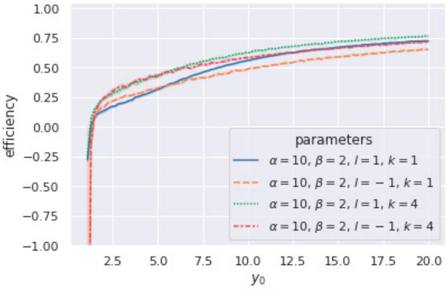

Figure 9. The efficiency of the $n = 100$ scholar one grant per scholar model as a function of the amount of funding y_0, scholars' qualities follow the beta distribution with $\alpha = 10$ and $\beta = 2$.

Discussion

We presented three different simple model of funding in science. Although are models are highly stylized, the results may still provide some insight. We here summarize our understanding of the results, and we discuss future research questions and improvements to the models.

Regardless of the model, if the amount of funding is very large, the efficiency almost always approaches 1. This is easy to see because the costs remain fixed, becoming negligible in the limit of large amounts of funding. On the other hand, in many of the scenarios, we are able to identify three distinct phases, that showed distinct dynamics. The first phase is characterised by both low and high quality scholars not having a dominant strategy. When increasing the funding, this transition towards the second phase, where only high quality scholars apply for a grant, leading to a highly efficient funding system. Increasing the funding further, transitions the system towards a third phase, where lower quality scholars again also start to apply for a grant, thereby decreasing the efficiency of the funding system. In scenarios where we cannot discern these three phases, we still observe a steep initial rise in efficiency when increasing funding, which levels off for further increases in funding. This suggest that increasing the amount of funding in the system may yield only modest increases in efficiency.

In all settings considered in this study, having a larger accuracy of peer review seems to help to increase efficiency. That is, if peer review is better able to identify high quality scholars, this increases efficiency. In contrast, how the cost of applying scales with a scholar's quality, seems to have less clear consequences for efficiency. Our results suggest that it would be beneficial to improve the review process of funding application, while (re)-designing the application procedure to modify the cost is less relevant. Of course, the accuracy of peer review may be something that is inherently limited.

In our results, we find that some high-quality scholars are needed in order to achieve an efficient funding system. However, too many high-quality scholars may create unnecessary competition and may reduce the efficiency. Moreover, the quality of a scholar cannot simply be modeled as a single dimensional variable. Quality may multi-faceted with dimensions such as creativity, novelty, or rigour. A more realistic model may also include such alternative dimensions of quality.

The funding allocation itself also affects efficiency. When allowing researchers to accumulate unlimited grants, we see that the efficiency is substantially lower than in grant models in which each scholar can receive only a single grant. In reality, the number of grant that a scholar can apply is limited. Having a clever design of the number and the size of grants available to different scholars can help improving the efficiency.

There are several limitations to our models. Firstly, the cost can depend on the amount of funding. It is natural that scholars spend more effort on preparing for a larger grant than for a smaller one. Although we capture this behaviour in the isolated scholar model, we ignored it later to simplify the models. Secondly, the payoff of receiving funding does not necessarily translate immediately to the amount of funding that is received. The interpretation of y_0 as the funding amount can therefore be discussed. Thirdly, it may be argued that the total amount of funding is simply a given, and that it cannot be changed. However, it is possible that the amount of funding for one funding scheme is increased, while other types of funding are decreased. Despite some unrealistic factors, we think our observations highlight what might be possible when we change the amount of available funding.

Abstract

Modern natural language processing techniques have given rise to embedding techniques that can represent documents based on their content or context, and several papers have operationalized these to perform bibliometric tasks. The relationship between these embeddings and conventional citation based or title and abstract based mappings remains unclear. Contrary to citation-based or term-based relatedness, embedding-based relatedness is not immediately interpretable. We consider four embedding-derived publication relatedness measures, based on: 1) word2vec embeddings of citation labels, sentence embeddings using 2) BERT and 3) SciBERT, and 4) title and abstract embeddings using SPECTER, and compare them with conventional bibliometric publication relatedness measures derived from citation relations and title and abstract noun phrases. We show that there is stronger overlap between these embedding-derived relatedness measures and citation-based relatedness than with title and abstract noun phrase-based relatedness, and that embedding-derived relatedness measures outperform conventional techniques when used to cluster publications cited with the same citation intent.

Introduction

The notion of relatedness of scientific publications is at the heart of many open problems in bibliometrics. Publication clustering and mapping techniques rely on publication-to-publication relatedness measures, conventionally based on citation relations, textual similarities of titles and abstracts, or occasionally combinations of these. It should come as no surprise that different relatedness measures produce different results (Gläser et al., 2017), which makes the informed choice of appropriate relatedness measures an imperative aspect of many bibliometric research tasks.

Meanwhile, advances in natural language processing (NLP) and information retrieval have introduced a host of new text-based methods for establishing relatedness of not only documents to one another, but also documents to terms in the vocabulary of these documents. The introduction of word2vec (Mikolov, Chen, et al., 2013; Mikolov, Sutskever, et al., 2013) marked a substantial advance, allowing vector representations of words to be learned that not only allow for easy computation of semantic similarities, but also preserve—to some extent—the semantic and syntactic relationships between terms. Doc2vec (Le & Mikolov, 2014) adapted this method, allowing for the generation of similar vector representations for larger bodies of text. Further advances in the field since then such as the emergence of large pre-trained language models like BERT (Devlin et al., 2018) have only expanded the suite of options for establishing relatedness between documents.

The case for using NLP techniques in science mapping and clustering is compelling. At their core lies the distributional hypothesis, the assertion that terms with similar distributions have similar meaning, i.e., similar terms are used in similar context. What is citation, if not the deliberate act of putting previous work in the context of a new author's design? Hence, papers that are cited in similar context, or that introduce similar language, can be assumed to be related to each other, and embedding techniques can capture this relatedness. Another important benefit of these embedding methods is that publications can be embedded along with terms, allowing researchers to learn relationships between embedded literature and concepts in the vocabulary, directly from the data.

Several recent publications have leveraged these new NLP techniques to explore new ways of representing publications, visualize research landscapes, and facilitate document search and retrieval. Approaches range from representing documents using the text in their abstracts (e.g. Hain et al., 2020) to embeddings derived from citation context (e.g. Berger et al., 2017; He & Chen, 2018), and a number of studies have explored combining text-based approaches with citation-based approaches (e.g. Cohan et al., 2020; Ganguly & Pudi, 2017). However, while many of these papers find that their representations of scientific literature capture useful and relevant aspects of publication context, topic, purpose, or overall relatedness, and often outperform traditional techniques in specific tests selected by the authors, embedding-derived relatedness measures remain difficult to interpret, and their resulting vector representations of papers are essentially black boxes. The nature of the resulting relatedness measures is difficult to compare to traditional bibliometric techniques, and this ambiguity makes the use of these new embedding techniques in science mapping and publication clustering less attractive.

Our research aims to compare a set of common NLP-based publication representations and their resulting relatedness measures with traditional citation-based and abstract-based publication relatedness measures. We follow the methodology introduced by Waltman et al. (2020), allowing us to compare the accuracy of clustering results obtained using various publication relatedness measures based on a selected baseline relatedness measure. We compare four methods for generating publication embeddings with two established bibliometric relatedness measures, one based on publication titles and abstracts, and one based on citations, in two data sets. Our goal is to establish whether embedding-derived publication relatedness measures more strongly resemble established text-based relatedness measures or citation-based relatedness measures.

Methods

Our first data set is selected from the Elsevier ScienceDirect corpus previously analyzed in detail by Boyack et al. (2018). We select scientometrics-related publications using the meso-level of the CWTS hierarchical publication classification system (Waltman & van Eck, 2012). This produced a total of 7825 publications, that are cited in 51003 full-text sentences (not limited to the scientometrics field). 3169 of these publications feature in at least five citing sentences, for a total of 44464 citing sentences. If a sentence features multiple citations, only the first citation is considered, to avoid associating the exact same context with multiple works.

The second dataset is the SciCite citation intent dataset introduced by Cohan et al. (2019). This consists of 6427 publications and 10817 sentences citing these publications, as well as annotated citation intent labels noting whether a citing sentence cites a paper as *background*, for its *methods*, or to compare *results*. Titles and abstracts of these publications, as well as publications cited by or citing them, were retrieved using the Semantic Scholar API.

Word2vec

Our first embedding-derived relatedness measure is a simple word2vec embedding of citation labels. In each citing sentence, the label referencing the cited publication is replaced with a token unique to the cited work, and a word2vec embedding is trained on the resulting corpus using the *gensim* python library (Rehurek & Sojka, 2010). For a schematic representation, see figure 1. Relatedness of publications is calculated as the cosine similarities of the unique publication tokens. The word2vec architecture has a few adjustable hyperparameters. We varied the embedding size, window size, epochs, and negative sample size, and tried both the CBOW and skip-gram methods. Skip-gram with a window size encompassing the entire sentence, keeping other parameters set to their default values, produced the most stable publication-to-publication similarities over multiple model runs.

Figure 1: example of word2vec embedding of citation labels, window size three.

Sentence-BERT

Entire sentences can be embedded using Sentence-BERT (Reimers & Gurevych, 2019). Averaging the embeddings of sentences that cite the same paper then offers us another way to generate representations for cited publications based on their citation context. In this procedure, we again associated sentences only with the first cited publication, and omitted citation labels entirely from the sentence. Since the Sentence-BERT architecture can use a variety of language models, we repeated this process twice, once using the original BERT base model (Devlin et al., 2018), and once using the SciBERT model (Beltagy et al., 2019) which was trained specifically on scientific text.

SPECTER

Our final embedding-based relatedness measure uses SPECTER (Cohan et al., 2020) to generate publication representations based on titles and abstracts alone. SPECTER's core feature is that it generates document-level representations using only titles and abstracts, in a manner informed by pre-training on a citation graph. This allows it to outperform other architectures that rely solely on title and abstract information in a variety of performance benchmarks such as citation prediction and topic classification (Cohan et al., 2020).

Conventional relatedness measures and comparison

Waltman et al. (2020) introduce a methodology for comparing publication relatedness measures based on the accuracy of clustering solutions, compared to a baseline relatedness measure. Following their work, we use the BM25 text similarity measure based on title and abstract noun phrases, and the combined direct citation, bibliographic coupling and co-citation (DC-BC-CC) relatedness measure, to represent baseline text-based and citation-based relatedness measures, respectively. All relatedness measures are also simplified and normalized, fist by keeping only the 20 most strongly related connections for each document, and subsequently normalizing their weights by dividing the relatedness of each outgoing edge by the total weight of outgoing edges for each node.

Waltman et al. (2020) then define the accuracy of a clustering solution based on relatedness measure X, evaluated against measure C, as

$$A^{X|C} = \frac{1}{N}\sum\nolimits_{ij}(c_i^X = c_j^X)r_{ij}^C$$

where $\left(c_i^X = c_j^X\right)$ equals 1 if the clustering c of document i is the same as that of document j, and 0 otherwise, with r_{ij}^C the relatedness between documents i and j per measure C. The normalization of the relatedness measures constrains this accuracy score between 0 and 1. Accuracy is computed for a variety of clustering solutions obtained using the Leiden algorithm (Traag et al., 2019), using a range of clustering resolution parameters, and the obtained accuracy is then plotted against the granularity of the resulting clustering solution in a granularity-accuracy plot, allowing us to easily compare the clustering accuracy of relatedness measures over a range of resolutions.

Results

Figure 2a displays the accuracy of the clustering solutions resulting from the various relatedness measures, using the BM25 title and abstract based relatedness as a baseline, over different clustering granularities. This analysis is limited to only the 2979 publications that are connected by relatedness in each of the six networks. Figure 2b uses the DC-BC-CC citation relatedness baseline, while 2c and 2d use word2vec and SPECTER-derived relatedness instead.

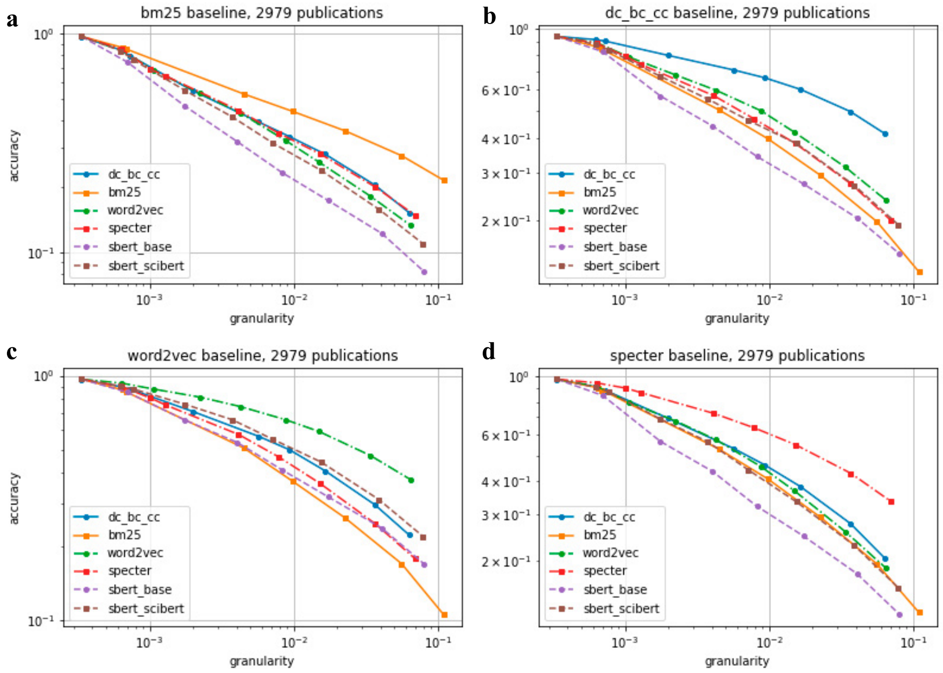

Figure 2: granularity-accuracy plots, scientometrics data set.

Figure 2c shows us that, in our scientometrics data set, the word2vec embedding derived from citing context resembles the citation-based relatedness measures more strongly than it does the title and abstract text-based relatedness measure. This is perhaps surprising, as it is fundamentally text-based, though this text originates from sentences that cite, which would explain the similarities to citation relatedness patterns. More surprising, figure 2d shows that the SPECTER-embeddings, despite being based on the same title and abstract text as the BM25 relatedness, behave more like the DC-BC-CC citation relatedness. Indeed, figure 2a shows that SPECTER and DC-BC-CC are approximately equally accurate when compared directly against the BM25 relatedness. Finally, figure 2b shows that word2vec, SPECTER and the SciBERT-based sentence embedding more closely resemble citation relatedness than BM25, which was previously found to be the best-performing title and abstract relatedness measure, at least in our sample in which publications with 5 or more in-text citations are considered. When also including publications with fewer than 5 in-text citations (not pictured), SPECTER and BM25 are the most similar to DC-BC-CC, followed by word2vec and SciBERT sentence embedding.

The SciCite dataset, moreover, contains not only citation context for each publication, but is hand-labeled with citation intent. These labels (*background*, *methods*, and *results*) make for a poor relatedness measure but can be assessed at the cluster level. We can express the diversity of these labels over the clusters using Rao-Stirling diversity (see e.g. Leydesdorff et al., 2019)

$$\Delta = \sum_{i,j} d_{ij}(p_i p_j)$$

in which d_{ij} is a distance measure between clusters i and j, and p_i is the proportion of nodes in cluster i. To compute a distance measure, we take the numbers of citing sentences labeled *background*, *methods* and *results* in each cluster as a three-length vector and take the cosine distance of these vectors between each cluster pair. This means that diversity is maximized if publications cited with the same intent are clustered together. We vary the clustering resolution and plot the resulting diversity of SciCite intent labels against cluster granularity in Figure 3.

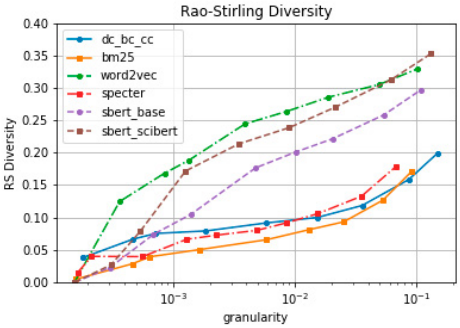

Figure 3: diversity-granularity plot of citation intent labels, SciCite dataset.

Figure 3 shows us that, with some margin, the citation context derived embeddings outperform the conventional relatedness measures, and that SPECTER improves only marginally over BM25 when it comes to clustering citation intent. Even BERT base, while lagging in figure 2, improves markedly on the conventional relatedness measures.

Discussion

Our research shows that embedding representations of publications have the potential to resemble conventional citation-based relatedness structures more accurately than the best-available conventional title and abstract-based relatedness measure. This holds true even for a simple word2vec embedding, provided enough citation context is available. Context-based embeddings also show a stronger correlation to citation intent labels in the SciCite data set than conventional citation-based or abstract-based relatedness measures.

It must be noted that the embedding-based relatedness measures used in this research might be further explored and optimized for the task of establishing publication relatedness. Especially BERT-based representations are typically fine-tuned for downstream tasks. Nevertheless, our research demonstrates the base feasibility of using embedding representations of publications and provides important insight into how they relate to traditional publication relatedness measures.

Abstract

Several studies have found that mentions of research articles in public media can have substantial effects on the articles' later citation counts and altmetrics. However, little attention so far went into investigating the potential relationship between qualitative properties of press texts that promote research and the research's impact. In this research in progress, we set out to manually analyze and compare the press releases published on *EurekAlert!* to promote a sample of 120 research articles, 60 of which later performed remarkably well concerning selected article-level metrics, while the remaining 60 articles later performed comparatively poorly. As a preliminary result, qualitative differences could be found regarding the press releases' structure, linguistic accessibility and the existence of narratives. First applications of our in-development codebook suggest associations between press releases with poor structure or accessibility and promoted research articles' metrics performance. We conclude with indications towards numerous promising paths for continuations of this study.

Introduction: Motivation and Related Work

In surveys on researchers' perceptions of bibliometric and altmetric indicators, a frequently encountered suspicion is that they might primarily capture visibility or curiosity, and therefore often ultimately the amount of effort made to advertise respective publications (Lemke et al., 2019; Nicholas et al., 2020). Besides efforts of *internal* science communication (i.e., communication primarily targeting other researchers, like for instance a presentation at an academic conference), this also includes the promotion research receives in channels of *external* science communication, e.g., by being featured in newspapers, podcasts, or television. Various studies analyzed the relationship between research publications' media visibility around the time of their publication and their later metrics, most often focusing on citation counts. For instance, several studies found newspaper coverage to be associated with substantially higher later citation rates for featured research articles (Phillips et al., 1991; Kiernan, 2003; Fanelli, 2013). Similarly, Chapman, Nguyen & White (2007) examined the association between articles published in the journal *Tobacco Control* receiving promotion in press releases and their later citations and usage metrics, finding the articles with accompanying press releases to be more likely to get cited, as well as to receive more downloads and web hits than similar articles without press releases. Lemke (2020) compared the citations and five prevalent altmetrics of a treatment group of 10,483 journal articles that were featured in press releases in 2016 to those of a similarly structured control group without known press release promotion, finding the treatment group to perform substantially better regarding all six examined indicators.

So while several previous studies revealed correlations between presence in different formats of external science communication and respective research articles' later metrics, it remains uncertain which processes and causalities explain these findings. Phillips et al. (1991) propose two hypotheses, the 'publicity hypothesis' and the 'earmark hypothesis'. The publicity hypothesis argues that it is the increase of visibility achieved by press release- or newspaper coverage that leads to more potential citers reading the featured articles and therefore increases their likelihood of receiving citations. The earmark hypothesis on the other hand suggests that the journalists selecting publications to cover and the researchers selecting publications to cite just independently of each other arrive at similar judgments regarding which literature suits their needs best. The citation advantage of a publication featured in mainstream media would therefore be the result of its own quality and not depend on the increased visibility. The results by Phillips et al. (1991) themselves provide a strong argument for the publicity hypothesis, as they found research articles featured in issues of the *New York Times* that had not been distributed due to a strike to receive considerably less citations than research articles featured in regular issues of the *New York Times*. However, the effects proposed by publicity hypothesis and earmark hypothesis are not necessarily mutually exclusive.

Despite the substantial number of studies evidencing an association between research articles' coverage in external science communication and later metrics, the 'hows' and 'whys' behind this association remain mostly unanswered. One reason for this could be most past studies' focus on purely quantitative relationships between mentions in external science communication and later citations, which typically regarded an article receiving press promotion as a numerical value or even as a binary event (i.e., without differentiation between promoting material's qualities). Potential structural or content-related properties of the actual press texts that promoted different articles on the other hand were mostly neglected so far.

This research in progress aims to address this gap through the qualitative analysis of press releases promoting research articles. By retrospectively analyzing press releases issued for journal articles that later received particularly high metrics and comparing these to press releases for journal articles published around the same time that later received comparatively low metrics, we aim to examine whether qualitative differences between the two groups of press releases are distinguishable. Our endeavor is guided by the hypothesis that PR activities, such as press releases, and press coverage can substantially affect research's overall impact, and that examining qualitative properties of said PR's and press coverage's individual instances could lead to a better understanding of the circumstances under which this is the case. As this article describes a study that is still in progress, its main purposes are twofold: (1) it intends to shed light on promising avenues for further research on the subject (and more specifically outline subsequent steps our own research will take), and (2) it shall give first insights into noteworthy observations we made during the manual coding of press releases to scholarly articles so far.

Within the framework of the news value theory, a substantial body of research already discussed the question which factors increase the likelihood for a topic to receive coverage in public media (see Badenschier and Wormer (2012) for a brief review of such works, as well as for a model explaining news factors for the particular case of science topics). Such factors (e.g., a topic's range, actuality, or surprise factor) explain why certain topics and therefore research articles might be selected for press releases in the first place. To complement this existing research, our main focus is on further properties of the press releases that should be largely independent of the promoted research's topic. In particular, we investigate whether particularly 'impactful' articles' press releases vary from others regarding their structure, linguistic accessibility, and the way they use emotionally engaging narratives to report the featured research's findings. Thus, our main interest is to describe how external science communicators, e.g., press officers of research institutions, publishers, or journals, might exert an influence over an article's later impact through the accompanying press releases they issue. It should be noted that such influence would obviously only constitute one component of a multifaceted and highly complex mélange of factors that affect research articles' impact metrics (Tahamtan et al., 2016).

For many research institutions and scholarly publishers, press releases constitute the quintessential instrument for marketing new knowledge (Autzen, 2014). As Carver (2014, p. 2) describes it, the press release is "essentially a short news article written in a journalistic style that explains a newly published scientific result in a common and not too specialized language". The arguably most important international platform for the dissemination of press releases on science is *EurekAlert!*, set up by the *American Association for the Advancement of Science* in 1996. According to Vrieze (2018), with over 5,000 active public information officers and more than 14,000 registered journalists from over 90 countries, the platform has become for scientific press and news releases "what *Google* is for searching and *Amazon* for online shopping".

Methods & Data

We use press release data provided directly by *EurekAlert!*. The data contains a comprehensive list of 11,110 unique DOIs of research publications for which at least one press release was published on *EurekAlert!* in 2016, 10,859 of which refer to journal articles according to the *Crossref* REST API. To be able to identify the articles with comparatively high and those with comparatively low metrics among the set, we obtain altmetric data for the 10,859 journal article DOIs promoted on *EurekAlert!* in 2016 from *Altmetric.com* as well as citation counts from the CCB databases[1] via the respective services' APIs. Metrics data was retrieved in October 2020. As a starting point for this research in progress, we focus on articles with particularly high or low impact regarding the six types of indicators which Lemke (2020) found to be associated with press release promotion: *Web of Science* citation counts, tweet mentions, *Facebook* mentions, blog mentions, mainstream media mentions, and *Mendeley* readership counts.

Using the method of characteristic scores and scales introduced by Glänzel and Schubert (1988), out of our 10,859 journal article DOIs we extract 2 subsets of articles for each of these six indicators: one set of articles performing remarkably and one set of articles performing poorly regarding said indicator. This provides us with 12 subsets of articles. From each of these 12 sets we draw 10 random articles, for which we then retrieve the respective press releases that promoted them from *EurekAlert!*. This leads to a set of 124 press releases to analyze.

The press releases are then coded manually by two coders with an inductive approach, meaning the iterative coding of subsets to continuously develop a codebook of properties that might be helpful in the explanation of different press releases' varying promotional effects for the featured research articles. Starting points for which structural and content-related characteristics to expect from press releases to research articles exist in the form of guidelines on how to write them.[2] Each round of coding consists of thorough reading and simultaneous notetaking. These notes are iteratively reviewed by both coders to identify relevant properties and ranges of values these properties can take. The revised codebook is then again applied to the dataset.

Preliminary Results & Discussion

In the following subsections, we first briefly describe our dataset and then summarize preliminary findings regarding properties in which the coded press releases differ from each other, which might also affect their (and promoted research articles') later uptake.

Article properties

In total, the 120 articles whose 124 press releases we analyzed were published in 72 different journals from 21 publishers, *Science* and *Nature* being the most strongly represented journals (with 14/12 articles respectively). We manually identified the articles' disciplines by reading their press releases (which should enable more accurate article-level mappings than consulting publishing journals' *Web of Science* subject categories), finding most of them to be related to medicine (56 press releases) or biology (28 press releases), followed by psychology, chemistry, economics, archeology, and geology. The dominance of life science topics, both in public media's science coverage in general as well as on *EurekAlert!* in particular, is in line with findings from previous studies (e.g., Elmer, Badenschier & Wormer, 2008; Hahn & Lemke,

[1] CCB refers to the German *Competence Centre for Bibliometrics*, an institution hosting annually updated citation databases built on data from *Web of Science*. The citation data used in this study reflects a state from April 2020.

[2] For examples, see https://www.cbsnews.com/news/how-to-write-a-press-release-with-examples/, https://esahubble.org/about_us/scientist_guidelines/, https://www.asbmb.org/education/science-outreach/how-to-write-a-press-release, or https://service.prweb.com/resources/article/editorial-guidelines/.

2020). The majority (116) of the 120 journal articles were published in the same year as their respective press release, 2016, two were published towards the end of 2015, the remaining two early in 2017. Table 1 describes the 60 remarkably performing and the 60 poorly performing articles regarding the six article-level indicators considered in this study, as well as their publishing journals' impact factors in 2016.

Of the 124 associated press releases, 83 (46 for high, 37 for low performing articles) had been submitted to *EurekAlert!* by institutes conducting research, e.g., universities, laboratories, or hospitals, 41 (17 for high, 24 for low performing articles) by scholarly publishers.

Table 1. Indicator-related statistics of both article groups

	Poorly perf. articles			Remarkably perf. articles		
	Mean	Median	SD	Mean	Median	SD
Citations	22.1	15	23.9	136.2	127	118.7
Mainstream media mentions	12.0	8	14.5	68.9	52.5	63.9
Blog mentions	1.2	1	1.8	11.1	10	8.5
Tweet mentions	17.5	8	24.5	282.2	179	291.1
Facebook mentions	1.2	1	1.7	14.4	10.5	17.2
Mendeley readership counts	79.0	54	89.5	450.7	386	408.9
Journal Impact Factor (2016)	8.337	4.259	9.948	24.130	16.761	14.110

Structure of press releases

Press release texts were analyzed for whether they follow a clearly discernible structure that supports a comprehensible line of argumentation. Ultimately, the coders evaluated a press release's structure as *clear*, *slightly unclear*, or *unclear*. A *clear* buildup could for instance start with a concise problem statement and a brief snapshot of the research, followed by definite paragraphs with comprehensible individual functions, e.g., more detailed descriptions of the research's methods, added value, and further implications. An *unclear* structure on the other hand might merge several diverse parts of information within few, long paragraphs. Another indicator for a structure not being *clear* might be the existence of unnecessary repetitions. Overall, most (96) of the press releases were evaluated as having a clear structure. Another 17 press releases stood out as having an unclear structure, for instance because of sudden jumps in their lines of argumentation or the connection between problem statement and the reported results being vague. Only 5 of those 17 press releases belonged to articles from the remarkably performing group, while the remaining 12 promoted articles which performed poorly.

Accessibility of press releases

Another aspect in which coded press releases differed is their accessibility due to their linguistic or technical complexity. Coders differentiated between *good*, *medium* and *bad* accessibility, depending on whether they deemed the press release understandable for readers that are no experts in the related field of research. A *bad* accessibility could for example result from the press release containing a high number of unexplained technical terms that an average reader would likely have to look up. Most (100) press releases were found to have *good* accessibility. Only 13 press releases were evaluated as having *bad* accessibility, most often because they were written in a highly technical language without sufficient explanations. In this case, 9 of these 13 belonged to articles from the indicator-wise poorly performing group of articles.

Engaging narrative

As another step, coders assessed the press releases' use of engaging narratives to report findings. Primarily, this refers to the press release's author's writing style and not to the promoted research's topic. We do however note that as certain topics will be more suitable for an engaging or emotional style, this category will be affected more significantly by the promoted article's content than the press release´s structure or linguistic accessibility. Coders assessed the degree to which a press release contained an emotionally engaging style on a five-level Likert scale from *low* (1) over *medium* (3) to *high* (5). *High* emotionality can be the result of a narrative that creates tension, or one that particularly effectively depicts research findings' relevance. *Low* emotionality on the other hand is indicated by an austere writing style dominated by technical information. Most press releases were found to have a *low* (58) or *low-medium* (21) level of engaging narratives, a *medium* score was assigned 19 times, *medium-high* 12 times, and *high* 14 times. Across all scores the two article groups were represented in almost perfectly equal shares. Thus, the degrees to which press releases were found to vary regarding their use of narratives does not seem to correlate with articles' performance concerning metrics.

Our finding of comparatively large shares of poorly performing articles among those with badly structured or linguistically inaccessible press releases suggests that there might be some association between an article's metrics performance and certain qualities of its press releases. However, we need to keep in mind two limitations of our preliminary results: first, our approach (for now) suffers from a small sample size, hindering any observations' generalizability. Second, we cannot make statements about potential associations' directionalities yet. Just as high metrics could (partially) result from the visibility generated by well-made press texts, bad press texts could (partially) be the result of 'bad source material'. As hinted at earlier, the ease with which an engaging narrative can be found to report about an article's findings certainly depends on its topic, and even press releases' structural or linguistic properties might not be independent from the promoted article's content. Thus, the latter's inherent flaws could at the same time be part of the reason for the article receiving lower metrics, as well as for its press releases to be more likely to be perceived as inaccessible or poorly structured.

Furthermore, the quality of press releases could be strongly connected to the publishing journal or institution, just like metrics are strongly affected by the journal an article is published in. Perhaps part of particularly prominent journals' success can be explained by their superior PR, which produces more accessible and better structured press texts than their competitors do. These are questions we aim to tackle in more detail in our research project's subsequent steps.

Conclusion & Outlook

First results from our coding revealed several inherent properties regarding which press releases to scholarly articles differ from each other. Also, the quantitative findings may suggest associations between some of these factors and a promoted article's later metrics. This research is still in an early stage and follow-up studies could take numerous directions.

The next steps in this study will consist of consolidating the observations made during coding to a reusable codebook, its validation through its application by 'blind' raters, which were not involved in its conception, and its subsequent formal assessment in terms of inter-rater-reliability. Regarding further manual coding, it could be insightful to additionally assess press releases regarding their extent of research content, i.e., the degree of detail with which the research itself is presented in them. It might also be interesting to complement raters' judgments of press releases' accessibility with automatically calculated measures of readability, e.g., Coleman-Liau index. Furthermore, upcoming efforts will go into analyzing correlations between properties' manifestations, individual types of metrics, and external factors like the press release's publisher or the promoted article's journal. Moreover, it could be worthwhile to retrieve full texts of news media reporting on the articles from our sample as well as other research articles that cited them to examine the whole alleged chain *research article – press release – media coverage – citation*. Such a comprehensive look might shed light on how certain qualities are carried over (or lost) between different formats and help to better explain the mechanisms behind the association between press coverage and increased article impact.

In later steps, machine learning methods could be applied to make the coding scalable for larger samples of press releases. Another in-depth content analysis could investigate how homogeneous press releases behave across individual journals or publishers – such a study could both enhance the effectiveness of a machine learning-based application of the codebook, as well as provide insights into how individual promotional activities of major players in the world of scholarly publishing shape external science communication.

Acknowledgments

This study is an outcome of research project MeWiKo, funded by the German Federal Ministry of Education and Research (grant number 01PU17018A). We thank *EurekAlert!* and the CCB for providing our project with access to their data.

Abstract

The present study aims to describe and discuss some characteristics of the citing documents of Wakefield's paper, a retracted article due to fraudulent data and analysis on the relationship between vaccine and autism. All metadata of the 1,578 citing documents of Wakefield's paper were downloaded from Scopus, considering two periods before (1998-2004) and post retraction (2005-2020). The main results indicate that the 79% of the citing documents are post retraction. In this period, we found the predominance of articles as well as other documents written in English but also in a wider-ranging of idioms. These documents are mostly associated with medicine and social sciences. These findings are a clear indication that this retracted paper is still popular and dispersed within a broader spectrum of fields in the global arena, from medicine and health sciences to social sciences. For future analysis, we intend to analyze the citing documents qualitatively, seeking to better understand the motivations for citing Wakefield's paper even after its retraction.

Introduction

During the 20th century, scientific journals have increased considerably not only in terms of quantity but also in field coverage. The success of this means of communication is related to many reasons, such as a lower production cost and logistics complexity as well as a faster speed in the diffusion of the new knowledge. Nevertheless, its main distinction concerns the peer review process, which acts as a self-control process to guarantee the quality of scientific work. (Meadows, 1974)

The process of peer review was introduced in the 1600's by Henry Oldenburg, the editorship of The Philosophical Transactions of the Royal Society that is considered one of the first world scientific journals. Gradually, this practice spread and was incorporated into the routine of the scientific journals' publishing process. At first, the main editor and an in-house staff of specialists assumed the responsibility for reviewing the submitted works. After the 1950's, experts out of the staff started to be invited to review and approve (or reject) manuscripts, a model that persists up to the present. (Burnham, 1990)

Although the peer review process has been consolidated as a central step in the publishing process and it has been supported by the majority of the world scientific community, the integrity of this process has been frequently questioned and criticized. Bornmann's review of literature on peer review presents a comprehensive view on the main issues raised by defenders and critics of peer review process (Bornmann, 2011)

Additionally, the peer review process has not been able to detect or to avoid the increase in science misconduct during the last decades, as estimated by the growing number of retractions (Fang, Grant Steen & Casadevall, 2012; Bar-Ilan & Halevi, 2017). It is true that the quality and the confidence of peer review has changed a lot due to the "high volume of submissions, turnover of editors, and dependence upon ad hoc reviewers and often a part-time (non-professional) managing editor" (Fox, 1994).

Such new context partially explains the increase in misconducting, while most are related to scientists' conducts. Yet, according to Steneck (2006), since 1980's the debate on misconduct in the scientific environment led to the consensus that misconduct is associated with two main groups of irresponsible research behaviors, named as (a) questionable practices, that is, when a study presents misrepresented, inaccurate or biased data or analysis and (b) deliberate misconduct practices that include cases of fabrication, falsification, and plagiarism.

An example of serious misconduct is the study developed by Andrew Wakefield and published in 1998 in *The Lancet* journal (Wakefield *et al.*, 1998), one of the world's most prestigious journals. The paper suggests a relationship between the triple viral vaccine (which protects against measles, rubella and mumps) and the development of autistic behavior in children. But in 2004, Wakefield's article was proved to be fraudulent and was retracted.

Despite the retraction, the myth of vaccines causing autism still persists in different regions of the world, since Wakefield's paper can be easily found in the internet and different social media. In fact, a quick look at the platform PlumX Metrics, owned by Scopus, revealed that up to January 2021 there were more than 9,200 shares, likes or comments of this paper on Facebook and almost 2,000 tweets. Similarly, in Google Scholar, an academic media, this paper is also alive: there were more than 3,600 documents citing it; one third of these documents were published in 2015 or after.

Due to its widespread and current repercussion, some studies consider this article as a central element in the resurgence and strengthening of the global anti-vaccine movement (Hussain, 2018). Hence, considering the social impact of Wakefield's fraudulent article and its long-trajectory within the scientific environment, the present study aims to find out answers to a central research question: why is this article still cited? In order to start getting evidence and answers for this question, we investigate some general characteristics of Wakefield's citing documents before and post retraction.

Methodology

In January 2021, Wakefield's paper (Wakefield *et al.*, 1998) was searched in Scopus database, a multidisciplinary specialized database, which is available for all Brazilian research institutes and universities through Portal Periódicos (http://www-periodicos-capes-gov-br.ezl.periodicos.capes.gov.br/index.php?). The search result display paper contained 1,578 citing documents which were downloaded. Among the citing documents, there was one published in 2021, but it was not included in the analysis.

Metadata were downloaded in two files according to the year of publication: 1998-2004 (named before retraction) and 2005-2020 (post retraction). Both files were downloaded in a CSV format and converted to Microsoft Excel format in order to proceed the descriptive analysis.

Results

The results are presented in three sessions. The first session aims to show the number of citing documents along the studied period and their main typology. The second session focuses on the origin and idiom of correspondence authors of these documents while the last one is about their main thematic. In all sessions, results are presented in two periods: before and post retraction of Wakefield's paper in 2004.

Time trend and typology

Analyzing the year distribution of Wakefield's paper citing documents (Figure 2), we observed a great number of citing documents just after its publication (more than 20 citations are in the first year after publication), with a very expressive growth between the years 2000 and 2003. In 2005, a year after the paper's retraction, a slight drop in the number of citing documents was noted. However, the downward trend is not maintained and Wakefield's paper remains highly cited throughout the analyzed period, including growth peaks in the years 2010 and 2013.

It is noteworthy that 79% of the citing documents (n = 1,248) occur post retraction of Wakefield's article (2004). In this period, we found an average of 78 citing documents per year, while the period before retraction presents an average of 47 citing documents per year. This picture clearly indicates the strong repercussion and impact of Wakefield's article within the scientific community since its publication, but mainly, post retraction.

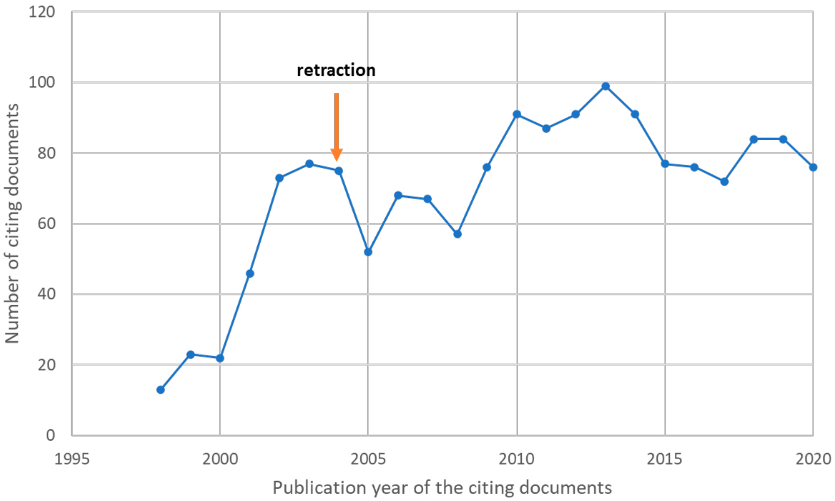

Figure 2. Time trend of citing documents of Wakefield's paper. Scopus

Regarding the typology of the citing documents (Table 1), we identified that most are of the article typology. Comparing before and after retraction, we noted that the share of citing documents in article typology increased 5%, suggesting that a larger number of the new scientific knowledge is still grounded on a retracted paper.

Considering the other typologies, we noted that a significant fraction of the citing documents post retraction comes from books (10.9%) and book chapters (5.6%); in the period before retraction, the share of both typologies was around 1-2 %. A quick look at the list of citing documents classified as books and chapters reveals that they are distributed in a broad spectrum of specialties in the health field, especially pediatrics, and there are also titles in other more general fields, such as scientific integrity. Such a general profile is somehow expectable, since the vaccine mentioned in Wakefield's paper is administered to children, so it is an issue that interests pediatricians, while the errors and misconduct attributed to this paper may serve as a typical case of misconduct in science.

Table 1. Citing documents of Wakefield's paper according to typology, before and post retraction in 2004. Scopus

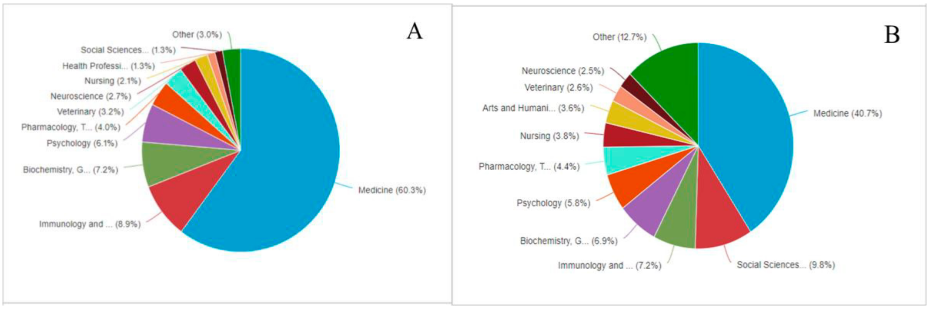
Typology	*Before*		*After*	
	Number	%	Number	**%**
Article	139	42.2	591	47.4
Review	107	32.5	268	21.5
Book Chapter	6	1.8	136	10.9
Editorial	23	7.0	79	6.3
Book	3	0.9	70	5.6
Note	15	4.6	40	3.2
Letter	9	2.7	28	2.2
Conference Paper	17	5.2	19	1.5
Short Survey	10	3.0	16	1.3
Erratum		-	1	0.1
Total	**329**		**1,248**	

Areas and thematic

Figure 4 presents the areas of the citing documents before (Figure 4A) and post retraction (Figure 4B). We noted that the general profile of the areas of the citing documents remains similar in both periods.

However, post retraction (Figure 4B), there was a strong reduction in the percentage of citing documents in the area of medicine (from 60% to almost 41%) and a remarkable increase in the percentage of documents in the area of social sciences (from 1.3% to almost 10%). Such increase may be related to ethical issues in science, a common and growing thematic among researchers from social sciences.

Figure 4. Area of citing documents of Wakefield's paper before (A) and post (B) retraction. Scopus



However, post retraction (Figure 4B), there was a strong reduction in the percentage of citing documents in the area of medicine (from 60% to almost 41%) and a remarkable increase in the percentage of documents in the area of social sciences (from 1.3% to almost 10%). Such increase may be related to ethical issues in science, a common and growing thematic among researchers from social sciences.

Conclusion and some remarks

The present study reveals some general characteristics of citing documents of Wakefield's paper that, despite being retracted in 2004, continued to be cited by the scientific community. We found that 79% of citing documents were published post retraction (Figure 2). In this period, most of the citing documents were in the format of articles (Table 1), written in English but also in a wide-ranging of idioms and countries (data not shown). At last, we showed that the citing documents after the retraction of Wakefield's paper are still mostly associated with medicine but we also noted an increase in documents related to social sciences (Figure 4).

These findings indicate that this fraudulent paper is still popular and dispersed within a broader spectrum of fields in the global arena, from medicine and health sciences to social sciences. Other analysis, not shown in the present paper, reveal that post retraction includes a large number of citing documents related to issues on science communication and ethics in scientific research as well as science education and parental responsibilities.

It is important to highlight that Wakefield's paper appeared as the number one in the ranking of most cited ranked articles, all published in very prestigious journals, as described by Fang, Steen & Casadevall (2021). The authors have found that retraction can cause a continuous reduction in the number of citations and, in some cases, also "an immediate and severe decline in citations". This conclusion, however, is not in accordance with the study developed by Candal-Pedreira et al (2020). These authors have found no association between retraction and citations in the long term.

In order to better understand the reasons beyond the persistent popularity of retracted papers, Bar-Ilan et al (2017) investigated 237 citing documents of 15 retracted articles found in ScienceDirect. After identifying the context of each citation (positive, negative or neutral), authors conclude that most of citing documents were used in a positive context, even in cases where retraction was due to serious and deliberate misconduct, as fabrication and falsification data. Authors highlight that the easy access to the retracted paper on the internet and the intensive media attention on retracted papers (such as Wakefield's paper) may contribute to continuing (and sometimes growing) interest in these studies not only by the general public but also by scientists, who may cite them in a positive or negative context.

The present study indicates a change in the thematic profile in the post retraction period, more focused on social science issues, which may be an indicative of a reflective citation, probably a negative one, on Wakefield's paper. However, the set of data and results presented here do not allow us to make such a statement. For future analysis, we intend to analyze the citing documents qualitatively, seeking to better understand the motivations for citing Wakefield's paper even after its retraction. These results can be useful for a better understanding of the scenario of scientific communication during the pandemic, in which we are witnessing a rapid repercussion of papers that in a short time have failed to confirm their main conclusion.

Have the European Union programmes made a difference to biomedical research outputs?

Grant Lewison[1]

Abstract

This study was designed to see if the several European Union (EU) research programmes, including the Coöperation in Science and Technology (COST) activities, had made a measurable difference to the Member States (MS) who took part in them. We looked at the internationally collaborative biomedical research outputs of six MS that joined the EU at different times (Greece, Spain, Sweden, Poland, Romania and Croatia), and compared them with those of selected similar non-EU countries (Egypt, Brazil, Norway, Russia, Ukraine, Serbia) to see if there was more work done jointly with other EU MS compared with the Rest of the World. We also checked whether the citation impact of their purely domestic biomedical research had increased more rapidly than that of the six comparator countries. The results were somewhat mixed, probably because EU support only accounted for a small fraction of the total cost of this research, but there were some discernible benefits. Suggestions are made for future investigations that would be more likely to reveal the effects of EU programmes.

Introduction

Research and development has been a major activity of the European Union (EU), and of the European Communities (EC) before that. In fact, each of the three Communities (the European Coal and Steel Community (founded in 1951), the European Atomic Energy Community (EURATOM), and the European Economic Community (both founded in 1957)) had their own research programmes. The latter grew to become much the largest, and the successive Framework Programmes, followed by Horizon 2020 and Horizon Europe, have become a major source of both funding and collaboration within the European Union, and in 13 other Associated Countries (including Israel, Norway, and Switzerland) who participate in the same way as Member States (MS). Their governments pay into the programme budgets on the basis of their national wealth.

Despite the current size of the recent EU programmes, they represent only a small fraction of the total R&D expenditure by the MS. The evaluation literature covers both the results of the EU research grants and other coördination activities such as Co-Operation in Science and Technology (COST), and studies on overall European research outputs in specific subjects. In the 20th century, the main concern was European success relative to that of the other members of the triad (the USA and Japan; Tikal, 1993; Leydesdorff, 2000), but the focus has now shifted to comparisons with the USA and China (Leydesdorff, Wagner & Bornmann, 2014; Evangelatos et al., 2018). Several papers examined the outputs of individual EU-funded research programmes (de Nettancourt & Klepsch, 1990; Lewison, 1994; Weydert, 2000; Sauter et al., 2011; David, 2016). However, rather more papers were concerned with the distribution of publication outputs within the EU, particularly papers on medical research (Parodi et al., 1993; Mela & Cimmino, 1998; Hefler, Tempfer & Kainz, 1999; Ramos et al., 2004; Soteriades & Falagas, 2005; Begum et al., 2016; Begum et al., 2017a; Begum et al., 2018; Kalo et al., 2019; Pallari et al., 2020).

This paper seeks to determine the overall effects of EU biomedical research activities by means of two comparisons between the outputs of six EU MS and those of six comparable countries that were not MS, although some of them were associated with the EU's programmes. The first parameter was the amount of collaboration between each of the pairs of countries and (a) other EU MS (at the time the new MS joined the EU) and (b) the rest of the world (RoW). The second parameter was the five-year mean citation score of *domestic* research papers. These were distinguished from ones with international co-authorship because their citation impact would be strongly influenced by the foreign co-authors. The idea was to see if EU Membership had led to an improvement in the impact of the country's own researchers. We compared the situation in the years *before* each of the six selected MS joined the EU, and in the subsequent years.

The six EU MS and the six comparator countries are listed in Table 1, with their International Standards Organization digraph (ISO2) codes, and their Gross Domestic Products in the accession year and in 2015 to show that they were broadly comparable. However, there have been great changes in the GDP of some countries, notably Egypt, Croatia and Ukraine, but very little in Romania.

Table 1. List of six European Union Member States (EU MS), with their ISO digraphs, the dates that they joined the EU (or the EC), and their GDPs both then and in 2015 (billion US $). Similar data are given for six comparator countries.

EU MS	*ISO2*	*Accession*	*GDP, US $ bn*		*Comparator*	*ISO2*	*GDP, US $ bn*	
			Then	*2015*			*Then*	*2015*
Greece	GR	1981	52	195	Egypt	EG	23	331
Spain	ES	1986	251	1193	Brazil	BR	268	1804
Sweden	SE	1995	264	496	Norway	NO	152	387
Poland	PL	2004	255	477	Russia	RU	591	1331
Romania	RO	2007	172	178	Ukraine	UA	111	906
Croatia	HR	2013	58	487	Serbia	RS	46	372

All of the comparator countries have participated in EU programmes to some extent. For example, Norway has been an Associated country since 1995, when it declined to accede to the EC as a result of its referendum. Poland and Romania have also been involved in EU programmes since the early 1990s when the EU envisaged enlargement to the countries of Eastern Europe, following the fall of the Berlin Wall in June 1990, although they were less active than other Eastern European MS, perhaps because of a lack of domestic investment in R&D. There have also been some European support programmes with Russia, Ukraine and Serbia. Egypt and Brazil also took some part in EC and EU programmes, though not as intensively as Member States. Finally, most of the comparator countries have been involved in other trans-national partnerships, such as the Centre d'Etudes de Recherche Nucléaire (CERN) in Geneva and the European Molecular Biology Laboratory (EMBL) in Heidelberg.

Methodology

For the 12 countries listed in Table 1, we determined their biomedical research outputs in each year from 1975 to 2019 in the Web of Science (WoS, © Clarivate Analytics) by means of a complex filter based on address words or contractions (Lewison & Paraje, 2004). These included names of diseases or parts of the body, such as *AIDS, CANC, HEART*, names of pharma companies, such as *BAYER, GLAXO**, *LILLY,* organisations supporting biomedical research, such as *INSERM**, *MRC, NIH,* and places where such research was conducted, such as *BETHESDA, HOSP*, INFIRM, KAROLINSKA**. [For the bottom three countries in each list, only papers from 1995 were identified.]

In order to check that the results would not be biased by some of the 12 selected countries having a rather unusual distribution of diseases within their biomedical research portfolios, we also determined their outputs in cardiovascular research and in cancer research, the two leading causes of death in high- and middle-income countries. These outputs correlated very closely with the biomedical research outputs ($r^2 = 0.97$ and $r^2 = 0.92$, respectively), so we felt confident that the latter were representative of health research in the selected countries.

We also determined the number of papers in collaboration only with the other EU MS at the time that they joined, and only with the RoW, and with no international collaboration. These four numbers of papers for each year were used to calculate the additions to their domestic outputs from the EU MS, from the RoW, and from both.

We then determined the mean five-year citation counts (Actual Citation Impact, ACI) for the domestic papers for each of the 12 countries for each fifth year (1975, 1980, etc). For a few countries in the most recent two years (2010, 2015) the numbers of papers exceeded the limit of 10,000 for the determination of citation counts in the WoS. In these instances, we divided the set of papers into two on the basis of the initial letters of their journals, thus: SO=(A* or B* or C* ....), and added the resulting citation numbers.

The results have mainly been presented graphically, with two parallel graphs for each parameter, one for the top three pairs of countries and dates 1975-2019, and the other for the bottom three pairs and dates 1995-2019. Some sample graphs showing the outputs of domestic biomedical papers from one country, Sweden, and the additions from the EU MS, the RoW, and for both have also been presented.

Now the world-wide output of biomedical research papers in the WoS has increased greatly over the 45-year study period, by a factor of almost eight, and the journal coverage has increased by a factor of more than six, see Figure 1. The number of journals covered shot up by over 4800 (46%) in 2015 when the Emerging Sciences Citation Index was created and incorporated in the WoS. Many of these were published in non-traditional countries. Another reason for the rise in world biomedical research output was the rapidly increasing presence of China, which went up from 0.13% in 1975 (171 papers) to over 19% in 2019 (196,843 papers). As a result, it may be more revealing to show the outputs of these European (and other) countries as percentages of world output in the given years.

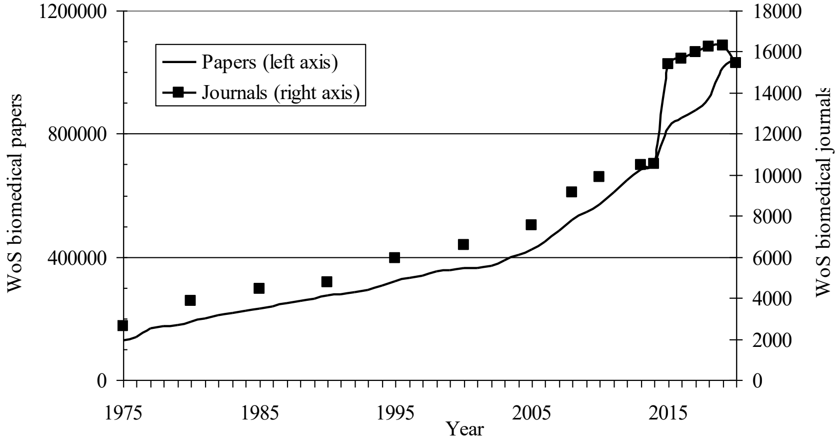

Figure 1. World outputs of biomedical research papers in the Web of Science (as defined by the address-based filter), 1975-2020, and the numbers of journals with one or more papers in the data-set. Note the sharp increase in the numbers of journals in 2015 because of the advent of the Emerging Sciences Citation Index.

Results

Numbers of papers and collaboration

Most European countries have increased their biomedical research outputs over the study period, but their percentage presence in the world has declined, mainly because of the very rapid rise in the output of China. Figures 2 and 3 show the absolute and percentage values respectively for one country (Sweden, which joined the EC in January 1995), with the outputs for its domestic papers, and the additions from other EC Member States, from the Rest of the World, and from both. The parameter of interest is the increase in the ratio of numbers of extra papers with collaboration from other EU MS (*i.e.*, the sum of the first and third additions) to the numbers of domestic papers. This is shown in Figure 4 for the first three selected MS to join the EC (Greece, Spain, and Sweden) and their comparators (Egypt, Brazil, and Norway). Figure 5 shows the corresponding ratios for the remaining three MS (Poland, Romania, and Croatia) and their comparators (the USSR/Russia, Ukraine, and Serbia).

Table 2. The ratio of the additional papers in collaboration with other EU MS to domestic papers for six new MS and their comparator countries

	Accession year	*Plus 5 years*	*Plus 10 years*
Greece/Egypt	0.82	1.03	1.25
Spain/Brazil	0.67	0.78	0.94
Sweden/Norway	0.65	0.81	0.77
Poland/USSR-Russia	0.78	0.85	0.61
Romania/Ukraine	0.51	0.26	0.82
Croatia/Serbia	1.20	1.33	

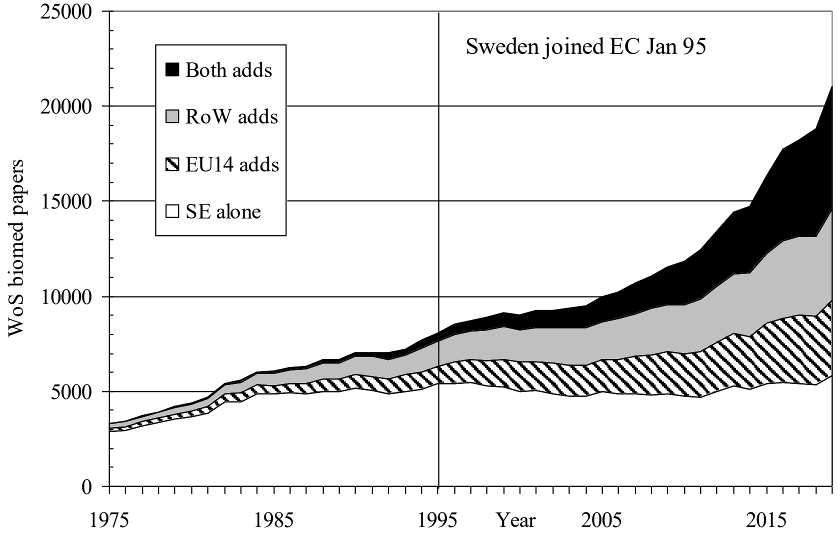

Figure 2. Biomedical research outputs for Sweden in the Web of Science, 1975-2019. Domestic papers alone, the addition of papers co-authored with other EU MS only, with countries from the Rest of the World only, and with both. Absolute numbers of papers.

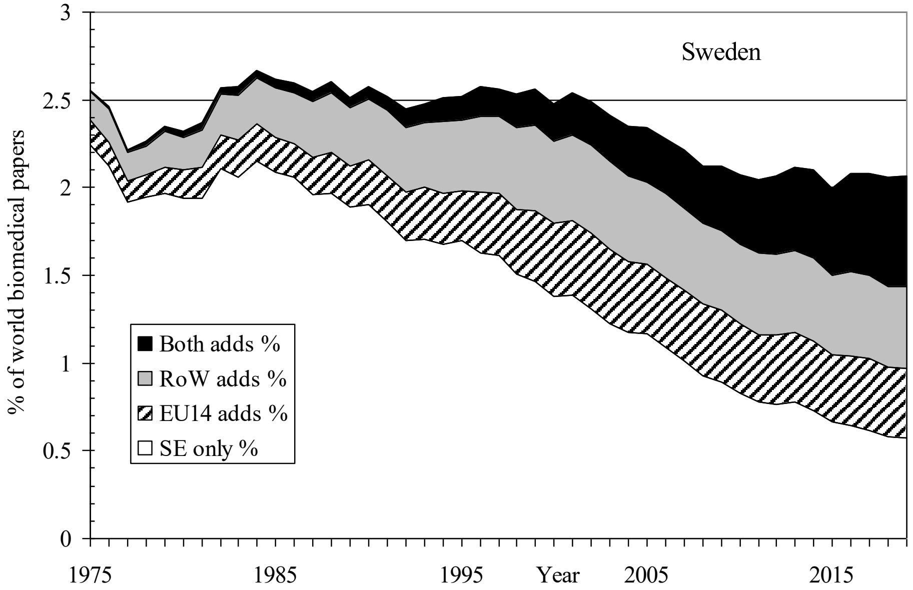

Figure 3. Biomedical research outputs for Sweden in the Web of Science, 1975-2019. Domestic papers alone, the addition of papers co-authored with other EU MS only, with countries from the Rest of the World only, and with both. Percentages of world outputs.

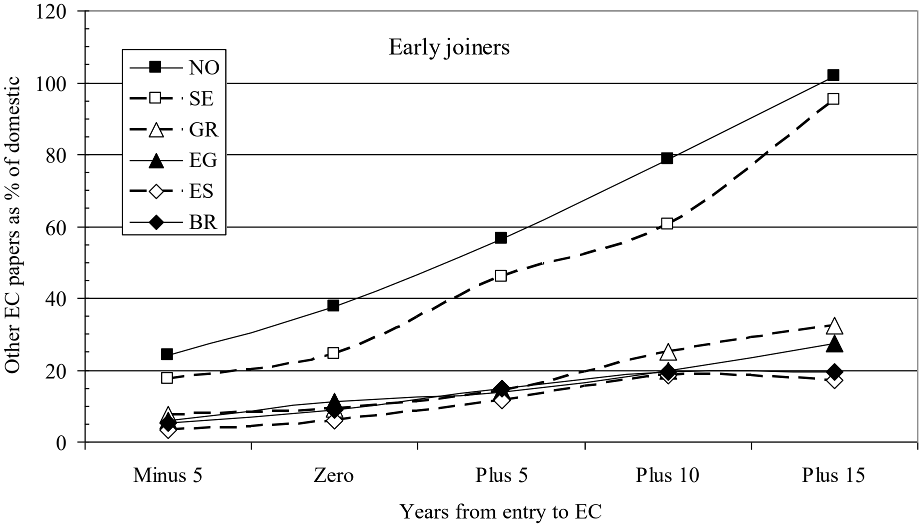

Figure 4. The changing ratio of additional papers co-authored with another EC Member State to domestic papers for three pairs of early joining countries

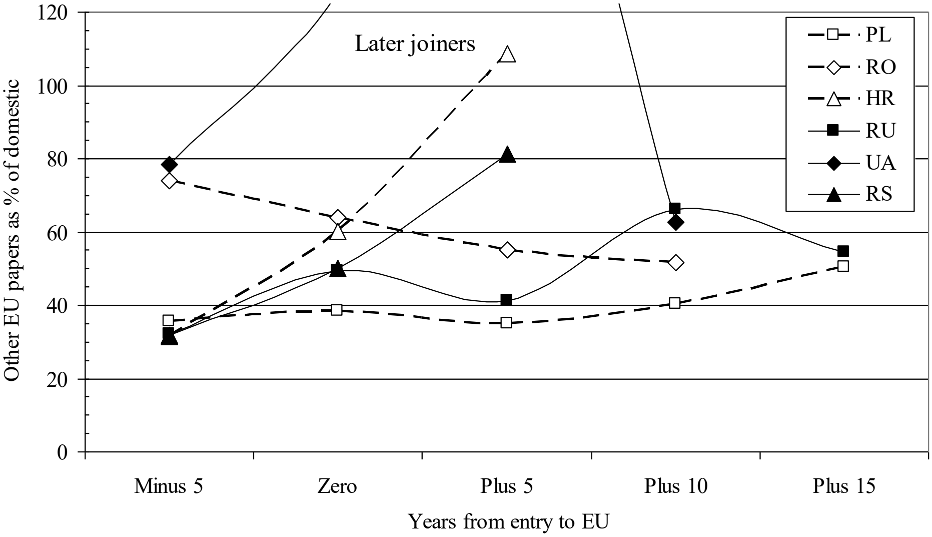

Figure 5. The changing ratio of additional papers co-authored with another EC Member State to domestic papers for three pairs of later joining countries

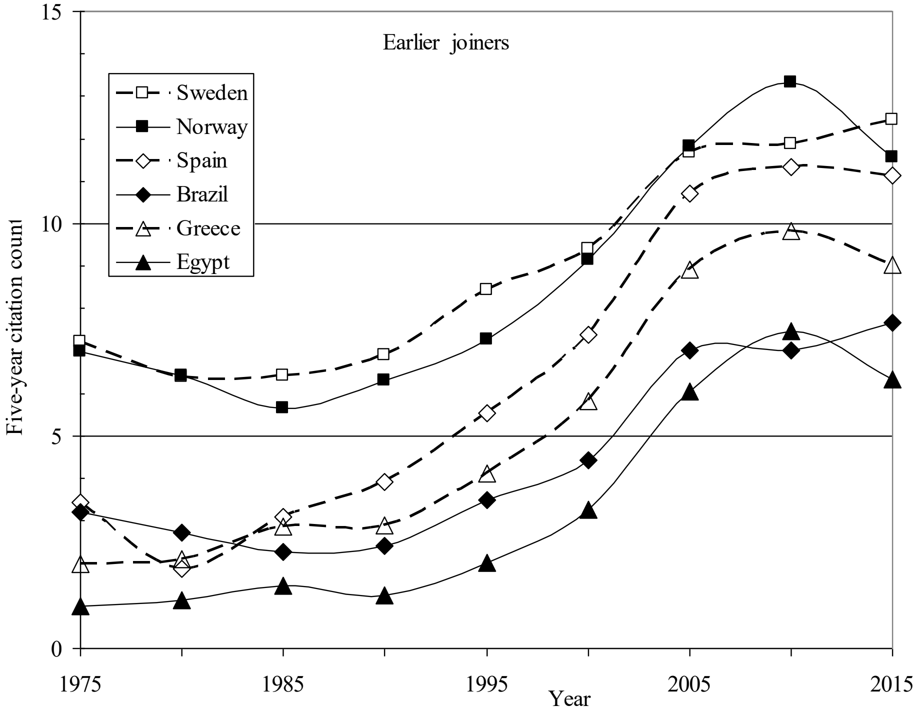

Figure 6. Five-year counts (arithmetic means) of Web of Science citations to domestic biomedical research papers of three new EC Member States who joined in 1981, 1986 and 1995, and their comparator non-EU MS countries.

Closer analysis (Table 2) shows that at ten years after each of the six new MS (five years only for Croatia) joined the EC or the EU, the ratio of additional papers in collaboration with other EU MS has improved for five of the six comparisons. The exception is Poland compared with Russia, where the ratio improved at five years after accession (2009) but declined at ten years (2014).

Citation scores for domestic papers

The five-year mean citation scores for the domestic papers for the six new EU MS and their comparator countries are shown graphically in Figures 6 and 7.

Discussion

This study has attempted to show that new Member States of the EU have gained advantages in their biomedical research activities through membership that were greater than similar changes that occurred with non-member countries. It is perhaps surprising that such advantages are even detectable because the amounts of financial support for research programmes, although measured in the billions of Euros, are really quite small in comparison with the total support provided by most national governments, private-non-profit (Knabe & McCarthy, 2012) and commercial sources. Thus Begum *et al.* (2018) showed that the support from the European Commission in 2009-13 for European cancer research only amounted to 2.4% of the overall total. In diabetes research, it was 2.7% (Begum *et al.*, 2017a).

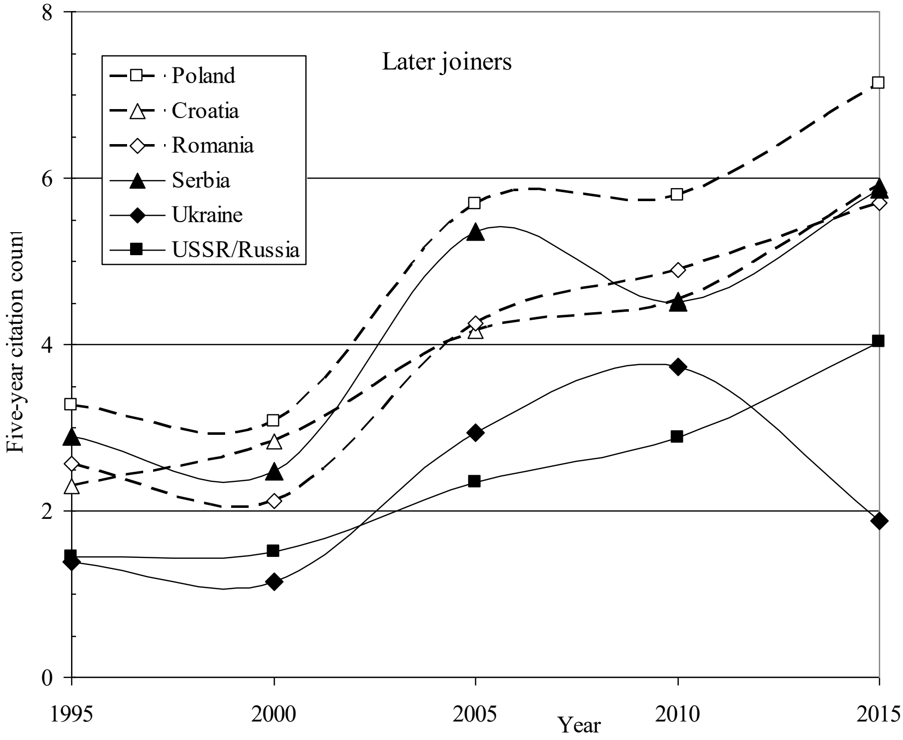

Figure 7. Five-year counts (arithmetic means) of Web of Science citations to domestic biomedical research papers of three new EC Member States who joined in 2004, 2007 and 2013, and their comparator non-EU MS countries.

Table 3. Table of five-year citation counts (ACI) for the 12 countries in the nearest year to their EU accession and 10 years later.

Country	*ISO*	*Joined*	*Near yr*	*ACI 0*	*+ 10 yrs*	*ACI +10*	*Change*	*Difference*
Greece	GR	1981	1980	2.11	1990	2.91	0.80	0.67
Egypt	EG			1.13		1.26	0.13	
Spain	ES	1986	1985	3.09	1995	5.53	2.44	1.23
Brazil	BR			2.29		3.5	1.21	
Sweden	SE	1995	1995	8.43	2005	11.67	3.24	-1.29
Norway	NO			7.29		11.82	4.53	
Poland	PL	2004	2005	5.69	2015	7.14	1.45	-0.24
Russia	RU			2.34		4.03	1.69	
Romania	RO	2007	2005	4.26	2015	5.71	1.45	2.51
Ukraine	UA			2.93		1.87	-1.06	
Croatia	HR	2013	2010	4.54	*2015*	5.91	1.37	0.02
Serbia	RS			4.51		5.86	1.35	

However, this is not the whole story. There are many other European activities that encourage the internationalisation of research, for example the several exchange programmes such as ERASMUS for students, and the Marie Curie programme for researchers. There is also the COST programme that brings researchers together for conferences and seminars. Closer links between EU MS are also encouraged by the European Regional Development Fund, which has improved the transport infrastructure (roads and railways), and the Commission's campaigns to reduce (since 2006) and abolish (since 2017) the trans-national roaming charges paid by users of mobile telephones. Some of the support also comes from the Cohesion Fund which benefits poorer MS. There has been a parallel effort to create a single market for aviation within Europe, which has increased competition, lowered fares, and removed the anti-competitive practices of national carriers found in, for example, Latin America. Safety has been improved by the Single European Sky (SES) programme. These moves have all made international collaboration in research much easier and cheaper.

The Single Market has also required public positions within the EU to be open to citizens of any MS. This has had the effect of improving competition and so driving up standards, including in research. For example, cancer researchers located in the UK in 2014-16 included almost 40% of people with non-British names (Begum et al., 2017b), and half of them were from other European countries. So this is one plausible means whereby the impact of domestic biomedical research may have increased more rapidly in EU MS than in the comparator countries.

There are two exceptions to this relative improvement in citation impact by EU MS relative to their comparator countries. Norway appears to have out-performed Sweden, and Russia to have out-performed Poland. In fact, Norway as a participant in the European Economic Area (EEA) Agreement (which also applies to Iceland and Liechtenstein) has for many years enjoyed the same free movement of people as EU MS. It is also particularly welcoming to foreigners, as measured by its 11th place in the Migrant Acceptance Index compiled by the Gallup polling organisation in 2016. It has also had an active strategy for international collaboration, and its wealth has facilitated this. The situation in Russia is rather different, because its scientific output and standing dropped very suddenly in 1990-95 as a result of the collapse of the Soviet Union. Its domestic biomedical research output declined to a nadir in 2000-07, and has been rescued by support from the European INTAS programme which started in 1993, and from George Soros in the USA. It may also have benefited more than

Poland from the addition to the WoS of the Emerging Sciences Citation Index (ESCI) in 2015, which had varying effects on different countries. Thus the ESCI papers from Poland in 2015-19 were only 11% of the total in the Science Citation Index – Extended plus the Social Sciences Citation Index, but in Russia they amounted to over 29%, and might have led to more citations, particularly from Russian authors.

In summary, the improvements in biomedical research collaboration between the new EU MS and the others, and in the citation impact of their domestic research, can reasonably be attributed to the activities of the European Commission over the last four decades. What we need to do next is to investigate how often research papers that involve two or more EU MS acknowledge financial support from the EU in its many different forms. This would be a major bibliometric study, not least because such support can be acknowledged in literally thousands of different formats.

As a preliminary exercise, we examined the acknowledgements on German papers in colorectal cancer research in the eight years, 2009-16. Ones written in collaboration with other EU MS were more likely to be in receipt of EU funding, see Table 4.

Table 4. Percentages of EU funding for German-authored papers on colorectal cancer, 2009-16, with different numbers of the nine leading other Member States who co-authored them. Mean five-year citation counts also shown for papers from 2009-15. ***Note: some of the papers with "0" other EU MS may have had co-authors from MS that were not analysed.***

Number of other EU MS	*Papers*	*With EU funding*	*%*	*Mean ACI*
0	653	22	3.4	26
1	347	45	13.0	33
2	99	17	17.2	32
3	65	13	20.0	96
4 to 6	84	14	16.7	83
7 or more	60	43	71.7	54

This table shows that papers from two or more EU MS are not only more likely to acknowledge EU funding, but also to be more frequently cited. Moreover, the presence of EU funding seems to attract a lot of additional support. For example, German colorectal research papers with EU funding attract an average of 16 other funders, but those without EU funding average only 2.8 funders in total, and 19% have no financial acknowledgements.

This study has some limitations. Time and resource constraints meant that the determination of ACI values was only performed for every fifth year, so that the results show some statistical scatter. We also limited the numbers of new MS studied to just six, and in particular omitted almost all of the cohort of MS that joined at the same time as Poland in 2004. The comparator countries were often not very like the MS, and their relationships with the EU varied greatly. They may also have varied in their relative commitments to biomedical research as a fraction of their GDP. We were also unable to measure the precision and recall of the biomedical filter as it was based on address terms, and these provide the means whereby subject-based filters are normally calibrated (Lewison, 1999).

Acknowledgments

The funding analysis of the German colorectal cancer research papers was carried out by Mursheda Begum, now of Queen Mary University of London. We are most grateful to Dr Charles Kessler, previously a scientist on the staff of the European Commission, for very helpful comments.

Abstract

The data paper is an emerging academic genre that responds to the rising importance of data in the scientific enterprise. It is a type of academic publication that focuses on the description of data objects. With a large number of data papers published in recent years, it is critical to understand their presence in the scholarly communication system. Our project aims to achieve this goal by investigating the rhetorical functions played by data papers. This research-in-progress paper reports preliminary results from this project. In this work, we expanded an established classification system of rhetorical moves in research article abstracts to make it applicable to data paper abstracts. We further applied this system to classify all sentences in 360 abstracts of data papers in two leading data journals, *Scientific Data* and *Data in Brief.* We identified four new rhetorical moves specific to data papers and examined how all rhetorical moves are distributed across the two journals. This work illustrates some important characteristics of data papers as a rhetorical device and informs future research directions towards a more comprehensive appreciation of data papers in the scientific system.

Introduction

Data have risen to be one of the most prominent epistemic objects in the scientific enterprise (Wynholds, 2011). The growing amount of data paves ways for new research questions and methods as well as large-scale scientific collaborations (Hey et al., 2009). All these changes, in return, require higher transparency of data in the scholarly ecosystem, as summarized into the FAIR Principles of research data stewardship, i.e., research data should be findable, accessible, interoperable, and reusable (Wilkinson et al., 2016).

One approach to addressing the new needs for research data in the scholarly system is through the concept of *data publication*. Data publication refers to the pipeline through which data are transformed into discrete, well-documented, publishable, and citable objects (Parsons & Fox, 2013). An implementation of this concept that is gaining momentum is to publish data objects as academic papers, as shown in the emerging academic genre of *data papers*. A data paper is defined as a "scholarly publication of a searchable metadata document describing a particular online accessible dataset, or a group of datasets, published in accordance with the standard academic practices" (Chavan & Penev, 2011, p. 3).

Data papers are becoming more popular from the mid-2010s, partly supported by the establishment of journals dedicated to this genre, or *data journals*. Candela and colleagues' survey (2015) identified seven dedicated data journals and over a hundred academic journals accepting data papers along with research articles. In 2014, the journal *Scientific Data* was developed by Nature Publishing Group (Hrynaszkiewicz & Shintani, 2014) and *Data in Brief* by Elsevier (Thelwall, 2020), both later grew into the most important exclusively data journals in the market (Walters, 2020).

Given the short history of data papers, we are still far from a clear understanding of their presence in the scholarly communication system. One critical aspect of this knowledge is how these publications are constructed differently from research articles from a rhetorical perspective. In this regard, data papers offer a valuable site to observe the diversity of scientific rhetoric. On the one hand, data papers have distinct purposes from research articles: they are only supposed to describe the datasets per se, instead of offering information about the research design and results (Callaghan et al., 2012). On the other hand, data papers inevitably share many similarities with research articles, as both genres are produced in the same scholarly system and highly similar research contexts (Li et al., 2020). However, how these two genres are compared with each other has never been examined by empirical studies.

Our project aims to fill this gap by evaluating various aspects of rhetoric in data papers and investigate how they are connected to the roles played by data publications in scholarly communication. In the present work, we report our preliminary findings by identifying and classifying rhetorical moves in abstracts of a selected sample of data papers in two flagship data journals, *Scientific Data* and *Data in Brief*. The rhetorical move is commonly defined as a "discoursal or rhetorical unit that performs a coherent communicative function in a written or spoken discourse" (Swales, 2004, p. 268). Thus, this work will contribute to a deeper understanding of data publications from a socio-linguistic perspective. Specifically, the following two questions are pursued in this research-in-progress paper:

RQ1: What rhetorical moves are used in abstracts of data papers? This question aims to examine all rhetorical moves used in data paper abstracts and identify new moves that are specific to data-related contexts. We used the manual coding method and applied a modified classification system to identify all moves from abstracts of a selected sample of data papers.

RQ2: How are these moves distributed in the two data journals? This question strives to understand the cross-journal differences in the use of rhetorical moves. In this preliminary study, we only connected the differences to the journal policies concerning abstracts to draw preliminary explanations.

Method

In this research-in-progress paper, we only used data papers included in *Scientific Data* and *Data in Brief*, two domain-independent flagship data journals, from Scopus on November 15, 2020. While both journals were categorized as *exclusively data journals* by Stuart (2017), they may contain document types beyond data papers, especially comments and reviews. We removed all other document types and retrieved 7,712 data papers from these journals, with 6,335 from *Data in Brief* and 1,377 from *Scientific Data*.

These two journals were selected due to the following reasons. First, they are the two leading, domain-independent exclusively data journals based on the journal impact factor, the number of publications, and the presence in empirical studies (Stuart, 2017). Second, both journals were founded in 2014, which facilitates meaningful comparisons over time. Third, these journals have a few differences in the author guideline, which can shed light on the diversity of data papers. Based on these reasons, we believe our sample is able to reflect how data papers in a broad array of research domains are composed.

This preliminary study focuses on the journal policies of the paper abstract, which are summarized in Table 1. While rules on both journals are similarly worded, especially what should and should not be included in the paper abstract, one major difference is that *Scientific Data* directly states that no reference should be cited in the abstract.

We selected all data papers published between 2015 and 2020, as both journals were founded in 2014 and there are not enough papers to be analyzed in that year. To enable a more meaningful comparison between the journals, we used a stratified sampling approach where we take 30 publications for each journal in each year. There are finally 360 data papers in our sample for manual classification, to be described in the next section. We used the NLTK package of the Python language (Loper & Bird, 2002) to parse paper abstracts into sentences. A total of 2,182 sentences were parsed from all selected data papers.

Table 1. Abstracted-related policies from the two journals

Scientific Data[1]	*Data in Brief*[2]
- They should succinctly describe the study, the assay(s) performed, the resulting data and their reuse potential. - It should not make any claims regarding new scientific findings. - No references are allowed in this section.	- Concisely describes the data, its collection process, analysis and reuse potential. - Do not: provide conclusions, results, or mention the word 'study'.

Classification of rhetorical moves in abstracts

We classified all parsed sentences based on its rhetorical function(s) in the texts. For this purpose, we modified the classification scheme of rhetorical moves in research article abstracts proposed by Hyland (2000) that is composed of *Introduction*, *Purpose*, *Method*, *Product*, and *Conclusion*. Based on existing empirical evidence, these moves are not sufficient for data papers, due to the distinct functions of the latter genre (Li & Chen, 2018). As a result, we expanded this system using 50 randomly-selected abstracts (from the original 7,712 papers), where two coders independently reviewed them to identify any additions to this system. In the end, we added four new moves that are specific to data papers to Hyland's scheme. Our modified scheme is illustrated in Table 2, with the four added categories highlighted. Moreover, we changed *Product* into *Results* in our scheme, even though we retained its original definition.

Table 2. The new classification of rhetorical moves in data paper abstracts

Move	*Definition*
Introduction	Context of the papers
Purpose	Purpose or intention of the paper/research
Method	Research design, procedure, assumptions, approach of the study
Results	Main findings or results
Conclusion	Interpretations of the results beyond the scope of paper
Data description	**Description of the data object that is the topic of the paper**
Data uses	**How the data object is supposed to be used or its implications**
Data accessibility	**How to get access to the data object**
Related research article	**The research article to which the data object is connected.**

In this classification system, we specifically separated moves that are focused on the data object per se and those on the research behind the data object, as the data-research dichotomy is an important distinction between data papers and research articles. In the former group, four added categories specifically focus on any information about the data object being described in the data paper.

On the other hand, while some traditional rhetorical moves are supposed to be used in the data paper abstracts, especially *Introduction* and *Method*, moves like *Results* and *Conclusion* are clearly discouraged to be used based on the journal policies in Table 1.

Using the modified classification scheme, two coders independently classified all sentences. The intercoder reliability between the two coders is 0.706, indicating a good agreement (Landis & Koch, 1977). All differences between the coders were resolved before data were analyzed.

In our coding, we allowed the co-existence of multiple moves in the same sentence, given the complexity of human language. In our final result, we identified 77 sentences with two moves.

[1] https://www.nature.com/sdata/publish/submission-guidelines

[2] https://www.elsevier.com/journals/data-in-brief/2352-3409/guide-for-authors

We used a fractional counting method for these sentences in the next section, with a sentence being counted as 0.5 for each move its covers.

Results and discussion

Table 3 summarizes the counts of sentences and papers with the nine moves. The table shows that *Introduction*, *Method*, *Data description*, and *Data uses* are the most frequently used moves on both the sentence- and paper-levels. This group of moves is composed of both research- and data-oriented functions. A notable finding, contrasting to the journal policies, is that *Results* and *Conclusion* are often used in abstracts, especially that more than 50% of articles have at least one *Results* sentence. Following our previous work (Li et al., 2020), this finding, again, sheds doubt on the boundaries between research articles and data papers.

Table 3. Counts of sentences and papers with moves

Move	*# Sentences (fractional count; n = 2,182)*	*# Papers (n = 360)*	*Sentences per paper*
Introduction	514	217	2.37
Method	527	249	2.12
Data description	357	233	1.53
Data uses	227.5	188	1.21
Results	185.5	97	1.91
Purpose	149	139	1.07
Related research article	89.5	90	0.99
Conclusion	67.5	52	1.30
Data availability	61	67	0.91

It is also worth noting that when these moves are used in a paper, there is a large variance in terms of the number of sentences with the specific move. For example, *Introduction* and *Method* have over two sentences per abstract as compared to *Related research article* and *Data availability* with lower than one. The latter moves have fewer than one sentence per abstract because they can be co-used with other moves in the same sentence. One obvious explanation for such differences is the different amounts of details related to all rhetorical moves: research-oriented moves tend to be richer in details than their data-oriented counterparts.

A major interest of this paper is to investigate how the rhetorical moves are used differently across the two journals. Table 3 illustrates the number of papers with specific moves in the two journals. There are two stark differences between the journals. First and foremost, *Related research article* is only used in *Data in Brief*. This can be explained by the fact that nearly all such sentences are accompanied by an in-text citation, which is disallowed by *Scientific Data*. Second, both *Introduction* and *Data uses* are adopted much more heavily in *Scientific Data* than *Data in Brief*. For both moves, their different usages in these journals cannot be explained by policies concerning paper abstracts, but these may be connected to the journals' different paper structures and peer review criteria, which warrants a future research.

Moreover, we also examined how these moves are used in these journals over time. A few key findings emerge from Figure 1. First, most of the moves are used similarly in both journals and consistently used over time. Second, for the three moves that are used differently across the two journals, there seems to be a generally converging trend between the journals. For example, the use of *Related research article* has been decreasing in *Data in Brief* over time and the opposite trend can be observed for *Data uses*.

Table 3. Counts of papers with moves in the data journals (for each journal, n = 180)

Move	*Scientific Data*	*Data in Brief*
Introduction	141	76
Method	119	130
Data description	132	101

Conclusions

This research-in-progress paper is part of our larger research project aiming to investigate the rhetoric in data papers, so as to better locate this new academic genre in the scholarly communication system. One step towards this broad goal is to evaluate the differences between data papers and research articles in terms of used rhetorical moves. In this work, we present some preliminary findings concerning how rhetorical moves are used in data paper abstracts in two prominent data journals, *Scientific Data* and *Data in Brief*. We expanded an existing classification system of rhetorical moves in research article abstracts and identified four extra moves that are commonly used in the data-oriented contexts: *Data description*, *Data uses*, *Data accessibility*, and *Related research article*. We found that *Data description* is among the most frequently used rhetorical moves in our sample, along with *Introduction* and *Method*. Moreover, we also identified some notable differences in the use of rhetorical moves between the two journals, some of which can be explained by the differences in their journal policies about paper abstracts.

This work serves as a pointer to some important research directions to be pursued during the next steps of this project. First, it is important to connect the use of rhetorical moves to broader journal policy contexts and the domains in which data papers are produced. For example, some differences in our results may be explained by the different paper structures in these journals. Second, the combination and order of rhetorical moves in the abstract are better indicators of the story being told in academic publications. As a result, they will be studied in our future work to better understand key characteristics of data papers as a rhetorical device.

Abstract

Interdisciplinary classification systems provide data sources for interdisciplinary research, and the representation learning can extract relevant subject characteristics at a deep level. This paper established four interdisciplinary classification systems and proposed two discipline representation model through knowledge representation learning and network representation. The results show that discipline groups can be merged into almost eight clusters, and discipline entity can be used to identify the compendex. The method of discipline expression not only helps to scientifically explore the inherent laws of disciplines, but also can quantitatively measure the relationship between disciplines.

Introduction

Discipline is the structure hierarchy of science, and a branch of scientific knowledge with specific research object. It could accelerate the comprehension and construction of science mapping to explore science inner construction and establish a comprehensive and systematic scientific structure system for researcher. Measuring interdisciplinarity can reveal characteristics of knowledge flow. As scientific research extends beyond a single discipline, many scientists have realized the potential of interdisciplinary research.

Bibliometrics are commonly used to measure the interdisciplinarity of research by citation analysis, which can show present, past and future activity in science. Through citation analysis, some researchers explored and constructed many categories classification systems, such as Journal Citation Reports (JCR), Essential Science Indicator (ESI), Ei Compendex (EI) and Scimago Journal & Country Rank (SJR). Thousands of journals were divided into different research areas with specific rules in four category systems.

Academic journals are important carriers of scientific activities and important academic communication media for scientific development. Journal classification of research unit in scientific knowledge represent discipline, which could promote scientific knowledge management. Scientific and technical workers usually publish the new discoveries, new laws, new theories and new methods in academic journals. Cluster analysis based on citation relations with journals can explore the relationship and structure between related disciplines, analyse the structure of interaction and the trend of penetration and derivation, so as to reveal the dynamic structure and development law of science.

In the past decades, many researches explored the internal rules of the discipline with different methods. Leydesdorff used citation analysis, multivariate analysis to classify journals , based on citation data in the database, and showed the change trajectory of discipline structure corresponding to different journal groups, revealed the dynamic structural characteristics of science. Porter proposed that integration is reflected in the diversity of the cited subject's categories as a compelling interdisciplinary research metric. Porter explored differences between similar or dissimilar interdisciplinarity by using the number of disciplines cited. Wagner gave a literature review of quantitatively measure of interdisciplinarity and pointed out that bibliometrics, such as co-authorship, co-inventors, collaborations, references, citations, and co-citations, were used to measure interdisciplinarity. Zhang considered the similarity between discipline areas through the diversity of references to research interdisciplinarity of journal.

Solomon explored multidisciplinary journal interdisciplinary between Nature and Science. The above researches had usually been used to measure the interdisciplinarity in journals.

As early as the last century, the founder of scientometrics, Price believed that citation data from journals could provide useful information for scientific structure researches and scientific classification systems, and journals were a very suitable research unit for the research of scientific structure from the perspective of citation analysis. It inspired the idea of using journals as units of science to study interdisciplinary research.

With the development of information technology, it is possible to analyse data and mine information with network graph. The representation learning method is used to mine multiple information entities to explore potential information. Representation learning was used to map symbolized data to a low-dimensional space to obtain information. Representation learning expresses the wide application of learning methods in the field of data analysis greatly and assists the analysis of multi-source information. Along with the vigorous development of deep learning technology, representation learning methods have developed rapidly in recent years, meanwhile, such methods have greatly facilitated the analysis of multi-source information.

The representation learning method combines multiple information entities to mine potential information. Representation learning is divided into knowledge representation learning and network representation learning.

Knowledge representation learning maps entities and relationships to low-dimensional dense vector space of the same dimension based on complex semantic associations between entities and relationships which are calculated with the spatial distance. Typical methods include Word2vec proposed by Mikolov, which used low-dimensional vectors to learn and represent semantic information. Knowledge representation learning was also used widely in the mining of text semantic information to learn the relevant information between text information effectively. Bordes proposed to embed the materialized relation into the TransE model in the low-dimensional vector space.

Network representation learning represents the semantic information of complex network nodes as dense low-dimensional real value vectors, which can calculate the semantic connection and solve the problem of semantic association extraction and computational complexity under sparse data effectively between nodes in the network , also can improve knowledge acquisition and reasoning performance significantly. Typical network representation learning took nodes as words by forming a network representation learning method based on node location information represented by deepwalk and node2vec. The above methods obtain the sequence data of the nodes in the complex network by random walk. These node sequences can be analogized to the sentences in word2vec, and the nodes are analogous to the words in the sentence, and then the node sequence data is input into word2vec model. The representation vector can obtain network information of each node. For example, Zhang used network representation learning to represent literature information and predict scientific research cooperation. By analysing the author's cooperative relationship and clustering the author according to the research topic, the relative authors can be minded with same research topic, which revealed research hotspot and accelerated scientific research cooperation.

In interdisciplinary research, journals and disciplines are the basic components that together form a discipline-periodical relationship network. There are similar research directions in different disciplines. The deep features of the disciplines can be quantitatively expressed through network representation learning to complete internal information mining.

Methodology

Analysis of four interdisciplinary classification systems

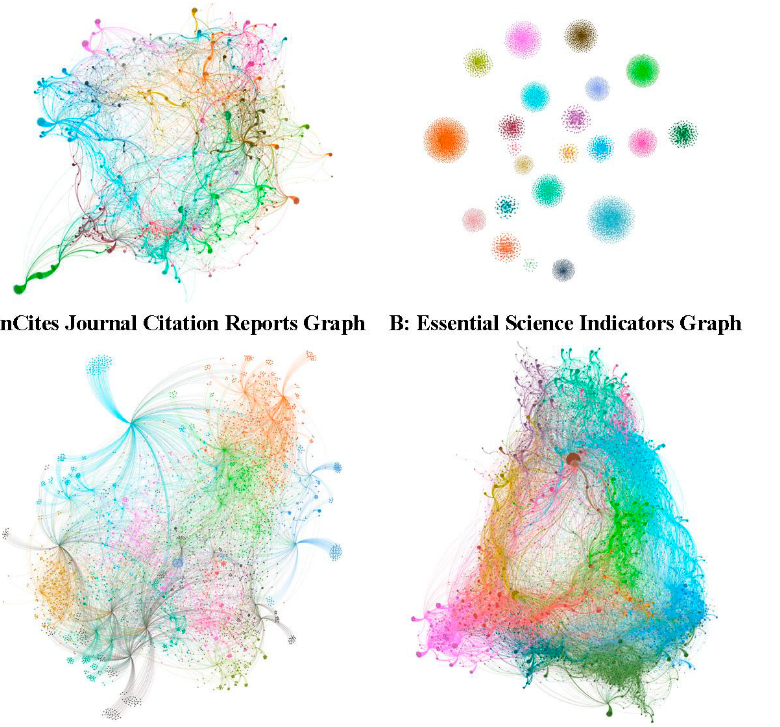
The current international interdisciplinary classification system includes the following four categories: Clarivate Analysis's Incites Journal Citation Report (JCR), Clarivate Analysis's Essential Science Indicators, Elsevier's Engineering Index (EI), and SCImago's Scimago Journal & Country Rank (SJR).

The discipline classification data of JCR is obtained by accessing the journal Citation of the Web of Science (JCR), the discipline classification data of ESI is obtained by accessing the module of Essential Science indicators of Web of Science (ESI), and the discipline classification data of SCImago Journal & Country Rank (SJR) and Ei Compendex (EI)is obtained by downloading their published journal list of discipline classification systems in the relevant home page.

JCR allows users to evaluate and compare journals using citation data from approximately 12,000 academic, technical journals and conference papers from more than 3,300 publishers in more than 60 countries and territories. Journal citation reports are the only source of journal citation data, covering almost all disciplines in science, technology and social sciences. ESI is an important analytical tool for measuring scientific research performance and tracking scientific development trends based on SCI and SSCI. As one of the important indicators for the evaluation of first-class disciplines, ESI highly cited papers are the top 1% papers in citation frequency of each discipline. Their quantitative characteristics can reflect the level of discipline development macroscopically and evaluate the discipline competitiveness of institutions. Its content characteristic may manifest the discipline research hot spot and the frontier, guides the discipline development direction. EI is an engineering research database created in 1884, which providing the most comprehensive searchable engineering literature and patent information index. Designed by the engineering community, this comprehensive platform provides peer-reviewed, in-depth index and accurate engineering research content for academic institutions, enterprises and government agencies. SJR is an open portal website that includes journals and national scientific indicators published in accordance with the Scopus database. These indicators can be used to assess and analyse the scientific field. Journals can be compared or analysed separately. Citation data is derived from 34,100 publications from more than 5,000 publishers and national performance indicators from 239 countries worldwide. According to the classification systems of JCR, ESI, EI and SJR, journals will correspond to one or more disciplines.

On the basis that the current four classification systems are standardized and reasonable, due to the existence of shared journals, explorations of crossover and integration can be carried out. The current work is to explore the integration of classification systems. Among different classification systems, we construct a discipline network through discipline-journal-weight tripartite. The edge of network is defined as: In the JCR classification system, if the A journal is included in the discipline C, the weight is 1; if other classification systems exist same discipline C, and the A journal is also divided into the discipline C, the weight is +1. According to the rules of the subordinate network, this paper constructs a discipline-journal map of four classification systems. Four discipline relationship graphs are shown in Figure 1.

In the Figure 1, different colors represent different discipline clusters, and node size indicates the importance of disciplines in the cluster. In the JCR classification system, different journals are divided into one or more discipline. According to the same journals included relation, a bridge is generated, and a complex interdisciplinary association is formed between different disciplines. Through the community discovery algorithm, the JCR classification system contains 8 major discipline clusters. In the ESI classification system, journals are divided into single discipline, so the discipline relationship graph is shown in the Figure 1.B forming 22 discipline clusters. In the EI classification system, 30 discipline clusters are identified and generated. A large number of journals belong to the only discipline of EI classification system, and discipline clusters are closely related to each other through cross journals. More than 28,000 journals are included in the SJR classification system, and the volume of journals is much larger than other classification systems. The interdisciplinary phenomenon is obviously observed in four classification graphs.



A: InCites Journal Citation Reports Graph **B: Essential Science Indicators Graph**

C: Engineering Compendex Graph **D: Scimago Journal & Country Rank Graph**

Figure 1. Different categories classification graph

In order to observe the current situation of scientific development comprehensively, the scientific graph of the merge multi-source classification system is constructed by merging the four categories classification graph. The comprehensive graph is shown in Figure 2.

The Figure 2 integrates four classification systems, where the community discovery algorithm is adopted to identify 18 disciplines clusters. Different colors represent different disciplines, and the node size indicates the node importance. In figure 2, Medicine, Social Science, Engineering and Mathematics occupy the dominance in the multitudinous discipline clusters, forming the intricate relationship among discipline clusters, but closely related disciplines can still be distinguished, and disciplines still have significant difference. We need to calculate the relative degree between the different disciplines quantitatively and excavate inherent law of science urgently.

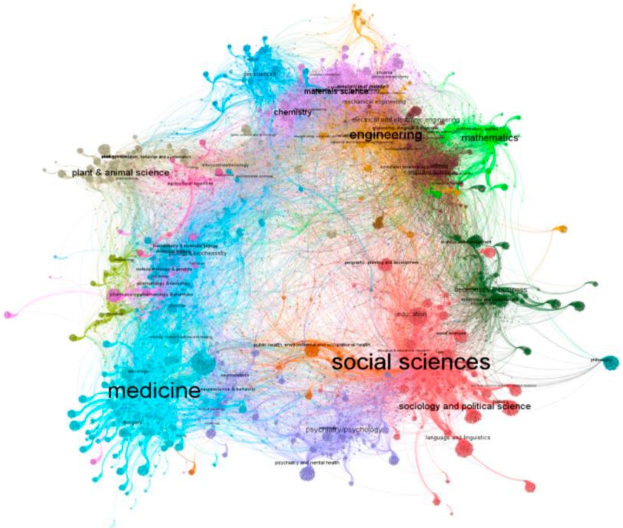


Figure 2. Comprehensive graph of four categories classification

Single-system discipline representation model

The single-system discipline representation model uses a discipline Vector Space Model to quantitatively analysis interdisciplinarity. The motivation of compendex included in a discipline is important to the development of discipline, regardless whether the journal is the core journal for other disciplines or not. All the core journals included in the same discipline have equivalent contribution to the discipline, and they have the same property for the discipline. Based on the assumption, we proposed the discipline vector space model to calculate the similarity between disciplines.

We constructed a 234-dimensional Vector Space Model to represent single-system discipline within the JCR interdisciplinary classification system, used cosine similarity to calculate the degree of interdisciplinarity. The vector of discipline is constructed by the number of multi-assigned journals among different disciplines. We used C discipline as a bridge to measure the degree of interdisciplinarity between A and B discipline. The number of Multi-assigned journals percentage between A and C as a dimension, and the number of Multi-assigned journals percentage between B and C as another dimension, then the relevance between A discipline and B discipline is calculated using these two dimensions as input for discipline vector space model. The construction of the vector is shown in the Table 1.

Table 1. Vector of The representation of Single-system discipline

Table	*ECONOMICS*	*MATHEMATICS APPLIED*	…	*Management*	*Law*
ECONOMICS	1	0	…	0.06	0.06
Mathematics	0	0.44	…	0	0.01

Multisource-system discipline representation model

Journals are classified to different disciplines according to the different discipline classifications system. The total number of disciplines is stable relatively, and the total number of journals is also stable relatively. The path of knowledge dissemination of science and the inherent law of science are embedded in the network of disciplines and journals. We used graph representation learning to solve the comprehensive graph embedding, comprehensive discipline embedding could excavate the potential law within the scientific system, calculate the relationship quantitatively between different disciplines, recognize the discipline compendex. The graph representation method is shown in Figure 3.

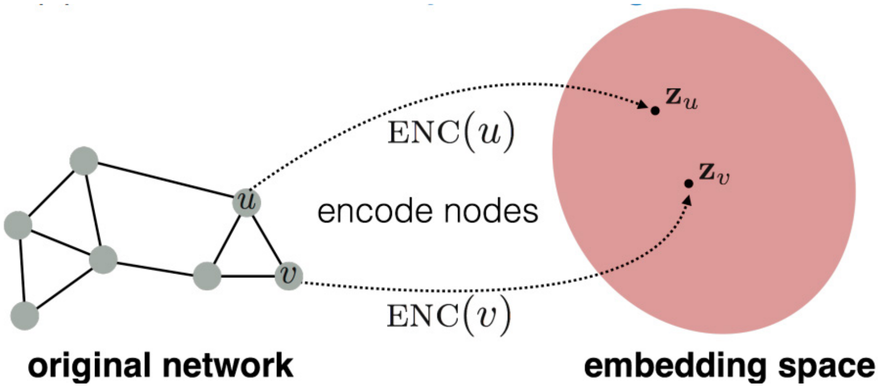

Figure 3. Network representation learning model

The network representation learning gold is to encode nodes so that the similarity in the embedded space is similar to the similarity in the original network. Two key components are encoder and similarity function. The encoder maps each node to a low-dimension vector.

$$\mathrm{ENC}(v) = Z_v \tag{1}$$

Where v is node in the input graph and Z_v is d-dimension embedding.

The similarity function is defined as follows:

$$\text{similarity } (u, v) \approx Z_v^T Z_u \tag{2}$$

Similarity is the edge weight between u and v in the original network. In order to train graph embedding, Loss function was used to calculate information loss, the loss function definition is as following :

$$\text{Loss} = \sum_{(u,v)\in VX\,V} \left|\left|Z_u^T Z_v - A_{u,v}\right|\right|^2 \tag{3}$$

Where the loss is what we want to minimize, $Z_u^T Z_v$ is embedding similarity and $A_{u,v}$ is adjacency matrix for the graph.

Graph representation learning in this paper adopts the node2vec(Grover and Leskovec 2016) model which used the Skip-gram method to extract representation for networks, and strike a balance between depth priority and breadth priority by using Random Walk. In the node2vec, definite the $A_{u,v}$ as log [exp $(Z_u^T Z_v)/\sum_{n\in V}$ exp $(Z_u^T Z_n)$]. By using the Node2vec model, each node in the final network is represented as a dense vector of 128 dimensions, which contain the importance, impact and correlation of disciplines and journals, the discipline representation vector can be used as represent discipline. Discipline represent vector used in the task of discipline correlation strength measurement, cross-discipline prediction and so on. Table 2 shows the example of multisource-system discipline representation vector.

Table 2. Example of multisource-system discipline representation vector

Table	*Dimension 1*	*Dimension 2*	…	*Dimension 128*
Management(discipline)	-0.7661	-0.4544	…	-0.7481
Scientometrics(journal)	-0.5728	-0.1878	…	0.9431

After the network representation learning model used on the information of disciplines and journals, each node in the network will be represented by the unique 128-dimensional representation vector. The further analysis of the representation vectors of disciplines and journals can excavate the rich implicit information in the network.

Experiment

Discipline group identification

Through the single-system discipline representation, we constructed the JCR discipline representation embedding, and multisource-system discipline representation embedding was constructed in the comprehensive discipline network. The above two representations are used to obtain a comprehensive discipline representation vector, which containing single-system discipline representation and the multisource-system discipline representation information through vector merge. Figure 4 shows the process of specific discipline representation vector:
The discipline representation vector is composed of single-system discipline representation vector (comes from the discipline vector space model of knowledge representation learning) and the multi-system discipline representation vector (comes from the network representation learning). The single-system discipline representation vector equal to 234-dimensional, the multi-system discipline representation vector equal to 128-dimensional. The comprehensive discipline representation vector is a linear connection of the preceding two vectors, which equal to 362 dimensions.

362 dimensions
COMPUTER SCIENCE
Comprehensive category embedding

Figure 4. The representation vectors merge of discipline

Through network representation learning, a variety of information in the discipline network is considered and integrated comprehensively into the vector, each information representation entity is mapped into the space of the same dimension, and the distance between all the information representation entity is calculated by using the cosine similarity (the closer the distance, the higher the similarity between the entities). The similarity calculation method is shown as formula (4).

$$\text{Cosine}\,(\text{x},\text{y}) = \frac{X\cdot Y}{||X||||Y||} = \frac{\sum_{j=1}^{t} c_{xj}c_{yj}}{\sqrt{\sum_{j=1}^{t}(c_{xj})^2\sum_{j=1}^{t}(c_{yj})^2}} \tag{4}$$

x,y are two disciplines, X , Y are discipline comprehensive vectors, c_{xj} is the number of representation vector between x discipline and j discipline, t is the number of vector dimensions , which is equal to 362.The result is a positive number which is in the range [0,1] , and the result is 1 when the two vectors are exactly equal. The larger the similarity between the vectors is, the higher the value of cosine method will be. The closer the research direction between disciplines, the greater their similarity, vice versa.

According to the calculation method of the similarity degree of the discipline representation vector, this paper calculated all of similarities between disciplines in JCR and constructed a discipline similarity matrix of 234 times 234. In order to analyse the correlation intensity between disciplines in a balanced manner, this paper selected disciplines with interdisciplinary similarity greater than 0.5, and constructed a cross-discipline network. The weight of the edge is the value of similarity.

Meanwhile, we used Gephi visualization software to make a data perspective on the cross-discipline graph of JCR and used the complex network community detection algorithm to identify the discipline clusters. Different colours represent different discipline clusters. Node size indicates the importance of disciplines in the cluster.

Figure 5. The interdisciplinary graph of JCR classification

Observing the Figure 5, the current mainstream of the subject will be merged into 8 disciplines clusters, the eight-discipline cluster are Physics & Chemistry, Environment & Ecology, Computer Science, Engineering Science, Biology Science, Social Science, Medicine Science, and Psychology Science. By using the discipline representation vector, information about journals and disciplines were integrated into the discipline representation vector. We enlarged the scale of the discipline and journal network to the multisource discipline classification systems, integrated the information transmission of journals in the discipline-related network through multi-system discipline classification, and then the disciplines were used as a bridge to explore the representation methods of the disciplines. Finally, the single-system discipline representation vector was integrated with the multi-system discipline representation vector to obtain comprehensive discipline representation vector in Web of Science. By observing the Figure 5, the comprehensive discipline representation vector can calculate the intrinsic correlation information between disciplines more accurately, and community detection algorithm can make a perspective on the discipline-related network constructed by the representation vector to analyse the present situation of the integration of the disciplines. Today's disciplines have formed about 8 broad categories, different discipline clusters only through a few bridge nodes to generate information transmission. The ability to transmit information is relatively weak between disciplines that are far apart, hence information needs to be transmitted through multiple disciplines.

Discipline group identification

Discipline consists of several journals, and the composition system of the journals is the foundation discipline development. Measuring the degree of cross-correlation between journal and disciplines is important for discipline research. We constructed a discipline entity, mining the similarity between this entity and various journals, thereby discovering compendex.

Taking science of science as an example, science of science is a research field formed by the integration of natural sciences, social sciences, and humanities, and it is a comprehensive discipline to explore the coordinated development of science, technology, economy and society. In order to analysis science of science research direction accurately, through the four core journals (Scientometric, Journal of Informetrics, INFORMATION PROCESSING & MANAGEMENT, Journal of the Association for Information Science and Technology) as science of science source journals, construct science_of_science discipline and add into discipline representation network system, calculate the representation vector of science_of_science . We used the cosine similarity to calculate similarity between discipline representation vectors and journals representation vectors. The calculation method is similar to formula (1). Specially, 128 dimensions network representation vector were used to recognize science_of_science compendex. By calculating the similarity between the representation vector of science of science and all journals, most relevant journals about science of science are shown in Table 3. For ease of observation and analysis, the science_of_science compendex is represented in Figure 6.

In addition to the four original journals, many journals still have strongly relation to science of science. Science of Science top 10 relevance journals as shown in Table 3, through manual examination, other relative journals are also the mainstream journals in which science of science researchers submit research results.

The closer nodes to science of science in Figure 6, the greater the degree of similarity will be. It can be observed that original four journals (Scientometrics, Journal of Informetrics, INFORMATION PROCESSING & MANAGEMENT, Journal of the Association for Information Science and Technology) still have stronger correlation. According to the discipline and journal representation vector, we set similarity threshold as 0.89. Using network representation vector to recognize compendex in discipline could make up empiricism deviation problem.

Table 3. Science of Science compendex (TOP10)

Rank	*Discipline*	*Journal*	*Similarity*
1	science_of_science	aslib journal of information management	0.905
2	science_of_science	information development	0.902
3	science_of_science	econtent	0.899
4	science_of_science	interlending & document supply	0.899
5	science_of_science	journal of documentation	0.898
6	science_of_science	australian academic & research libraries	0.898
7	science_of_science	african journal of library archives and information science	0.897
8	science_of_science	knowledge organization	0.894
9	science_of_science	electronic library	0.889
10	science_of_science	library and information science	0.889

In this way, for any discipline or research field, it is possible to dig out the compendex in discipline and their correlation strengths in the discipline field by constructing the original discipline subordinate network by using the discipline representation vector model. In the process of identifying the compendex of the discipline, it can assist the scientific research scholars to further identify discipline hotspots and excavate discipline cooperation.

Figure 6. Science of Science compendex graph

Conclusion

The construction of disciplines is inseparable from the establishment of a discipline classification system. Rigorous discipline division criteria and clear journal division standards are the basic support for discipline construction. The four interdisciplinary classification systems provide the possibility of integration due to the existence of interdisciplinary journals. This paper proposed two discipline representation models through four interdisciplinary classification systems, analysed the internal domain division of disciplines, constructed two types of discipline representation network. Discipline vector space model of knowledge representation learning model was used to obtain single-system discipline representation vector, network representation learning model was used to obtain comprehensive representation vectors of all disciplines and journals. The two models are dedicated to solving the problems of identification of interdisciplinary groups in the discipline measurement, quantitative calculation & recognition of discipline compendex.

In this process, we used the novel network representation learning model in the field of deep learning for discipline modelling. The applications of the discipline representation learning model proposed are also helpful for issues such as pre-evaluation of discipline development, discipline planning, and prediction of scientific evolution direction. In our work, the representation learning model proposed is not a replacement for traditional bibliometrics, but a method innovation that inherits the essence of classical bibliometrics. It is a preliminary exploratory study in the field of interdisciplinary classification systems, which is to provide a methodology for large-scale data mining when the explosive information growth. In the future work, we would incorporate more information to quantify the discipline representation， explore more effective methods to represent disciplines, integrate the existing discipline classification system for relevant analysis more closely , and summarize more enlightenment brought by the interdisciplinary.

Abstract

Outstanding young scholars play an important role in national development, and thus their cultivation and funding are thriving research topics in academia. This paper studies the common characteristics of the Chinese scholars in the computer science area when they got funded by *the National Science Fund for Distinguished Young Scholars* project (i.e. CCSDY scholars) and creates a persona based on these characteristics. The persona of the CCSDY scholars in this paper includes personal attributes, educational attributes and academic attributes. The personal attributes and educational attributes are extracted from the data of their curricula vitae. The academic attributes are obtained by two processes: conducting a bibliometric analysis of their high-quality papers, and using the three-stage time series topic analysis model to get the most common research topics of these scholars in different time periods. This study accomplished a persona for the CCSDY scholars, reveals the crucial elements in their development and contributes to the guidance for countries to cultivate and fund scholars.

Introduction

As Chambers et al. (1998) argue: “Better talent is worth fighting for”. It is fundamental to cultivate outstanding academic scholars because their contributions are crucial to the development of countries. Therefore, the Chinese government has carried out various projects that facilitate young scholar cultivation and encourage overseas scholars to work in China (Zhu, 2019). It has been found that there is a positive correlation between paper usage (e.g. citation) and funding, which also shows the benefits of funds to the scholars from an academic perspective (Zhao et al., 2018). The funded projects financially support young scholars’ research, and in return, their research achievements can help China make progress in science and technology improvements (Yu et al., 2020). With the rapid growth of artificial intelligence, the computer science area is currently of great interest and attracts more and more scholars devoting themselves to it. And the Chinese scholars in computer science area also made notable contributions to the development of artificial intelligence (Lu et al., 2018).

Creating personas of target users is a widely-adopted method for building a concrete user representation (Pruitt & Grudi, 2003). Although persona is fictitious, it comes from the data of real users and can effectively embody users with demographic and biographical characteristics under modelling (Junior & Filgueiras, 2005). Persona is a useful approach to understand target groups and is mostly used in the user interface (Johansson & Messeter, 2005). In the age of big data, personas can be created with rich and easily accessible data (Guo & Ma, 2018). However, there remains a paucity of studies using personas to describe and model scholars so far.

This research gap is filled in this paper by combining CV analysis method to conduct a multi-dimensional analysis and accomplishing a persona of the scholars when they won *the National Science Fund for Distinguished Young Scholars* project (NSFC, 2018) in computer science area[ii] (i.e. the CCSDY scholars). To derive the research topics and presents their evolution, this paper proposes a three-stage time series topic analysis model (TTSTA model) to extract and analyse the research topics of the CCSDY scholars in three time periods: early, mid-term and recent. Recommendations for practice and policy in scholar cultivation and funding are also set out. The remaining part of this paper proceeds as follows: structure of scholar persona, data collection and processing method, multi-dimensional attribute analysis, result and conclusion.

Scholar persona

The researches on scholar characteristics mainly focus on three aspects: personal, educational and academic attributes. First, within personal attributes, the relationship between the scholars' age and research output has always been of interest (Frosch, 2011). Gender is also a well-studied element, and there have been reflections on the phenomenon of gender imbalance in academia (Lin, 2017). Second, regarding educational attributes, previous research has shown that the guidance of mentors plays a significant role in talent development (Margot & Kettler, 2019). Through the education experience analysis, many meaningful common characteristics were discovered, such as research-embraced culture, a dedicated mentor and partnerships (Archer, 2007). Finally, academic attributes is a growing research area, and the number of papers is the most frequent researched factor (Shen et al., 2016). As a step moved forward, researchers have paid more attention to the research interest of scholars. The topic mining algorithms include the LDA algorithm and the HDP algorithm (Blei et al., 2003; Teh et al., 2006). And Xie (2019) proposed the social network analysis method, which can construct a scholar-paper-journal relationship network to identify potential author collaborations, journal publication trends, and research topics. Moreover, understanding the evolution of research topics is also an important research focus (He et al., 2009).

In this paper, the persona of CCSDY scholars is established based on the three attributes introduced above which are worthy of research and can depict scholars almost completely. Personal attributes include age and gender, educational attributes consist of the level of graduate institutions and academic ability of doctoral mentors, and academic attributes refer to the number of high-quality papers and research topics of high-quality papers obtained from Web of Science.

Method

Data collection

The data used in this paper were collected from the scholars who got funded by the CCSDY project from 1998 to 2019[iii], in all 80 scholars. For personal and educational attributes, the information of age, gender, graduate institutions and doctoral mentors of the CCSDY scholars was obtained from their online profiles on the university websites and various academic web databases. As for academic attributes, the title, publication date, journal or conference information of the papers that published by the scholars before they won the CCSDY project were extracted from the website AMiner, based on Scrapy technology. AMiner was used in this study as an academic database, which chronologically matches scholars to their papers from DBLP, ACM DL, CiteSeerX and other online data libraries (Wan, 2019). Once the data extraction was completed, the high-quality papers of CCSDY scholars were selected according to the academic conference and journal recommendation list released by the China Computer Federation (CCF)[iv]. Finally, to conduct the topic mining, the title of each high-quality paper was entered into the Web of Science search box. If the result existed, the abstract and keywords information in the web page would be parsed, and then Selenium technology was used to download them.

Curriculum vitae analysis method

Curriculum vitae analysis is a method for evaluating candidates by investigating their demographic information and work and education experience, which is often applied to research evaluation (Cañibano & Bozeman, 2009). Combining with statistical analysis methods and multi-aspect data visualization technology, curriculum vitae analysis is adopted in this paper to examine the personal and educational attributes.

Three-stage time series topic analysis model

The HDP algorithm, a hierarchical topic mining algorithm based on the Dirichlet process, is adopted as the core algorithm of the TTSTA model proposed in this paper. Unlike the LDA algorithm that requires users to preset the topic numbers, the HDP algorithm can automatically generate the number and content of the topics according to the characteristics of document sets (Teh et al., 2006). As an extension of the LDA algorithm with no parameters, the HDP algorithm is widely used in various text topic mining tasks (Zhou, 2011). The topic distribution of the document set in the HDP algorithm is represented by the probability distribution DP ($\boldsymbol{\alpha}$, H). For document J in a document set, its topic distribution G_j follows the distribution represented by DP (α_0, G_0) and the generation process of its topics is as follows: first determining the topic distribution of the document set by forming the Dirichlet process based on the base distribution H and parameter $\boldsymbol{\gamma}$, and then deducing the topic probability distribution $G_i \mid \alpha_0 G_i$ ~DP (α_0, G_0) of document J by forming the Dirichlet process based on the base distribution G_0 and hyperparameter $\boldsymbol{\alpha}$. The formula (1) for modelling the frequency of words in topics is shown below:

$$f(x_1, x_2 \ldots x_k, \alpha_1, \alpha_2 \ldots \alpha_k) = \frac{1}{B(\alpha)} \prod_{i=1}^{k} x_i^{a^i - 1} \tag{1}$$

B (α) in the formula (1) can be calculated by formula (2):

$$B(\alpha) = \frac{\prod_1^k \tau(\alpha_i)}{\tau(\sum_{i=1}^k \alpha_i)} \tag{2}$$

To analyse the research topics of CCSDY scholars in different periods and their topic evolution, the TTSTA model is proposed as shown in Figure 1. According to the publication date, all of the papers which can be found in Web of Science and published by each scholar before they got the CCSDY funding are sorted chronologically and in order to ensure the accuracy of the HDP algorithm and avoid the margin division error, these papers are equally divided into three stages: early, mid-term and recent. In case the number of papers can not be equally divided, the extra papers will be assigned to the stage where their closest published paper locates. Next, the HDP algorithm is used to obtain the research topics in each stage, and thus the common research topics and their evolution are finally acquired.

Personal Attribute Analysis

Age

The age of scholars can reflect the progress of relevant disciplines and the time patterns of scholar development. This study finds that the age of CCSDY scholars when they got funded was averagely 41 and ranged from 31 to 45. When they won the CCSDY project, only one of them was 31 years old, while there were 17 of them was 45 years old. Most CCSDY scholars were between 40 and 45 years old, and there were only five scholars younger than 35 years old. From 1998 to 2009, the average age of each year has generally shown an upward trend. And after 2009, the average age of each year was stably between 40 and 45.

These results can be explained by two possible reasons. Firstly, there is an age limit in the project requirement, where China stipulates that the applicants have to be under 45 years old on the first day of the application year. Therefore, scholars may strive harder when they were older than 40 years old to catch the last chance of being funded by the CCSDY project. Secondly, scholars need a long period to accumulate research achievements, cultivate academic sensitivity and judgment, and assemble excellent research teams. And it is unlikely that scholars who are new to the academic career can have such abilities and reach this stage.

Gender

Among 80 CCSDY scholars, there are five females (6.25%) and 75 males (93.75%), indicating a significant gender imbalance in the CCSDY project.

Such imbalance exists in various industries and research areas and can be attributed to many reasons. For instance, the traditional view that females are less good at engineering than males may cause a negative impact on female scholars in the computer science area (Smeding, 2019). Meanwhile, affected by the eastern traditional history and culture, female scholars in China often face more pressure than man when balancing family and scientific research, which also harms their long-term investment in the academic career (Xu, 2019).

Before 2018, only two female scholars got funded by the CCSDY project, and both of them had top doctoral mentors. One of them was supervised by a leading researcher of the Chinese storage field. And the other was supervised by an academician of Chinese Academy of Sciences, whose research on the *Goldbach conjecture* is widely acclaimed by the worldwide mathematicians (Wikipedia, 2020). Nevertheless, from 2018 to 2019, three female scholars accepted CCSDY funding, making positive progress on this issue.

Educational Attribute Analysis

Educational experience

After personal attribute analysis, the level of institutions the CCSDY scholars graduated from will be analysed in this section, including their bachelor, master and doctoral degrees. In China, universities can be ranked by academic level from highest to lowest in the following order: 985 universities, 211 universities, ordinary universities, and junior universities, and there are also some universities in Hong Kong and Macao. Other than universities, the Chinese Academy of Sciences (CAS) is also a top scientific research institute that can grant an academic degree in China. Three pyramids of the graduate institutions that cultivated more than two CCSDY scholars are presented in Figure 2.

Figure 2. Pyramids of the graduate institutions of the CCSDY scholars

It is found that most CCSDY scholars completed their academic degree programs in 985 universities, among which the proportion of universities of science and engineering is significantly higher than comprehensive universities. This phenomenon may due to the fact that 985 universities possess relatively richer and better resources than other universities (Huang, 2014). Plus, universities of science and engineering focus more on practice than comprehensive universities, which better meets the cultivation need of CCSDY scholars owing to the practical features of computer science. Among the top part of the pyramids, Xidian University is the only 211 university, while the rest are 985 universities. Xidian University has long focused on electronics and information technology, which may indicate that an advanced level of certain disciplines can facilitate the development of scholars in relevant areas.

Tsinghua University is at the top of all the three pyramids. As a leading university in China, Tsinghua University has a strong computer science faculty and vast laboratory resources, contributing numerous outstanding scholars. Note that CAS joins the topmost part of the doctoral pyramid. In CAS, researchers identify themselves more as research staff instead of students, leading to different cultivation system from universities. And such enterprise-oriented education may have a positive incentive effect on the development of CCSDY scholars.

From left to right, Figure 3 reveals the path of the graduate institution level of CCSDY scholars, including bachelor's, master's, and doctoral degrees. Studying in 985 universities for the three academic degrees is the most common path among CCSDY scholars. Thirty-nine CCSDY scholars followed this path and got access to top mentorship and sufficient laboratory resources starting from their bachelor program. Besides, the education path of CCSDY scholars who completed bachelor programs in 211 or ordinary universities shows an upward curve in Figure 3, which means they tended to turn to research institutions at a higher level for better educational resources. However, it is found that CCSDY scholars who enrolled in Xidian University for their bachelor's degree prefer to continue studying in Xidian University instead of applying for a 985 university, which further manifests the advantage of Xidian University in cultivating computer science scholars.

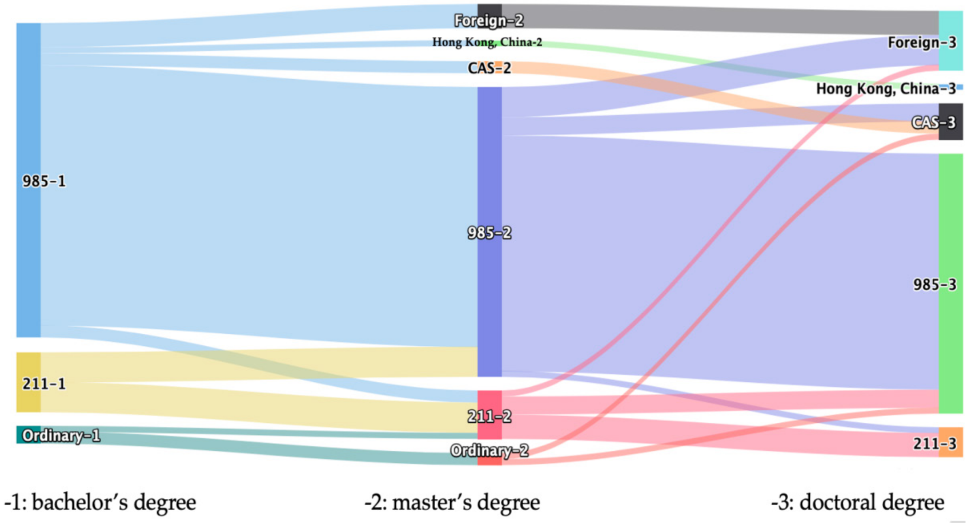

Figure 3. Higher education tracks of CCSDY Scholars

Furthermore, there has been a growing trend for CCSDY scholars to study abroad. Studying abroad allows scholars to absorb knowledge under superb guidance and broaden academic visions, which is an efficient way to improve creativity, develop new insights and help scholars make research breakthroughs.

Interaction and selection between research institutions and scholars. It can be seen from the educational experience that there exist two-way interaction and selection between universities and scholars. On the one hand, scholars prefer research institutions with more outstanding talents, advanced equipment and excellent mentors. On the other hand, academic institutions also tend to recruit distinguished scholars. Although it can not be denied that scholars already had high research potential before entering universities, the fact that most CCSDY scholars graduated from 985 universities shows a strong effect of research environment on the development of scholars.

As only five CCSDY scholars were younger than 35 years old when they received the funding, their curricula vitae were analysed in detail. Three of them worked as researchers in the top Internet companies in the United States, which helped them acquire practical experience and apply enterprise problem-solving skills to their research.

Doctoral mentorship

Mentorship is also a crucial factor in educational attributes. Based on the CCF field classification[v], this paper divides research fields of CCSDY scholars into seven: multimedia, network, architecture, software, data mining, cross and information security. The most popular research field is multimedia, which attracted 24 CCSDY scholars to contribute to it. After classifying CCSDY scholars into the seven research fields, their PhD mentors are divided into the corresponding fields. As shown in Figure 4, this paper classifies scholars with excellent academic ability into the following five categories: Academician of Chinese Academy of Science (ACAS), Academician of Chinese Academy of Engineering (ACAE), State Council Special Allowance Expert (SCSAE), the CCSDY scholars (CCSDY-mentor), and other top scholars. The scholars who do not belong to any of the five categories are called ordinary scholars in this paper.

Top mentors. It is found that two-thirds of the CCSDY scholars were guided by top mentors in their doctoral program. And the proportions of top mentors in software (77.78%), architecture (90.91%), and cross (77.78%) are relatively large. Top mentors can help students develop research interests, proper research habits and critical thinking skills. At the same time, students can use their mentors' personal networks to gain better resource. For example, they can know more outstanding scholars with whom they can communicate and get excellent inspiration. However, many scholars can still become outstanding without top mentors, especially in applied fields such as network (33.33%) and information security (40.00%). Because these applied fields involve a wide range of research objects and applications and are in a vigorous development period, scholars can independently exert their research strength on a specific issue in these fields. Interestingly, a leading scholar in architecture cultivated two CCSDY scholars, and one of them also supervised one CCSDY scholar, presenting a clear line of the mentoring relationship.

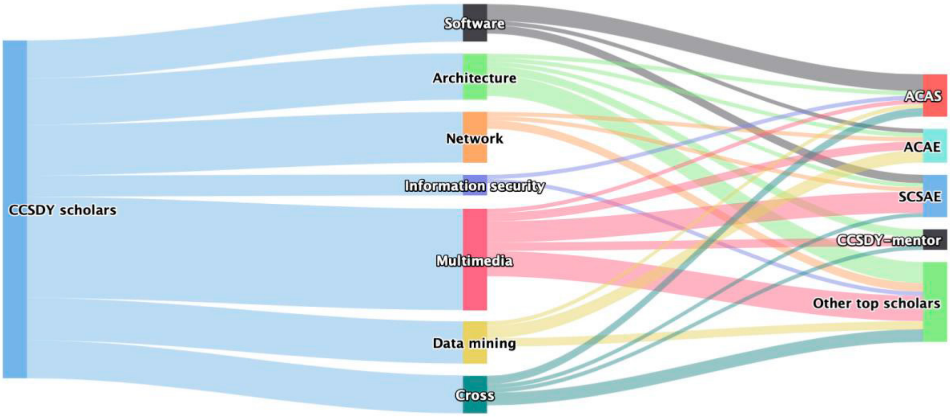

Figure 4. Mentor's field and academic ability classification

Academic attributes analysis

High-quality papers

A bibliometric analysis was conducted on high-quality papers published by scholars before being funded by CCSDY project. The average number of high-quality papers published per year shows a gradual growing trend from 1998 to 2019, which rose rapidly in 2015. On average, each CCSDY scholar published 63 high-quality papers before they received the funding. In recent years, CCSDY scholars have published an increasing number of papers on international journals and conferences, sharing research achievements with worldwide researchers. Following the lead of CCSDY scholars, there will be a growing trend of Chinese computer science scholars to be active on the international stage and contribute to the whole world.

Research topics

Although the research of CCSDY scholars may not be the most representable in computer science area, it is useful and meaningful for the country's development, which can help other scholars for reference. The research topics of CCSDY scholars are examined by the proposed TTSTA model from both vertical and horizontal perspectives. Vertical perspective refers to discovering common research topics among multiple scholars and focuses on the research hotspots. Horizontal perspective means to analyse the evolution of the research topics and focuses on the academic development of one single scholar. Due to the enormous quantity of data, only the research topics of 3326 papers from 37 scholars who got funded in the last five years are analysed, and only the research topics of four fields are displayed in Table 1 and discussed in the analysis below.

Table 1. The samples of CCSDY scholars' research topics in different fields.

Fields in computer science	*Early Topics*	*Mid-term topics*	*Recent topics*
Multimedia	Face detection/recognition Facial expression recognition Image segmentation ...	Facial expression analysis Expression recognition Image retrieval ...	Activity identification in group Object segmentation Facial expression analysis ...
Data mining	Keyword extraction Web topic discovery Citation recommendation ...	Biological relationship mining Academic data analysis Name disambiguation ...	Recommended friends on Social networks Topic extraction Cross-language knowledge Base construction ...
Network	Network data packet transmission method Data packet Network data packet transmission efficiency ...	P2P network Packet compression Route lookup ...	Video delivery Network attack detection Network transmission loss data recovery ...
Software	Software component configuration Component management Web container ...	Web application overload control Version compatibility of software evolution Location and recovery of failed components ...	Open-source project development and maintenance Classification of problems in software development Analysis of community members in open source software projects ...

Firstly, in the multimedia field, scholars all contribute to applying technology to practical scenarios. Most multimedia scholars focus on the classification, positioning, detection and segmentation of information in videos and images. In its sub-field of video research, the analysis of the movement in videos and the video plagiarism detection are the research focus. In another sub-field, image research, the most popular topics are face recognition and facial expression recognition, which have high commercial and practical value. As for the topic evolution, from face recognition, facial expression recognition to micro-expression recognition, it can be seen that the research in this field is more refined and the technical complexity becomes higher, which can bring more accurate results. For example, micro-expression recognition can be used to determine the change of people's emotion, and thus can be utilised in the medical field for mental treatment or in the national security field for deception detection (Takalkar et al., 2018). All in all, such refinement in research can help lead to a broad prospect of practical application.

Secondly, CCSDY scholars in the field of software are most interested in web services and software development. The former includes evaluation, optimization, search and recommendation of web services. The latter consists of component configuration, combination, management, faulty component location and recovery. Besides, it is discovered that the evolution of research topics in software development is highly consistent with real-life technical needs. Thirdly, in the data mining field, one of the research paradigms is first conducting topic mining and keyword extraction, based on which the later research will explore new topics with prospects of technical integration and practical application. Another paradigm is to first focus on practical issues in specific fields, and continuously deepen and refine the research topics. Finally, the network field mainly focuses on basic research subjects, for example, routing lookups of data transmission, and the avoidance and detection of network congestion.

Three topic evolution paths. From the changes of research topics in different periods, it can be concluded that there are three paths of research topic evolution among the CCSDY scholars: (a) from basic technical problem to practical applied problem; (b) from existing technology to new integrated technology; and (c) from macroscopic topics to in-depth topics.

The persona of CCSDY scholars

After analysing the common characteristics of CCSDY scholars through three attributes, the persona of CCSDY scholars is established as shown in Figure 5.

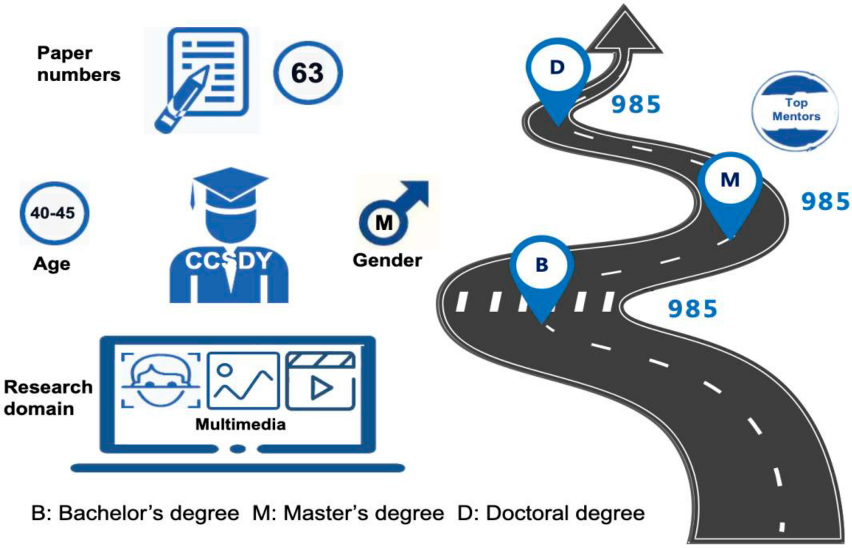

Figure 5. The persona of the CCSDY scholars

From this persona, the image of CCSDY scholars can be interpreted as follows:

1. Most CCSDY scholars are between 40 and 45 years old, and there are far more male scholars than women scholars.
2. As for higher education, CCSDY scholars tend to study in 985 universities from bachelor to doctorate and be supervised by top mentors in their doctoral study.
3. The average number of high-quality papers published by the CCSDY scholars is 63, showing an upward trend. And many of the CCSDY scholars mainly work in image and video research, in which face recognition, image segmentation and video detection are the most popular research topics.

Discussion and conclusion

This paper has analysed common characteristics of the CCSDY scholars and completed a persona of them, based on which the following conclusions and practical implication on scholar cultivation in the computer science area are drawn.

To begin with, the ageing and gender imbalance of CCSDY scholars should raise the attention of the funding institutions. The energy and passion of young scholars are invaluable, and thus the relevant preferential policies to promote young scholars are expected to be introduced. This paper has also shown the lack of female CCSDY scholars, suggesting that more support for females in education and research funding are needed to ensure a fair environment for them to study and work.

By analysing the work experience of relatively young CCSDY scholars, this paper has found that most of them worked as researchers in American top Internet companies. The research experience in an enterprise can enhance coding ability and understanding of practical applications, which improves both problem-finding and problem-solving ability. Therefore, more school-enterprise cooperative research projects will be more conducive to the development of computer science scholars.

Through the analysis of educational experience, it is found that there are interaction and selection between research institutions and scholars. It is more beneficial for scholars to apply for a higher-level institution, and capable universities are inclined to recruit excellent students. Also, the top research strength and reputation of high-level institutions are of great help for scholars to win the funding project. And studying in universities of science and engineering are advantageous for the development of scholars in the computer science area.

Next, the guidance from top mentors is a strong positive incentive for CCSDY scholars. Two-thirds of CCSDY scholars were supervised by top mentors, which caused the Matthew effect of distinguished scholars. If the country makes more efforts to cultivate the CCSDY scholars, they will also bring more outstanding students and core scientific research outputs. The dependence of top mentors varies in different fields. Scholars in applied fields such as network and information security are not reliant upon top mentors. For the fields of architecture, software, and cross, the proportion of top mentors is relatively large.

Besides, the distribution of CCSDY scholars in different computer science fields is also unbalanced, and there are far more CCSDY scholars in multimedia than in other fields. It is crucial to develop hot research fields, but other fields also need advancement. Moreover, basic research is the foundation of technological development and insufficient support for basic research may cause stagnation after a short period of boom. Therefore, academic funding projects should pay more attention to less popular fields and basic research fields.

Finally, there are three main characteristics of the research topics of CCSDY scholars: (a) in-depth exploration, which means refining research questions; (b) interdisciplinary expansion, which means extending and applying existing technology to new research objects and fields; and (c) integration, which means the combination of existing technology and new technology. Based on consolidated basic research, promoting communication among scholars within the field can facilitate integrating new technologies. Sharing of cross-disciplinary hot topics, technical exchanges, and research collaboration will also benefit the interdisciplinary expansion.

Limitation

This paper has conducted an in-depth analysis of factors in talent development and provides a deeper insight into the cultivation of computer science scholars in China. Nevertheless, there are still several limitations and recommendations explained as follows:

- Family and work experience are essential elements in the growth of scholars. But this paper is limited by the lack of these information attributed to the difficulty of relevant data collection. A further study could assess the effects of family and work experience factors.

- There are correlation and interactions between multiple subjective or objective factors in the development of scholars. Unfortunately, the paper did not examine the relationships between these factors, which would be a fruitful area for further work.
- Since there is no public information about the scholars who applied to *the National Science Fund for Distinguished Young Scholars* project but failed, it is difficult to explore the correlation between funding and the three characteristic groups.
- In the research topics section, because the sources of all high-quality papers are varied, abstracts and keywords are difficult to get, so we only use the papers which come from Web of Science. If we can analyse all high-quality papers, this research will be more complete.
- The data used in this paper were obtained from several open web databases, and there is a small part of missing data, which may lead to slight deviations in the analysis.

Abstract

China’s science and technology evaluation policy (S&TEP) guides China’s science development. The purpose of this research is to analyze the topic evolution of China’s S&TEP and the public’s response to the S&TEP. We take reform and opening up in 1978 as the starting point and divide the development process into four stages. We collected 170 S&TEP retrieved from database. Latent Dirichlet Allocation (LDA) modeling was used to identify policy topics of each stage. Then, taking the policy *Suggestions on the Correct Use of SCI as Research Evaluation Criterion and the Establishment of Proper Guidelines for Research Evaluation (2020)* as an example, the public understanding of this policy was summarized by analyzing comment data from Chinese newspapers, academic papers, social media, and foreign media websites. The results show that: (1) most significantly, the topic of China’s S&TEP has shifted from tilting to the quantity of publications to raising the quality of publications; (2) the evaluation approach has shifted from peer review to quantitative evaluation, and to breaking quantitative evaluation and building a comprehensive system at present; and (3) the text of China’s S&TEP has the implications beyond the text itself, but they are easy to reach common acceptance among Chinese scholars.

Introduction

Since the implementation of the reform and opening-up in 1978, China has made significant progress in science and technology innovation. Science and technology (hereafter referred to as S&T) evaluation is an important part of S&T management. Looking back at the changes in China’s science and technology evaluation policy (hereafter referred to as S&TEP) over the past four decades, they are often accompanied by major problems encountered in S&T management. In early 2020, the Ministry of Education and the Ministry of Science and Technology jointly issued two policies on discouraging the use of SCI and paper-oriented evaluation system, which marks the beginning of the reform of China’s S&T evaluation system. Such a revolutionary transition keeps drawing serious attention of the entire S&T community in China and even abroad from the very moment they were brought about (Mallapaty, 2020). Discussions on them appear on newspapers, journals, online forums, social media, etc. However, the discussion appears to be highly controversial and non-systematic. Some questioned the rationality and viability of specific items in the policy documents or the policies as a whole (Li, 2020), while others concerned what are to be the adoptions over the renunciations (Chen & Zhang, 2020; Ye, 2020). Still others seek to reveal the “real intentions” of the policy makers, evaluating the situation that China’s science and technology has been in face of (Qian et al.,2020).

Our study aims to analyze the topic trends of China’s S&TEP and public response to the new policy, and reveals the evolution pattern and inner meaning of China's S&TEP to help researchers better understand policies and provide insights for the future adjustment of S&T evaluation systems. The study is divided into two parts. In the first part, we investigate the development history of China’s S&TEP and grasps the characteristics of each stage by analyzing the topic evolution of policies at different stages. The second part is presented as a case study, in which we take the policy about reforming SCI-oriented evaluation system as an example and conduct a systematic investigation of the public discussions on the policy.

Data and methodology

Data collection

The data set includes S&T policy documents and the data of public comments. The policy documents are obtained from PKULAW (A Database of China Policies developed by Peking University). In order to cover all the important policies related to China's S&T evaluation formulated at the national level since 1978, we conducted full-text retrieval with search terms such as "research evaluation" and "S&T evaluation". Due to the large number and diverse content of the policies, we manually sorted the policies according to the following criteria to ensure the accuracy of sample selection: (1) the effectiveness of the policy is administrative regulations and departmental rules, which were issued by the CPC Central Committee, the State Council and related departments; (2) the type of policies does not include leadership speeches, letters, instructions, etc.; and (3) the content of the policies is closely related to S&T evaluation. After repeated selection and verification, 170 effective policies were finally sorted out. Figure 1 shows changes in the number of policies over time.

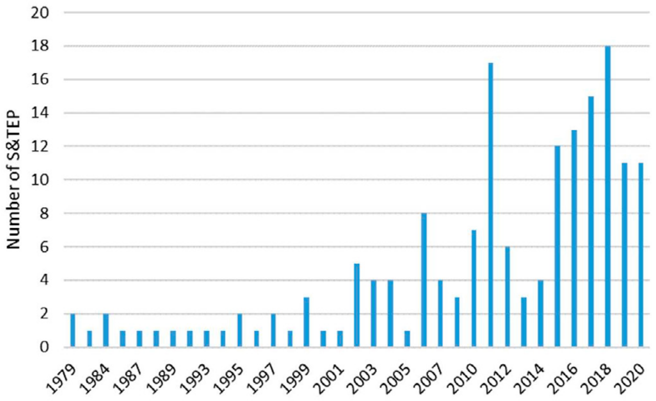

Figure 1. The annual number of China's S&TEP since 1978.

The public comments data set is about the policy *Suggestions on the Correct Use of SCI as Research Evaluation Criterion and the Establishment of Proper Guidelines for Research Evaluation*. Since the S&TEP is mainly for S&T workers, the data we selected come from four channels: domestic official media, academic online forum, scientific papers, and foreign media. Among them, domestic official media data are obtained from two important Chinese newspapers--the People's Daily and Guangming Daily. They are authoritative sources for obtaining official news, policy propositions, and mainstream ideas in China. The academic online forum comment data is collected from the ScienceNet website (http://www.sciencenet.cn/). ScienceNet is currently the world's largest Chinese science community and an important platform for Chinese scholars to conduct academic exchanges. The relevant data of scientific papers is obtained from CNKI, which is a Chinese academic journal database. The number of policy comment data for various channels is shown in the Table 1.

Table 1. The number of comment text in each source.

channel	*source*	*number*
Newspaper	People’s Daily & Guangming Daily	35
Online forum	ScienceNet	48
Scientific papers	CNKI	59
Foreign media	GOOGLE	15

Methodology

For sorting out the development process of S&TEP, we adopted the LDA topic model method. LDA (Latent Dirichlet Allocation), is an important text mining method used in topic discovery tasks to reveal hidden topic patterns in large-scale corpora. The model is developed from pLSA (Hofmann, 1999), which solves problems of pLSA such as overfitting (Blei et al., 2003). Since it is an unsupervised learning method that does not require labeled training set samples, it is one of the most widely used models today.

LDA is essentially a three-level hierarchical Bayesian model. It uses “bag-of-words” model to represent documents and maps complex high-dimensional words in unstructured documents into a low-dimensional space of "document-topic-word" to obtain document clustering. The basic idea is that the documents in corpora are represented as the probability distribution of a series of latent topics, and each topic is represented as a series of word distributions (Blei et al., 2003).

In this study, LDA was performed by using Gensim Python library. Before modeling, some preprocessing work has been done on the policy texts such as eliminating stop words. Then we apply the LDA model to the full text of the policy at each of the four stages. Ten keywords with the highest probability are selected to represent the characteristics of each topic. For each policy text, the topics are ranked according to probability values, and the top 3 categories are selected as the most representative topics. Through the comparison of the probability distribution of the topic, the evolutionary characteristics of China’s S&TEP are discussed.

How to determinate the best number of topics is an important but controversial matter (Arun et al. 2010). Perplexity is a topic clustering performance evaluation method based on a small data set, which is often used as a criterion to determine the number of topics (Blei et al., 2003; Miyata et al., 2020). It refers to the degree of uncertainty of the model about which topic the document d belongs to. We draw the perplexity curve after trying different topic numbers, and use the pyLDAvis tool to visualize the generated topics. The appropriate number of topics can be found by combining the visualization results and perplexity values.

Analysis of the development stage of China’s S&T evaluation system

Scholars have different opinions on how to classify the development stages of China’s S&T evaluation system. Xu et al. (2018) divided the development history into three stages: restoration and reconstruction(1978-1984), exploration and practice(1985-2003), and institutional regulation and construction(2003-); Gou et al. (2020) analyze the development of research evaluation policy in China and divided it into four stages: initial development period (1949-1976), restoration and adjustment period(1977-1989), wandering change period(1990-2001), and perfection and advancement period(2002-); through the analysis of science and technology evaluation papers, Du et al. (2020) divided China’s S&T evaluation research into four stages: 1978-1993, 1994-1997, 1998-2007, 2011-2015. In general, scholars’ division of the stages of S&T evaluation system development is mostly based on important national historical events or strategic shifts, but the analysis of policy development after 2000 is relatively weak. In order to fill the gap, based on the reform of S&T system and the release of important policies in S&T evaluation activities, we explore new division of the development of

S&T evaluation in China since 1978. The evolutionary history can be divided into four periods, which have their own characteristics.

1978-2003

We conducted a topic analysis of the 29 policy documents in this phase, and the keywords and their corresponding probabilities of each topic are shown in Table 2. Talent development (A1), S&T awards (A2), and research management (A3) were the key topics in this stage.

Table 2. Latent Dirichlet Allocation results for the period 1978–2003.

Topic	*Keyword*	*PR*	*Keyword*	*PR*
Talent Development (A1)	S&T Evaluation	0.007	Life Benefits	0.0023
	S&T	0.0044	S&T	0.0023
	Human Resources	0.004	Jury	0.0022

	Evaluation	0.0032	Committee	0.0021
Research Management (A3)	Colleges and Universities	0.0049	Research Institutions	0.003
	Assessment	0.0032	Review Experts	0.0027
	Humanities & Social Science	0.0032	Change	0.0024
	Program	0.0031	Training Program	0.0022
	Basic Research	0.0031	Originality	0.0022

The most recent revolutionary shift in China's strategy of S&T development can be dated back to the late 1970s. In March 1978, the first National Congress of Science was held in Beijing (Wang, 2018). The congress sought to rectify the attitude of government and the people towards S&T as well as S&T workers. These events signalled that China has entered a new phase in the development of Science and Technology. Since then, China has successively restored its professional title system and S&T award system. Topics A1 and A3 of policy in this stage also illustrate the point. In 1985, China began to reform the S&T evaluation system, proposed to break the long-term planned economic system, and gradually increased funding for various competing projects (Wang et al., 2018). This reform marked the beginning of project funding from a government-led model to a competitive model. Project establishment and review, S&T achievements evaluation, and performance evaluation have become important parts in scientific and technological activities.

The reforms have largely reshaped the S&T community in China. The urgency of compatible and efficient evaluation systems was uttering. Before the 1980s, the evaluation system in China was generally criticized as highly subjective which is mainly based on the opinions of experts and administrators of institutes. The peer-review-based evaluations without well-designed instructions and restrictions were not proved to be well-functioning in the society where *guanxi* (a Chinese word representing the complex social relationships between individuals) played a significant role (Zweig, 1997; Zweig, 2006; Zweig & Wang, 2013). The introduction of foreign bibliographic databases such as SCI into China's evaluation systems in the 1980s started an era of "quantity". In 1987, the Institute of Scientific and Technical Information of China (ISTIC) first used the numbers of publications indexed in several bibliographic databases to evaluate the research ability of institutes in China. This is marked as the first formal attempt in China to use quantitative methods based on bibliographic indexes in the evaluations. For the evaluation of individuals, Nanjing University was the first to build direct links between the number of SCI papers and monetary awards (Shao & Shen, 2012). Owing to such a policy, Nanjing University produced the largest number of SCI papers among all the universities in China for 7 straight years in the 1990s. Some argue that they have opened the "Pandora's box" because the usage of bibliographic indexes spread quickly to the whole country and eventually turned the research evaluation systems into SCI-based and SSCI-based ones (Cao, 2008; Quan et al., 2017)

2003-2010

We conducted a topic analysis of the 24 policy documents at this stage, and the results are shown in Table 3. The topics of the second-stage can be sorted into three categories: research integrity (B1), research evaluation (B2), and talent evaluation in various fields (B3).

Table 3. Latent Dirichlet allocation results for the period 2003–2010.

Topic	*Keyword*	*PR*	*Keyword*	*PR*

	Academic Ethics	0.0046	Evaluation	0.0035

In the 1990s, the introduction of SCI and the promotion of quantitative indicators such as the number of papers caused S&T evaluation activities to heavily rely on quantitative indicators (Xu et al.,2018). The practice of "judging heroes by quantity" and the linking of S&T evaluation results with profits have led to scientific researchers' eagerness for quick success and profit. At the same time, the problem of "guanxi" of peer review in the evaluation activities such as project, job title and achievement have still not been well resolved. In addition, the development of the scientific research evaluation system is not perfect. The evaluation of research results in different disciplines and fields often adopts a unified evaluation standard. The irrationality of this approach has gradually been exposed. These problems began to arouse the attention of academia and the government. A very important topic of evaluation policy issued by government in this stage is research integrity (B1).

The year 2003 was an important turning point in the development of China's S&T evaluation. Five departments jointly issued the Decision on Improving the Work of Science and Technology Evaluation. The decision clarified that S&T evaluation should always put quality in the first place, pay attention to original innovation, and must not replace quality with quantity. For talents, different evaluation indicators should be determined according to different levels and types of scientific and technological work. Subsequently, in 2007, the NPC Standing Committee revised the Law of the People's Republic of China on Science and Technology Progress and formally established the legal status of the S&T evaluation system, pointing out that the state should "establish and improve a science and technology evaluation system that is conducive to funding innovation", and implement classified evaluation in accordance with the principles of fairness, justice and openness.

On the whole, China's S&T evaluation activities have gradually become formal and standardized at the stage. Various policies have emphasized two initiatives that focused on the quality of results rather than numbers and the implementation of categorical evaluation. The evaluation methods for talents are gradually standardized. As it can be seen in Topic B3, policies related to talent evaluation are beginning to be developed in areas such as agriculture and medicine and health.

2010-2018

We analysed 76 policy texts in this phase, and the results are shown in Table 4. Research evaluation in universities (C1), research evaluation in medical field (C2), S&T talent evaluation (C3) and talent evaluation in various field (C4) were the key topics in this stage.

Table 4. Latent Dirichlet Allocation results for the period 2010–2018.

In 2010, the State Council successively issued the *Outline of the National Medium and Long-term Talent Development Plan (2010-2020)* and the *Outline of the National Medium and Long-term Education Reform and Development Plan (2010-2020)*. Subsequently, China's 12th Five-Year Plan was launched. *The outlines* propose to "improve the innovation and quality-oriented scientific research evaluation mechanism" and "overcome the tendency of only academic, only qualifications and only papers". The dissemination of the outline lays the foundation for the formulation of Research Evaluation in Universities and talent evaluation plans. Various fields have successively issued policies related to the evaluation of scientific and technological talents in this field. It can be reflected in the policy texts as Topic C3 and Topic C4.

In 2013, the Ministry of Education issued the *Suggestions on Deepening the Reform of Scientific and Technological Evaluation in Colleges and Universities*, pointing out the problems in S&T evaluations such as focus on quantity at the expense of quality and focusing on form and neglecting content. And *the Suggestion* emphasized the need for classified evaluation in colleges and universities, increasing international peer evaluation and third-party evaluation, focusing on the quality of technological innovation and practical contributions. In 2016, president Xi proposed at the National Science and Technology Innovation Conference to "establish a classification and evaluation system oriented on the quality, contribution, and performance of scientific and technological innovation", which further pointed out the direction for optimizing S&T evaluation.

2018-present

We conducted a topic analysis of 40 policy documents at this stage, and the results are shown in Table 5. The policy text at this stage can be summarized into research evaluation (D1), *Four only* (D2), and S&T innovation (D3).

In July 2018, the Chinese government has issued a policy aimed at reforming the evaluation systems of projects, workers and institutes in the S&T section. For the evaluation of workers in the S&T section, specifically, the policy document prescribes that "such tendency must be renounced that the evaluation for individuals based solely on their academic papers, solely on their professional titles, solely on their educational backgrounds or solely on their received awards and honours". A formulation later widely referred to as *four only* thus came into being. Later in November 2018, the *four only* formulation was extended into *five only* by the Chinese Ministry of Education who then launched a special action aimed at implementing such policies in universities. Behind the simplistic formulations are a series of principles, rules, restrictions and ideas that seek to govern China's S&T evaluation practices in all aspects. For simplicity, in the below text, we will refer to the policies related to the *four only* or the *five only* altogether as *the only*. Topic D2 reflects this focus of work during the stage.

The ultimate goal of *the only* is, as is prescribed by the Ministry of Education, to reform China's S&T evaluation systems into quality-oriented ones which mainly consider the quality, contribution and impact of works. It is also proposed that the evaluation be based on the representative works, i.e., a subset of all the works, of the subject, thus breaking the quantity-oriented traditions to a larger extent. This main purposes of *the only* can be broken down into two. The first is that the evaluation activities not be over-simplified so that a single evaluation item, which could be academic paper, professional titles, etc., becomes of paramount importance and decisive for the evaluation. Another intention is to standardize the use of foreign bibliographic indexes such as SCI, SSCI and EI. These bibliographic indexes have greatly re-shaped the evaluation systems in a way that they became the only criteria to judge the quality of research outputs (Cao, 2008; Quan et al., 2017). Such an orientation has indeed helped China's S&T earn higher impact and a prestigious position in the global society over the past few decades. However, as they no longer fit China's current quality-oriented evaluation systems, they are to be criticized and renounced.

The *only* is, of course, not merely advocations. The Chinese governments have shown great resolution through a series of policies and actions that followed up. In February 2020, for example, two back-to-back policies were issued by the government aiming specifically at renouncing the mis- and over-using of academic papers in the evaluations. The former, issued by the Ministry of Science and Technology, prescribed several punishments for institutes that refuse to practice their evaluation activities in accordance with the policies. The latter, issued by the Ministry of Education and the Ministry of Science and Technology, was more particular in that it explicitly targeted at standardizing the use of Science Citation Index (SCI).

Topic trends

Fig. 2 shows the topic trends of the development of china's S&TEP. The size of the circles indicates the number of policies corresponding to each topic.

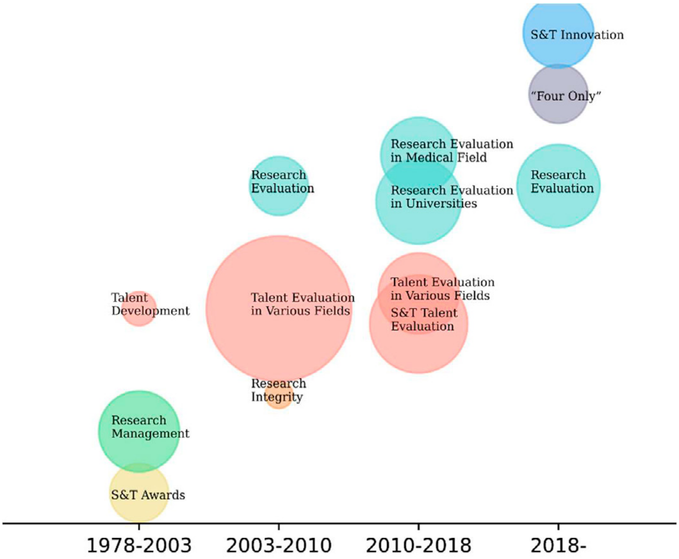

Figure 2. The topic trends of the development of china's S&T evaluation policies.

First, the figure shows that China's S&T evaluation policies involves various aspects such as S&T awards (A2), talent evaluation (A1, B3, C3, C4), research management and evaluation (A3, B2, C1, C2, D1), and research integrity (B1). Talent evaluation and research evaluation are two important topics evenly distributed in all stages, and involved fields are expanded in the development process. Secondly, combined with the keywords in each topic, it reveals that the policies in different periods are closely related to the social context in which they are located and the development of national S&T innovation. The fundamental driving force of the periodic transformation of S&TEP is the inability of the policies to adapt to the current situation of S&T development. After China's reform and opening up, S&T development is back on the agenda. Evaluation activities such as awards and titles are in urgent need of support from the evaluation system, so China's S&TEP has entered a period of exploration, achieving a transformation from non-existence to existence. The traditional peer-review method was mainly adopted at the stage. With the introduction of quantitative indexes such as SCI and CSSCI, quantitative evaluation methods began to be emphasized. However, imperfect evaluation system and the abuse of quantitative indexes leads to various problems, which prompting S&TEP to enter the stage of standardization. In this stage, evaluation policies were gradually standardized and the quality-oriented classification evaluation was proposed. Since the beginning of the 12th Five Year Plan, china formulated long-term plans for talents and education, which has greatly promoted S&TEP into the stage of innovative development. Innovation and originality become the primary evaluation criteria. Nowadays, China's modernization has put forward higher requirements for national science and technology innovation capacity, the proposal of breaking the *four only* and SCI-oriented system is regarded as the key point, and S&T evaluation activities are moving towards a new stage of comprehensively breaking the quantitative evaluation system and building a new evaluation system with Chinese characteristics.

In general, China's S&TEP has moved from singularity to diversification, from imperfection to standardization, from peer review-based to quantitative evaluation stage to the present stage of breaking quantitative evaluation and building a comprehensive system.

Public understanding of China's S&TEP

On 23, February 2020, the Ministry of Education and the Ministry of Science and Technology published and disseminated *Suggestions on the Correct Use of SCI as Research Evaluation Criterion and the Establishment of Proper Guidelines for Research Evaluation* (hereafter referred to as *Suggestions*), aiming to remove the distortions in the research evaluation system. These suggestions addressed the disproportionate, excessive and distorted use of SCI in research evaluation, offering ten suggestions and measures as guidelines for the use of SCI in academic evaluation. Since *the Suggestions* discouraged the current regulations on SCI papers and related indicators in the S&T evaluation, it has aroused intense public discussion. Numerous comments about this policy have emerged in various media. These data are an important basis for studying the public's response to this policy. We compare key points between policy comment from different sources. The results are shown in Table 6.

The commentaries in the newspaper are mainly written by reporters through interviews with scholars engaged in scientific research evaluation, or by invited staff members as guest commentators. Newspaper reports discussed the reasons and objectives of this policy and how China's scientific research evaluation should be reformed in the future. Firstly, the reason for problem of the current SCI-oriented evaluation system is that this indicator is directly linked to the evaluation of titles and resource allocation, thus leading many Chinese researchers to blindly pursue the number of papers instead of sinking their hearts to research. Second, some scholars analyze that the purpose of *the Suggestions* issued by the state is to break the situation of blindly imitating the SCI journal evaluation system and to construct evaluation methods, indicators and tools in line with China's value orientation. One of the important points is to create domestic academic journals with high quality and abstract more outstanding research achievements published in them. Third, scholars also discuss direction of reform in the future from various perspectives. For example, in the evaluation of research achievements, more attention should be paid to the construction of multiple expressions of research results and corresponding evaluation standards; In terms of talent evaluation, it is an effective way to implement masterpiece system and classification evaluation system to replace the old way of simply counting SCI papers.

Table 6. Comparison of key points of policy comment from different sources.

Content		*Newspaper*	*Scientific papers*	*Blog*	*Foreign media*
Similarities	Background	1. The singularity of evaluation indexes; 2. The phenomenon of researchers' eagerness to make profits			
	Purpose	1. Create and improve domestic academic journals; 2. Constructing evaluation methods, tools in line with Chinese values			
	Suggestions	1. The establishment of a diversified assessment framework; 2. Maintaining the quality and integrity of peer-review			
Differences	Purpose	Doesn't mean abolishing the SCI	Improving domestic academic journals; Constructing Chinese evaluation methods	Abolishing SCI in evaluation	Abolishing SCI in evaluation
	Suggestions	-	How to do with journals, research evaluation, especially in universities	Originality-oriented evaluation	-

The content discussed in Chinese scientific papers is quite different from the report. It is mainly about how to implement China's research evaluation activities in the future after the policy is released. Specifically, the issues discussed include the development, quality improvement and evaluation of Chinese academic journals, how to adjust the research evaluation system, and the evaluation of scientific research in universities and various disciplines.

For social media, we analysed 48 blogs and comment data after each blog. The topics discussed by scholars are roughly the same as newspapers and academic papers. But there is a different point of view. One of the points is that SCI did nothing wrong. Many scholars point out that SCI has made a great contribution to China's research evaluation system for a long time in the past. Its emergence has played an important role in breaking the circle culture formed by the old forces in the academic world. The problem with China's S&T evaluation is not the SCI, but the simplification of evaluation. It is worth mentioning that there are some scholars whose opinions about this policy are quite different from the official media's interpretation. They believe that the fundamental purpose of this policy is to abolish SCI in evaluation rather than just to weaken the importance of SCI in evaluation activities. Considering a series of policies recently released, one of the measures after the elimination of "only papers" is to attach importance to domestic scientific journals with international influence. In addition, some blogs analyse that the essence of moving away SCI-oriented evaluation system is to break the privileges and discrimination in S&T evaluation. An original and scientific comprehensive evaluation system should be established. That is, scientific research should be aimed at solving practical problems, not publishing papers. Scientific research results must be innovative and reflect service contributions.

Foreign media have paid great attention to China's S&T evaluation system. However, they analyse this policy from a more international perspective. On the one hand, scholars believe that this policy reflects China's new attitude towards SCI. The purpose of China's move is to abolish China's scientific research evaluation system that uses SCI as a core evaluation indicator, thereby helping the development of the domestic academic journal industry. On the other hand, scholars consider that this move may affect the participation of Chinese scholars in international academic cooperation, causing China to derail the development of international academics.

Overall, for all types of commentary texts, official media such as newspapers and academic papers interpret the research evaluation policy; while an important part of scholars' discussions about the research evaluation policy in social media and foreign media is the real purpose of this policy. To a certain extent, this difference reflects the policy tendency contained in the scientific research policy under China's authoritarian state.

Discussion and conclusions

Based on the text of S&TEP, this research explains the evolution and the focus of the China's S&TEP in each stage by using the method of LDA theme model. The results indicate that, China's S&T evaluation system has roughly gone through four stages, the trend of which is shift from publication number to publication quality. At present, China's scientific research evaluation system has entered a stage of deepening reform, with a trend of abandoning quantitative evaluation and constructing comprehensive evaluation system. Next, we take the policy "moving away only SCI evaluation system" in early 2020 as an example. From the four sources of policy comment texts, we can see that scholars have proposed the background, reason, purpose and future development of the S&T evaluation system of this policy from different perspectives. What's more, the text of China's S&TEP has the implications beyond the text itself, but they are easy to reach common acceptance among Chinese scholars.

The results of this systematic analysis are instructive for our understanding of China's S&T evaluation activities in the past, present, and future. The development of China's S&TEP is a long-term and continuous process of improvement. The current and future China's S&T evaluation system will focus on building a comprehensive and flexible evaluation system that remain focusing on originality and research quality. Promoting the construction of a scientific, fair and reasonable peer review system may be one of effective solutions after breaking evaluation framework with only quantitative indicators. Besides, it is also worth considering how to keep up with international academic exchanges while build an evaluation system with Chinese characteristics.

This study has two main contributions. First, this study provides a new division of the stages of China's S&TEP and reveals the evolutionary trends of research evaluation from the perspective of policy themes, providing new ways to understand the reform of China's S&T evaluation policies. On the other hand, we innovatively use policy comments data to broaden the data sources for S&TEP analysis. In our work, we only conducted qualitative discussion on policy review data. Since the review data is of great significant, we will consider using text mining technology to further mine the information contained in the review data in future work.

The Effects of Rhetorical Structure on Citing Behavior in Research Articles

Wen Lou[1], Zilong Su[1], Shaodan Zheng[1] and Jiangen He[2]

Abstract

Aiming to explore the distributions of reference location in rhetorical sections of research articles and examine the relationship between the selection of rhetorical structure and the characteristics of references, we conducted a scheme with six types of rhetorical roles of literature review in research articles and applied to 4,931 JASIST research articles. The results showed that the pattern of selecting rhetorical structure of literature review in JASIST have evolved three stages from citing throughout to conventional literature review. Conducting a standard literature review section has become predominant for preparing scientific papers since early 21st century. We also found that the selection of rhetorical structure regarding literature review affect the disciplinary distribution of cited references. We will further investigate whether the rhetorical roles of distribution are related to the individuals' knowledge structure in selecting references.

Introduction

To facilitate scholarly communication in the context of globalization and international collaboration in science, conventional rhetorical structures are used by scientists in the field of their scientific interest (Kanoksilanpatham, 2005). Swales' approach to genre analysis has enhanced our understanding of rhetorical structure of the research articles (RA) that follow the conventional IMRaD (Introduction, Methods, Results, Discussion) macro-structure (Swales, 1990). Many studies have analyzed the rhetorical structure of individual sections of RAs in various disciplines, such as studies of computer science (Posteguillo, 1999), applied linguistics (Yang and Allison, 2004), biochemistry (Kanoksilanpatham, 2005), and comparative studies of multiple disciplines (Lin and Evans, 2012). In a microsense, rhetorical moves in each of the four main sections of RAs have been also well-studied (Bruce 2008; Peacock, 2012). As far as Literature Review section is concerned, it is less considered in the macro-structure in these analyses of RA rhetorical structure, though it is a common section and a necessary argumentative step in RAs. The function of Literature Review is also implemented as rhetorical moves in Introduction section. According to the Swales' CARS model (Swales, 1990), RA introductions contain three obligatory moves: (1) establishing a territory; (2) establishing a niche; and (3) occupying the niche. Move 1 and Move 2 of an RA introduction may fully implement the function of a Literature Review if there is no separate Literature Review section in the RA. The variation and effects of literature review in rhetorical structure of RAs largely remains an unexplored territory.

References cited in rhetorical sections have been found to have different characteristics. For example, the age of references varies by section, with older references in the Methods and more recent references in the Discussion (Bertin, 2016). Highly cited can be mainly selected for Methods purpose (Small, 2018), but also can be largely found in Introduction, Literature Review, and Discussion (Ding, Liu, Guo and Cronin, 2013; Thelwall, 2019). Hu, Chen and Liu (2013) found that citations are more likely to locate in the section of Introduction. Therefore, the selection of rhetorical structure for RA may affect the citing behavior of what kinds of reference would be cited in scientific writing.

Previous studies have found some factors that affect the author's citation behavior. For example, Milojević (2012) concluded that the collaboration level is an important factor related to citing behavior, especially in fields with extensive collaborative practices. A great deal of research has been done on citing behavior is about the reason for citing references, such as citing is guided by self-interest (Merton, 1957) or personal character (Kaplan, 1965). Lipetz (1965) characterized 28 and Duncan, Anderson, and McAleese (1981) concluded 26 different reasons for citing references. There are also many studies on the citation motivation. Garfield (1965) divided citation motivation into 15 categories, such as paying homage to pioneers, giving credit for related work, identifying methods, etc. Later lots of studies have listed various citation motivations from different perspectives. (Jurgens, Kumar, Hoover, McFarland & Jurafsky, 2018).

The selection of rhetorical structure determines how we organize and present a literature review in RAs in significant ways. For example, the distribution of cited references in a RA is greatly affected if the RA has an independent literature review section. Besides, since authors tend to cite different references across rhetorical sections, we believe the rhetorical structure regarding literature review may affect what references are cited and the rhetorical structure of scientific articles may also be a negligible factor for explaining citing behavior. Even the potential implications of rhetorical structure in citation studies, to our best knowledge, we have not found existing studies have examined the impact of the selection of rhetorical structure on citing behavior. In this article, we identify the evolving pattern of rhetorical structure regarding literature review by exploring the main sections for literature review in RAs. We also examine the relationship between the selection of rhetorical structure and the characteristics of references. We aim to answer the following research questions:

(1) How does the role of literature review evolve in rhetorical structures of RAs?
(2) How does the selection of rhetorical structures affect what kinds of references being cited in the literature review?

Research design

Data collection

We selected the Journal of the Association for Information Science and Technology (JASIST), a well-known peer review journal in the field of library and information science (LIS), as the data source. Full text and metadata of 5,623 articles in JASIST from 1950 to 2018 were downloaded in June 2019. We excluded several types of articles including brief communication, opinion paper, call for papers, and biographies. 4,931 articles in total were finally considered in our study. The metadata of all the references of 4,931 articles were downloaded as well in Web of Science, including the authors, journals, and publication years. Web of Science only provides JASIST information since 1985. So, 127,356 references since 1985 in total were collected and classified into LIS and Non-LIS categories based on the Journal Citation Report classification.

Coding process

First, to build up a coding scheme in terms of rhetorical structure, we randomly chose 100 articles (six to eight articles in every ten years by a random number generator) as coding samples. We manually read through all the articles and summarized the resemblances of how references distribute in an article based on the literal names of section headings. The resemblances eventually formed into six types of rhetorical structure regarding literature review. Type A and B both contain literature review sections. Type C and D are in line with IMRaD format. Second, we trained the coder to learn the six types among the coding samples.

And the coder passed a validation test via another 50 articles by an accuracy of 92%. Finally, the coder manually classified all the rest of articles.

A. Articles with specific sections entitled Literature Review, Related Work, etc.;
B. Articles with specific sections about literature review without entitled as Type A, but as headings with relative topics;
C. Articles that include literature review in the introduction section. A brief but standard literature review was placed in the end of or spread through introduction;
D. Articles that include literature review in the background section. Several citations instead of a standard literature review were placed in the beginning of introduction;
E. Articles without literature review but citations are spread throughout the full text;
F. Articles without any reference.

Findings

Overview

5.84% of total articles did not cite reference. They are mostly introduction of new concepts, techniques, and case studies. The most popular rhetorical structure in JASIST is surprisingly Type E, which exists the whole publishing life of JASIST. 45.79% of articles have cited reference all over the article. Type E dominates all indicators in Table 1, except the number of total reference and per article. The conventional structure of literature review, Type A, is secondarily most applied in JASIST articles. It showed appearances in most of the years. We observe that literature review in the introduction and background sections can be fairly acceptable in scientific writing. They yielded to almost 25% of all articles. Interestingly, Type B is the least the choice among JASIST authors, yet it occupied the largest number of references per article. It indicates the topical wise of literature review can possess a large proportion of references in individual articles compare to other structure.

Table 1. Statistics of rhetorical roles of literature review

Type	# articles (N)	% total	# appearance year (A)	Ave # per appearance year (N/A)	# total reference (R)	Ref per article (R/N)
A	1,178	23.89%	51	23.10	43,760	37.15
B	83	1.68%	24	3.46	3,788	45.64
C	817	16.57%	48	17.02	31,760	38.87
D	307	6.23%	34	9.03	12,788	41.65
E	2,258	45.79%	69	32.72	35,260	15.62
F	288	5.84%	34	8.47	0	0.00
Total	4,931	100%	69	71.46	127,356	25.83

Note. Appearance year is a year when a type of rhetorical roles appeared.

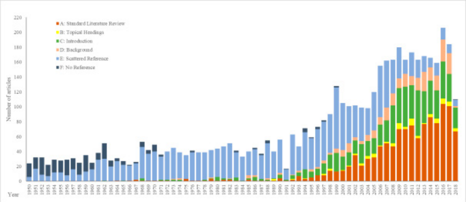
The distributions of rhetorical roles of literature review in research articles

The annual and proportional distributions certainly demonstrate couples of patterns with dynamic stages' shifts. We divide the total phrase of nearly 70 years into three stages.

Stage 1: Format-less stage (early time to the 1980s). Before scientific articles were published with a globally accepted format, citing behavior was even impossibly measurable and predictable. Although the IMRaD started to be adopted in science in the 1950s, the JASIST authors seemed to separate the roles of writing standard and citing preferences in this stage.

Stage 2: Formatting stage (the 1980s to the early 21st century). Along with the widely accepted standard for preparation of scientific articles (Day & Gastel, 2006), updated APA style (the only format accepted for JASIST all the time) version by version, and the rapidly increasing number of publications, the diversity of citing preferences in JASIST started to make a difference in this stage. Even though the scattered citing style (D) remained predominant, the emergence of other types of rhetorical roles began blossoming.

Stage 3: Standardized stage (the early 21st century till now). Conducting literature review sections in academic writing overthrew the domination of various cohabit citing behaviors. Citing reference in the conventional sections has become a trend in scientific publishing. Moreover, a norm of citing preferences in the specific literature review section appeared to be fundamental to publish in JASIST.



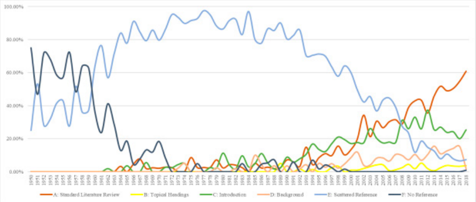


Figure 1. The annual distribution of rhetorical roles of literature review (left)
Figure 2. The annually proportional distribution of rhetorical roles of literature review (right)

Figure 3 compares the overtime changes of articles with literature review sections (Types A, B, C, D) and articles without literature review sections (Type E). Obviously, the proportion of articles with literature review sections has been increasing continuously. Although Type E dominated for the most of the time, especially before 2001, the turning point occurred in the early 1980s. This is when the American national standard for the preparation of scientific papers for written or oral presentation (ANSI Z39.16-1972) was published in 1972 and again 1979 (Day and Gastel, 2006). After 2001, the proportion of articles with literature review sections has begun to be higher than that of articles without literature review sections. The latter was below 50% for the first time. Presumably, the community of library and information science attracted and required researchers to submit manuscripts according to standard writing manual. Therefore, literature review has become an indispensable part in terms of scholarly communication standard since 2001. The growth rate increased from 2001 to 2010 and slowed down from 2010 to 2018 (a current peak has appeared). This slightly stability may result from the words limitation in the recent submitting instruction from Wiley.

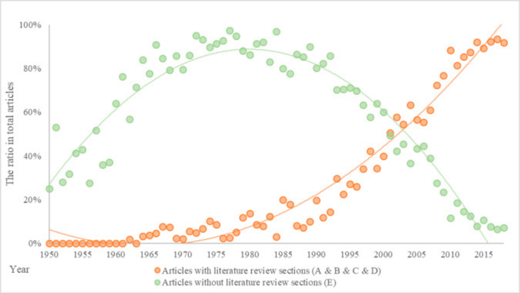

Figure 3. Comparison of articles with and without literature review sections

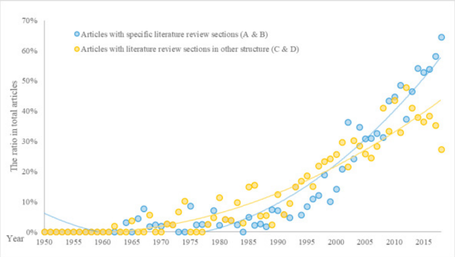
Note. The ratio is calculated from the total number of different types of rhetorical roles in one category dividing the total number of articles. Hereinafter as Figure 4 and 5.

Type A, B, C, and D all represent articles which contain literature reviews to some degree. Figure 4 shows the comparison between inner groups. The two trends are similar (Spearman correlation test result is 0.832, P<0.01) and generally show an upward trend. However, the slopes of them illustrate that the conventional literature reviews have drawn more attention than the other, especially after the early 21st century. The growth rate of those articles with specific literature review sections increased even more since 2012 with a current peak of 64.55% in 2018. This interests us. JASIST has started to limit word count currently. We presume the new policy would have affected the writing pattern regarding the selection of rhetorical structure in terms of literature review as literature review is normally considered as a word-demanding section. The results failed our assumption.



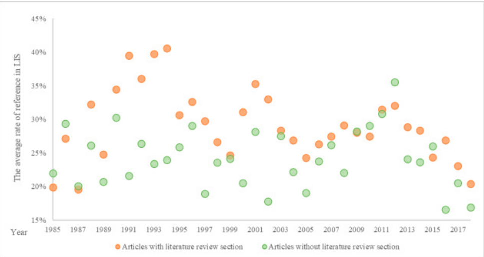


Figure 4. Comparison of articles with specific literature review sections and within other parts of manuscripts (Left)
Figure 5. Comparison of reference in articles with and without literature review sections (right)

The relationship between rhetorical structures and references

The analyses above have given the distributions of rhetorical structures from the perspective of publications. We collected the references of all the publications to examine the distributions of the relationship between rhetorical structure and references. We composed a comparison in Figure 5 between Type A and Type E, respectively representing articles with and without literature review sections. We assume that articles with literature review section would contain more LIS references (references were published in LIS journals) than those without literature review section. Mann - Whitney U test was conducted to examine whether articles with literature review section would have relationship with the results of these articles have cited. The results show the significant difference between the articles with literature review sections and the ones without such sections ($U = 274$, $z = -3.738$, $P = 0.000 < 0.005$). Apparently, articles with literature review section have distributed on the higher rate than the other in Figure 5 (logistic regression result shows the difference is 5.83 times). This suggests the conventional literature review clusters inner-disciplinary topics rather comprehensive topics.

Conclusions and future research

In this article, we made a preliminary statistics and analysis on the distribution of the literature review in rhetorical sections. The pattern of selecting rhetorical structure of literature review in JASIST has been three stages from citing throughout to conventional literature review. Conducting a standard literature review section has become predominant for preparing scientific papers since early 21st century. Our preliminary results also show that the rhetorical structure may have effects on the disciplines where cited references are from. Future studies will consider how the selection of rhetorical structure affects selecting the types of cited references, and how these citations in turn impact on the knowledge structure of the essay. Furthermore, we will examine the selection preferences of rhetorical structure from the authors' perspective and disciplinary differences.

No Metrics for Postdocs: Precarious Labour in Science Policy

Lai Ma[1]

[1] *lai.ma@ucd.ie*
School of Information and Communication Studies, University College Dublin, Belfield, Dublin 4, Ireland

Abstract

In recent years, the pressure of producing impacts such as the creation of intellectual property and other commercialisation activities ('knowledge transfer') has increasingly dominated the discourse of research institutions and universities. Research projects can be comparable to 'gigs' when they employ postdocs on precarious fixed-term contracts. However, there seems to be little consideration in research and science policy about the career development of postdocs beyond funded projects and there seems to be no metrics about the contributions of postdocs to knowledge production, nor data about 'brain drain' as a result of precarious contracts. Using in-depth, semi-structured interviews with postdocs, PIs, and support staff, this study aims to understand the perceived roles of postdocs as a career stage and the perceived success factors that help them transitioning from precarious contracts to long-term academic/research positions. The work-in-progress paper will discuss some preliminary findings including the meanings and contexts of postdoc, as well as the problems and issues of precarious, fixed-term contracts in relation to publication and knowledge production. This paper also calls for comprehensive data collection and analysis about the contributions by postdoctoral researchers and the potential loss of knowledge as a result of the precariousness of academic career.

Introduction

For decades, scholarly works and scientific research have been driven by a reward system that primarily recognises research funding, research metrics and 'mobility' or internationalisation (Ackers, 2008) as key performance indicators. The reward mechanisms have lent powers to governmental bodies and funding agencies who set priority areas and allocate funding accordingly. The pressure of producing impacts such as the creation of intellectual property and other commercialisation activities ('knowledge transfer') has increasingly dominated the discourse of research institutions and universities. Research projects are comparable to 'gigs' when they employ a large number of gig workers (PhD students, Postdocs) whose career paths are insecure and unclear. However, there seems to be little consideration in science and research policy about the career development of postdocs beyond funded projects. There is also no metrics about the loss of precarious labour—and the many contributions they would and could have made to science and society.

The recent OECD report (2020), *Resourcing Higher Education*, has highlighted the harmful consequences of extensive casualisation of academic staff, for example, low retention of researchers, teachers, and students and lower quality of teaching and learning. Kwiek (2019) has examined stratifications in academic performance and power, pointing to the need of predictable career advancement for early career researchers. Flynn (2020) has described the disheartening experiences of being precarious with no clear paths to obtain a research grant or land a permanent position years after earning her PhD. The casualisation of work also limits the participation of the 'gig workers' in university and research governance.

The development and challenges faced by early-career researchers, especially postdocs, have been studied in terms of regimes of valuation (Fochler, Felt and Müller; 2016), symbolic violence (Roumbanis, 2019), practices of appraisal devices (Nästesjö, 2020) and so forth. Most recently, a survey of postdoc conducted by *Nature* (Woolston, 2020) reveals 'great distress' experienced by postdoctoral researchers worldwide. Notably, Milojević, Radicchi and Walsh

(2018) have found dramatic shortening of careers of scientists from 35 years in the 1960s to only 5 years in the 2010s, some of whom as supporting authors only in their entire career. There is, however, a lack of metrics about the (loss of) productivity and performance of postdocs in this competitive research environments due to the limited number of academic and research positions.

This exploratory study aims to understand postdocs as a career stage and the perceived success factors that help transitioning from precarious contracts to long-term academic/research positions, as well as career beyond academia. This work-in-progress paper will discuss some preliminary findings of semi-structured interviews with postdocs and support staff in research institutions, focusing on the relationship between precariousness and knowledge production. It is the goal of this study to establish the need for future empirical and quantitative studies pertaining to the contributions of postdoctoral researchers in knowledge production.

Method

The first phase of the study was conducted between July and September 2020. Twenty in-depth, semi-structured interviews were conducted with postdoctoral researchers and research support staff in universities and research centres in Ireland. The list of potential participants was collated by searching university websites using the title, 'postdoc' and similar terms[1]. It is worth noting that, however, the contact information of postdoctoral researchers is not necessarily listed by research centres and universities. As a result, most respondents were receipents of the Irish Research Council (IRC) Postdoctoral Fellowship, partly because their affiliation and contact information have been made publicly accessible. The potential participants were invited to participate in the study by individual emails. An information sheet and an informed consent form were sent to respondents prior to the interviews.

During the interviews, the postdoctoral reseachers were invited to talk about their research career and their plans for the future, their experience as a postdoctoral researcher and the pros and cons of postdoc as a career stage, while the support staff were asked to comment on the needs of the postdoctoral resaerchers, including support for grant applications and career development. The interviews were conducted using Zoom or Skype and are approximately 35-70 minutes in length. They were transcribed fully first by otter.ai and then checked and corrected manually. The transcription is anonymized and coded based on emerging themes. The data collection will continue in early 2021 until saturation has been reached.

Preliminary Findings

In this section, emerging themes will be discussed based on the coding and analysis of the first phase of the study. These preliminary findings show the impact of precarious contracts on publications and related issues for postdoctoral researchers, highlighting the need for future quantitative studies to shed light on the scope and depth of the problems.

Postdoc as a Career Stage

Many senior faculty/academic staff in research institutions and universites have not been a postdoc themselves, for it was not considered as a bridge between doctoral studies and

[1] There is not a clear definition of 'postdoc'. Doctoral researchers can be working on funded projects with various levels of freedom in pursuing research interests of their own, while some— most respondents in this study—are awarded with fellowship to engage in individual projects. However, it should be noted that many individuals with a PhD can be working as research assistants, research fellows or under other titles in a research institution or university in Ireland. It is unclear as to whether they should be considered as 'postdoc' because they are not classified as academic staff.

permanent (or tenured-track) positions decades ago. Today, despite the lack of data about the percentage of faculty/academic staff with or without postdoc experiences, it is generally understood that newly graduated PhDs would be in at least one and indeed often multiple postdoctoral positions. Many respondents in this study reported that it is not uncommon to have 3-5 postdoctoral contracts before landing a permenant position, or before one decides to quit academia altogether.

Is postdoc a necessary a career stage? Most respondents said yes. However, the reasons demonstrate the complexity of 'surviving' in a very competitive environment—that it is considered impossible for anyone to land a position without working as a postdoc for several years, that it needs the time period as a postdoc to increase the number of publications for applying for grants and/or permanent positions, that it is a career stage where one can develop networks considering the preferences for internationalisation and mobility in research career (see Archer 2008).

For respondents who have been awarded an individual fellowship (e.g., IRC, Marie-Curie), the postdoctoral position affords them time and space to prepare publications based on their PhD studies or embark on a new project. These respondents were conscientious of the privilege of the fellowship, for they do not have obligations to undertake teaching or administrative responsibilities in the host institutions. In other words, they can devote all of their working hours to pursue their own research projects and they are also avail of research budget for buying materials and traveling to archives and conferences. Many stated that the time offered by the fellowship has been essential for them to develop as an independent researcher/scholar, partly due to the projectification of doctoral training (see Torka, 2018). For respondents who are working on funded projects, the postdoctoral position affords them to acquire and develop skills before applying for grants as a principle investigator (PI). The respondents mentioned project management and supervision as essential skills in their career development—whether they plan to pursue a career in research institutions or industry. Many reported that they are also developing expertise in methodologies and techniques as a postdoc.

Timeframe

While the respondents articulated the many benefits a postdoctoral position can offer, all commented that the duration of postdoctoral contracts are often too short. Most agreed that a three-year contract is about optimal while shorter contracts tend to create stress and sometimes mental health issues due to the following reasons: first, the lack of job security means that the postdocs would be looking for the next position and working on applications from Day 1 which constitutes a substantial workload in addition to the 'day job'. Second, their workload can be compounded by the pressure to publish from their PhD work or previous project(s)—with the assumptions that publications will eventually lead them to a permenant/stable position. Third, a new contract usually requires relocation, meaning the lack of support by family and friends. Indeed, as many have reported, an academic career often entails delaying family and personal plans due to the frequent relocation in different cities/counries at the postdoctoral stage, which usually lasts 5-6 years and sometimes longer[2].

The respondents reported that the precariousness of the postdoctoral positions has negative impacts on knowledge production as they find it difficult to finish writing from previous projects, and/or they sometimes cannot finish a study due to the time constraint of the contracts. There are also cases where one does not have an affiliation and hence loses access to materials

[2] The estimate of 5-6 years is based on anecdotes as there is a lack of official data.

and support provided by academic libraries and other support units. Many lamented that the short and rigid timeframes simply do not work for the nature of scientific research and scholarly inquiries, which can have unexpected delays or take unexpected turns.

The Pseudo-Employee Status

The precarious, fixed-term contracts also affect the employee status of postdocs. Since postdocs are mostly funded by research councils or other funding agencies, there are no commitments or obligations for the employers to retain the postdocs after the fixed-term contracts. While some universities do provide career development support for postdocs, the options can be minimal compared to those provided for permanent staff. Some respondents reported that they do not have a sense of belonging to the university—which may be better described as 'host institution'—even though they are supposedly 'employees'. While some are affiliated with research hubs and communities, some are totally isolated. For instance, the respondents reported that they do not attend staff meeting and/or decision-making processes in their host institution and some felt that they were treated as 'second-class citizens'. During the intial stage of data collection of this study, it is also clear that postdocs are not necessarily listed as academic staff or faculty on university websites, meaning that often these postdocs cannot be easily found by a Google search. Some respondents maintain their own web presence by hosting a website themselves, or by using third-party services such as academia.edu.

Due to the timeframe of their contracts, the respondents' involvement in university life is usually limited to their research group, if any. Some respondents were aware of research staff associations, but commented that their activities can be sporadic, and may be discontinued, when active members leave. At the same time, they are also most concerned with their career and spare little time on social activities. Postdoctoral researchers can be seen as a group of 'gig workers' who receive limited benefits and have no say on university and research governance, while their contributions to research and knowledge production have been under-documented and understudied.

Summary and Future Studies

This study aims to understand the postdoctoral experiences in the context of science and research policy—Is postdoc a necessary career stage? What are the benefits and challenges? What are the implications for knowledge production and the future of scientific research and scholarly inquires? The respondents reported that their postdoctoral experiences have been useful for concentrating on a project, learning new skills, and most importantly, developing into an independent researcher/scholar. Postdoc as a career stage, however, can be attributed to the competitive market, that is, the lack of academic positions, for one can argue that PhD graduates can develop their projects and skills in a permenant/tenured-track position without going through precarious contracts. There are many epistemic and labour issues pertaining to the fixed-term, precarious contracts of postdocs, including the loss of knowledge when one switches from one contract to another, or when one leaves the academic/research career altogether. As of now, however, there is no data or metrics recording the contributions to publications by postdoctoral researchers, nor data about the potential loss of knowledge—brain drain—due to precarious contracts. As Stephan (2013) has aptly pointed out, 'the low price of postdocs hides the true cost of postdocs to society' (p. 245). While warnings have been raised about "postdocs in crisis" during the pandemic (Nature Editorial, 2020), data and analysis about the publication patterns of postdocs can unearth issues about the consequences of precarious contracts on scholarship and scientific progress.

Abstract:

We propose institutional mobility indicators based on researchers' mobility flows in 22 major fields of science across 1,130 Leiden Ranking institutions from 64 countries. We base our indicators on data from the Dimensions and GRID databases. We use researchers' first and last affiliations to estimate the extent authors have moved across institutions as well as universities' degree of internationalization. For each institution, we quantify the shares of researchers with the same affiliation (insiders), those who came from another institution within the country (domestic outsiders) and those coming from a different country (foreign outsiders). Institutions in Central, Eastern and Southern Europe have the highest share of insiders, whereas institutions in Northern America and Western and Northern Europe have a higher share of foreign outsiders. Foreign outsiders are most common in small and wealthy countries. No disciplinary differences are observed, as captured by the field classification scheme of Dimensions.

Introduction

There is an increasing need to account for how institutions internationalize (Hoekman, 2012; Robinson-Garcia et al., 2019). Evidence suggests that cross-national mobility flows are increasing (Sugimoto et al., 2017) as is the strengthening of global collaborative research networks (Wagner and Leydesdorff, 2005). Research institutions foster internationalization as they compete to attract and retain foreign talent in a global market (Hazelkorn, 2011; Seeber et al., 2016), with foreign born researchers accounting for 42% of life sciences postdoctoral research in Europe, and 57% of these coming from outside the European Union (Moguérou and Di Pietrogiacomo, 2008). As a result, there is a policy interest in monitoring and understanding the process of academic mobility and internationalization of universities (OECD 2008, European Commission 2012, Jacob and Meek 2013, Sugimoto et al. 2017).

The lack of global and harmonized datasets has been a persistent challenge in developing global indicators of mobility (Sugimoto et al., 2016; Welch et al., 2018). This is especially problematic at the institutional level, due to the difficulties in obtaining fine-grained mobility data and lack of scalable methods. Recently, bibliometric databases have significantly improved the consistency of publication metadata, particularly author-affiliation linkages, allowing the tracking of affiliations of individual researchers and opening up new opportunities for studying long-term mobility patterns at scale (Moed and Halevi 2014, Sugimoto et al. 2016). Previous work has been concerned exclusively with the quantification of movement of scholars across countries and disciplines (Aref et al., 2019; Robinson-Garcia et al. 2019). In this paper we attempt to develop mobility indicators for research institutions.

In this paper we deliver novel insights on the composition of the academic workforce of universities and national research systems worldwide. We base our results on the Dimensions database and the Global Research Identifier Database (GRID). We propose three indicators by which institutional workforces can be characterized based on researchers' first institution of affiliation. By comparing the institution to which researchers were affiliated in one of their first publications with the most recent one, we distinguish between:

i) *insiders*, defined as researchers who are currently affiliated to the same institution to which they were affiliated in one of their first publications;
ii) *domestic outsiders*, that is, those who were originally affiliated to a different institution within the same country from their current one; and,
iii) *foreign outsiders*, researchers who were originally affiliated to an institution located in a different country from their current one.

The paper is structured as follows. First, we review the existing literature on academic mobility and the related concept of inbreeding. Then we describe the mobility indicators with a description of how we built the dataset. Next, we present the empirical findings from an aggregate perspective and analyze the heterogeneity of universities with regards to researchers' institutional mobility between countries and across the world. We conclude by discussing implications, limitations of this approach and future research lines derived from this study.

Literature review

Academic mobility is widely perceived as beneficial to the scientific enterprise (Wagner & Jonkers, 2017; European Commission/EACEA/Eurydice, 2015). It is considered important to promote the dissemination of knowledge, acquiring experience in different research environments, career advancement, and for creating opportunities for collaboration (e.g., Sugimoto et al., 2017; Stephan & Levin, 2001; Wagner & Jonkers, 2017). Mobile researchers serve as important bridges between countries (Meyer, 2001), they reinforce existing or create new ties with other national and foreign institutions, thus generating collaborative research networks that span the globe. When researchers move, they bring with them knowledge and ideas that differ from natives, which are essential for knowledge recombination and interactive learning, which in turn may lead to innovation (Ganguli, 2015; Stephan & Levin, 2001).

The notion of academic mobility is closely related to the concept of internationalization (Wagner & Jonkers, 2017). The process of internationalization has become an essential part of universities' strategic planning as it involves the implementation of programs that support the periodic movement of researchers, building ties with top universities, and improving visibility. The increasing orientation towards internationalization is in part due to strategic considerations in the context of a global competition for talents (Seeber et al., 2016). Internationalization strategies are particularly used by universities in developed countries (Lepori et al., 2015), which are increasingly dependent on the movement of researchers as a way of maintaining their attractiveness and international reputation.

The lack of institutional internationalization - which translates into low workforce mobility in a given institution - is thought to be decisive in influencing academic productivity and improving researchers' performance (Franzoni et al., 2014; Horta et al., 2010; Horta, 2013) and citation impact (Ganguli, 2015; Sugimoto et al., 2017). A recent large-scale bibliometric study reported that mobile researchers (more than one affiliation to different countries) were more cited than non-mobile researchers (Sugimoto et al., 2017). A similar finding was report by Ganguli (2015) who found that Russian scientists who have migrated to the US have been more cited by US scientists than those who have not migrated. In the US context, Foreign-born faculty has also been found to publish more (Mamiseishvili & Rosser 2010) and publish more breakthroughs (Stephan & Levin, 2001) than their US-born counterparts. One explanation for lower levels of impact and productivity of immobile researchers is that this kind of faculty has less access to varied information and exchange dynamics which may explain their lower scientific productivity (Horta, 2013).

Other studies suggest that academic mobility may or may not have a negative effect on the researchers' careers. For example, Melin (2005) has shown that mobile scholars returning to Sweden after a postdoctoral period abroad do not benefit from their foreign experience. Cruz-Castro and Sanz-Menéndez (2010) have found that non-mobile careers are a strong predictor of the timing of rewards in the form of early permanent positions in Spain, while mobile careers in the US increases researchers' chances of obtaining tenure. This suggests that the relationship between mobility and scientific performance varies widely across national research systems (Cruz-Castro & Sanz-Menéndez, 2010).

A related stream of literature contrasts mobility with the practice of having PhD graduates employed by the university that also trained them. This is known as "academic inbreeding" (Yudkevich & Sivak, 2012; Caplow & McGee, 1958; Berelson, 1960) or "institutional inbreeding" (Horta, 2013). Like the lack of mobility and internationalization, inbreeding is seen as negative for both the institution and researchers and has also been an indication of poor institutional performance (Horta, 2013). For example, academic inbreeding has been associated with lower output (Horta et al., 2010), fewer articles published in peer-reviewed journals than non-inbred (Horta, 2013), and fewer foreign co-authors (Scellato et al., 2012), effectively slowing down the career development of scholars (Inanc & Tuncer, 2011). Low productivity levels of inbred scholars emphasize the need for mobility and calls for policies to curtail academic inbreeding (Horta, 2013).

Data and methodology

The university's reliance on insiders among its workforce producing scientific results, can be interpreted as the university tendency to academic inbreeding. Empirical evidence on publication activity of PhD students indicates that even though differences between disciplines matter, the first papers' affiliation can be used as a proxy for Ph.D granting institution of the individual researcher. For example, Lee (2000), Lariviére (2012) and Waaijer et al. (2016) found that PhD students publish their first article before graduation quite frequently in natural and health sciences, though less so in social sciences and humanities. Nevertheless, PhD students may acknowledge affiliation to their alma mater, even if the dissertation research is published only after leaving the university due to publication delays in peer-review journals. Macháček and Srholec (2020) directly tested this assumption in a random sample of 90 researchers affiliated to major Western and Central European universities derived from the Scopus citation database. They found out from publicly available sources, from which university the researcher graduated, and compared that with outcomes of the bibliometric approach outlined above. The conclusion on whether the researcher is currently based on her alma mater matched by 77% in biochemistry, genetics and molecular biology, 90% in physics and astronomy and 87% in social sciences. There was of 7 false positives and false negatives, which tend to offset each other, thus the impact in aggregated data is even more limited.

Database

We use the Dimensions database version from June 2019 that is available in the CWTS database system, including data on publications, affiliations, researchers as well as disciplines (Herzog et al., 2020), which in total contains data for more than 100 million documents. Dimensions has a similar coverage to Scopus (Thelwall 2018), at least for publications with a Digital Object Identifier (DOI), which are predominantly journal articles but also book chapters, conference proceedings and others.

The Dimensions database has its own author name disambiguation procedure. In general, author name disambiguation algorithms attempt to group citation records of the same author by finding some similarity among them or try to directly assign publications to the individual who wrote them (Caron and van Eck, 2014). The Dimensions author name disambiguation algorithm is a two-step procedure. First, it uses "affiliation data, co-authorship and citation patterns as well as subject area traits" (Hook et al., 2018, p. 8) to produce clusters of publications that belong to potential individuals. These clusters are then connected using Open Researcher and Contributor ID (ORCID) and DOIs. Each disambiguated author is then assigned a researcher ID by which is unique identifier, producing almost 20 million researchers. Researcher IDs have been successfully assigned to about 87% of publications-authors combinations (Hook et al. 2018).

However, author-disambiguation algorithms (including the ORCID) are prone to errors (Caron and van Eck 2014, Gurney et al. 2012, Levin et al. 2012), and there is a need to establish a balance between precision (i.e. *How many identified publications truly belong to the same researcher?*) and recall (*Are all researchers' publications correctly identified?*). The Dimensions algorithm favors precision over recall (Bode et al. 2018), which is particularly relevant for us, since mobility events can cause splitting researchers into multiple IDs, and the precision preference can lead to the under-estimation of mobility events. For example, the publications of a researcher are split in disconnected clusters across her affiliations because the algorithm may not be able to merge them together.

Dimensions combines publication metadata with its own database of harmonized research institutions – the Global Research Identifier Database (GRID). This allows us to easily track the movements of scholars from one institution to the next. Aside from the unique institution identifier, GRID provides detailed geographical information, such as coordinates and city, region, and country names and codes. Other attributes include the institution's year of establishment and its type, which is divided into eight categories, one of which identifies educational institutions and universities.

Dimensions also includes a field-classification scheme for publications based on Australian and New Zealand Standard Research Classification (Australian Bureau of Statistics, 2008), which is a three-level hierarchical system of categories. Because more detailed disaggregation leads to a limited number of observations in the sub-disciplines, we use the top-level of this classification (FoR-division) in this paper, which refers to 22 major disciplines across all fields of sciences.

Determining the mobility category of researchers

We used *2018* as the reference year to identify researchers affiliated with specific institutions. Furthermore, we only include researchers with sufficiently long publication histories (i.e., more than 6 years since their first publication). The first year of publication is used as a proxy for measuring academic age (Nane et al. 2017), preventing researchers with very short publication histories from driving the results. All researchers publishing their first paper in 2012 or later are excluded from the analysis.

Each researcher r can belong to multiple sets as researchers can be affiliated to multiple universities and publish in multiple disciplines. Consider researcher r is affiliated to institution u and publishing in discipline d in 2018. She has a set of publications $P \subset p_{p,t}$ where at least one $p_{p,t>6}$, in which p is the publication index and t is the index for the number of years since the first publication (t is calculated from the publication calendar year). To determine where the researcher r started her career we select a subset of her initial publications published in the first two calendar years of her publication history, where:

$$P^{start} = |p_{p,t} where\ t < 2|$$

Based on P^{start}, we derive our indicators – whether researcher r started her publication career at the same university ($r^{start,u}$) and country ($r^{start,c}$). $r^{start,u} = 1$ if r is affiliated to u in any publication in P^{start}, otherwise $r^{start,u} = 0$. Similarly $r^{start,c} = 1$ if r is affiliated to any institution in country c in any publication in P^{start}, otherwise $r^{start,c} = 0$.

This allows us to split researchers into three mutually exclusive categories. For each university u and discipline d we then report the share on the total number of researchers of:

1. Insiders: Researchers starting at the same university – $\{\mathrm{r}|r^{start,u} = 1\}$
2. Domestic outsiders: Researchers starting at another institution in the same country – $\{\mathrm{r}|r^{start,u} = 0 \text{ and } r^{start,c} = 1\}$
3. Foreign outsiders: Researchers starting abroad – $\{\mathrm{r}|r^{start,c} = 0\}$

Selecting research universities based on the Leiden Ranking

We only consider established research universities that are included in the Leiden Ranking. The GRID category of "educational institutions" is far too broad for this purpose. Therefore, we use the Leiden Ranking methodology to identify the most productive research universities worldwide (Waltman et al, 2012). This results in a fairly homogenous group of well-established universities with significant research activities. We use the Leiden Ranking 2020 data (see van Eck, 2020), which includes a total of 1,176 universities, only 7 of which we were unable to match with the initial set of GRID identifiers. While most universities have been created before World War II and only about a tenth of them in the mid-1970s or later, there are some universities in that were established in 1998 or later according to the GRID database. We removed those universities from our sample since younger, less established universities have had less time to employ their own graduates. Using a cut-off year other than 1998 has no effect on the main results and the final sample includes 1,130 universities.

We rely solely on author-affiliations linkages as reflected in researchers' publication record. That means that researchers will be labeled as *insider* regardless of the type of position they have at a given institution. For example, some students might have a first publication already in the undergraduate studies. Or some universities might not provide doctoral education in some disciplines. Unfortunately, there is no easy way to identify all this diversity of affiliation linkages, unless one connects the bibliometric records with administrative data, which is not feasible at the global scale.

Results and discussion

Overall, the share of insiders in total researchers differs markedly across the universities. On an average university nearly half of researchers hold the insider status, but this share ranges from less than a third in about one fifth of the universities to more than three quarters in a tenth of them; with some notable outliers at both ends of the spectrum. As can be expected, the flipside of employing initial outsiders also varies significantly with a clear predominance of locals over foreigners. Only about a tenth of the universities maintain more than a third of researchers who started publishing with affiliations abroad.

Figure 1 displays the share of insiders in universities worldwide. Each node denotes one university. The size of the node is proportional to the number of researchers in the respective university. The intensity of the colour reflects the share of insiders. Areas with the highest share of insiders are concentrated in the South and East regions, while low shares of insiders predominate in the North and West regions. Oceania, namely Australia and New Zealand, are the only exceptions. We also observe an overrepresentation of North American and European universities in contrast with other regions of the world such as Africa, Southeast Asia (except for China and Japan), and South America.

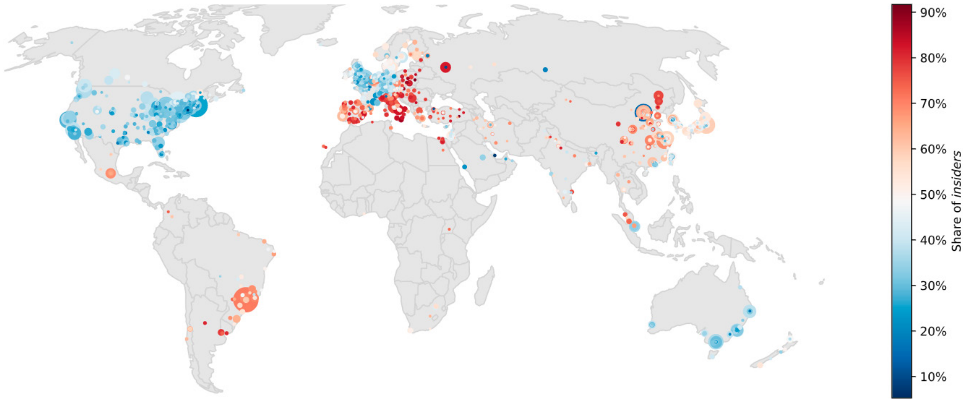

Figure 1. World map of universities included in the dataset and share of insiders per university.
Note: Only universities included in the Leiden Ranking and established before 1998 are included. Nodes denote universities. The size of nodes denotes the number of researchers identified. Colour reflects the share of insiders. Red indicates the highest share while blue reflect lower shares of insiders.

Figure 2 shows the distribution of universities based on the share of insiders in each geographic region. Europe, which is well represented in the sample, is further subdivided into three sub regions (Western and Northern Europe, Southern Europe and Central and Eastern Europe). Traditionally advanced countries in North America, Western and Northern Europe and Oceania attract researchers originating from their own universities. Within North America and Oceania, there is relatively little variation; half of the universities are boxed in a fairly narrow range, indicating that this is a systemic feature of how labour markets for researchers operate therein. Universities in Western and Northern Europe appear to be more diverse, with some high values, particularly in Scandinavian and Benelux countries.

In contrast, a higher share of insiders is typical for universities in former soviet countries from Central and Eastern Europe, as well as in Southern Europe, where the tendency to employ insiders is roughly twice as high as in the Northern and Western parts of the continent. This shows that there are lingering differences within the European Research Area (ERA), even among the "old" member countries. In fact, Southern, Central and Eastern European universities have a propensity to employ insiders that is above of what is common in developing countries, including Africa, although evidence from the latter should be taken with a grain of salt due to a low number of observations from this continent.

For example, only one out of every four researchers at Harvard University, the University of Chicago, the University of Warwick and the Humboldt University of Berlin, but also the University of South Carolina, the Coventry University, or the University of Paderborn, started their career at the same institution. However, more than three out of every four currently affiliated researchers started publishing at Sapienza University of Rome, the University of Seville, the University of Warsaw, the University of Szeged, or the Moscow State University.

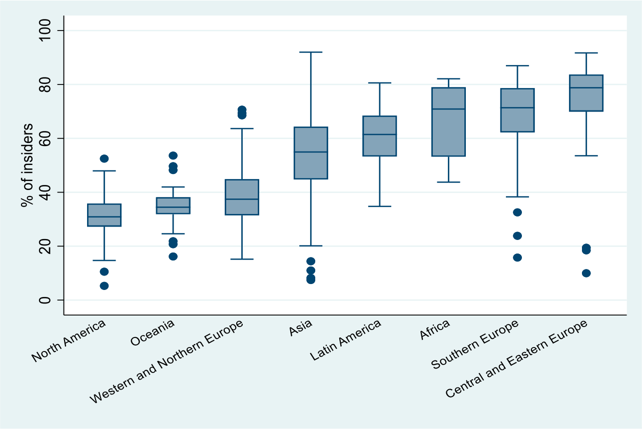

Figure 2. Distribution of the share of insiders in universities grouped by geographic region
Note: Only Leiden Ranking universities that were established before 1998.

When we rank the continents by the median, Latin America and Asia fall between the two extremes. However, this masks vast differences within Asia, which is an amalgam of diverse countries ranging from advanced Japan through emerging China to developing India, but which proves difficult to divide by geography or other lines due to a low number of observations in the potential constituent parts and because the majority of them would be dominated by the largest countries. As illustrated below, the diversity within Asia is best understood by examining evidence from individual countries.

The outliers below the lower limit of the whiskers are predominantly elite local universities that seem not follow the suit in the higher shares of insiders that is common in their national environments. For example, this includes National Research University Higher School of Economics and ITMO University in Russia, Pompeu Fabra University in Spain, University of Cyprus, Qatar University and the University of Chinese Academy of Sciences. On the other end of the spectrum, with the share of insiders above the upper limit of the whiskers, the main outliers include Ghent University and University of Liège in Belgium or Åbo Akademi University in Finland.

Figure 3 complements these patterns by providing details on individual countries, for which results for at least 10 universities are available. Poland comes out clearly at the top of the list: more than four out of five researchers are typically classified as insiders, and none of Polish universities goes below two-thirds of insiders. Next are Italy, Turkey and Spain with below the lower limit of the whiskers lower rates than Poland, but far more variability of the values. The largest variability is detected in China and India; both big countries with emerging and diverse university systems, where the share of insiders ranges from the highest figures in the world to the minimums observed in advanced countries. United States, France, Australia, the United Kingdom and Germany appear at the bottom of the list, which confirms that there is a strong developmental dimension in this ranking.

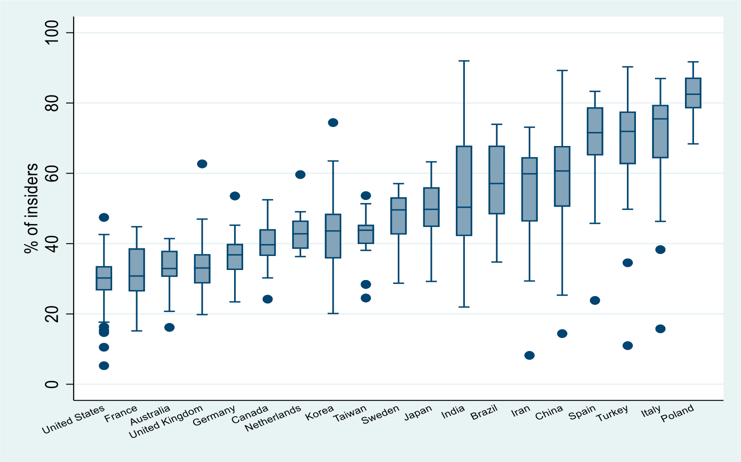

Figure 3. Distribution of insiders in universities grouped by country

Note: Only Leiden Ranking universities that were established before 1998. Only countries with results at least 10 universities.

The share of foreign outsiders is negatively correlated to the size of national research systems. Thus, in large national research systems with many researchers, universities can draw from a large pool of domestic candidates, hence their chances to find a suitable candidate at home are naturally higher than in small research systems with a limited supply. For example, a university in Iceland is just for this reason likely to display a far higher share of foreign outsiders than otherwise similar university operating in the United States. Hence, one should compare in this regard universities from countries with research systems of a roughly similar size.

The largest differences are observed for countries with small research systems. It could be argued that these countries would need to internationalize more their research workforces, particularly if they aim at achieving research excellence in a foreseeable future. However, universities in countries like Slovenia, Croatia, Slovakia, Romania, Lithuania, Algeria, Pakistan and Uganda seem not to attract researchers who started their careers abroad, which is in contrast to Iceland, Cyprus, Lebanon or Jordan. Arabic oil-rich countries in the Persian Gulf, namely Kuwait, Oman, United Arab Emirates, Qatar and Saudi Arabia stand out with high shares of foreign outsiders. This reflects their development strategy based on attracting foreign researchers (Schmoch et al., 2016), but this can also reflect the controversial strategy of universities in Saudi Arabia and elsewhere of offering secondary affiliations to highly cited researchers from abroad to boost their bibliometric profiles and ascend in rankings (Gingras, 2014). Arguably, this reiterates the limitation already mentioned above that we do not have any information on the parameters of contracts that underpin the affiliations of researchers in the published papers, although in practice these researchers contribute to the production (and visibility) of these universities.

Finally, we examine how the results differ by disciplines and thus to which extent these underlying differences could affect the patterns detected above. Using the Dimensions database, we can distinguish between 22 major disciplines across all fields of sciences, including social sciences and humanities. In order to present robust evidence, we narrow the sample only to universities with at least 30 authors in the respective discipline and present the results only for disciplines, for which such data is available in at least 30 universities. On these grounds, we eliminated from the analysis three disciplines (*Law and Legal Studies*; *Philosophy and Religious Studies*; and *Studies in Creative Arts and Writing*). The resulting dataset contains information on 10,408 pairs of university-disciplines of 1,129 universities across 19 disciplines.

Figure 4 displays the boxplots for the share of insiders by disciplines. The main finding is that there is little variability across disciplines but a large diversity within them. The central tendencies are limited to a narrow range, the interquartile ranges are highly overlapping, while the whiskers tend to reach from close to zero to almost hundred percent in most disciplines. Arguably, this picture pales compared to the significant differences that we have observed between universities across the national research systems above.

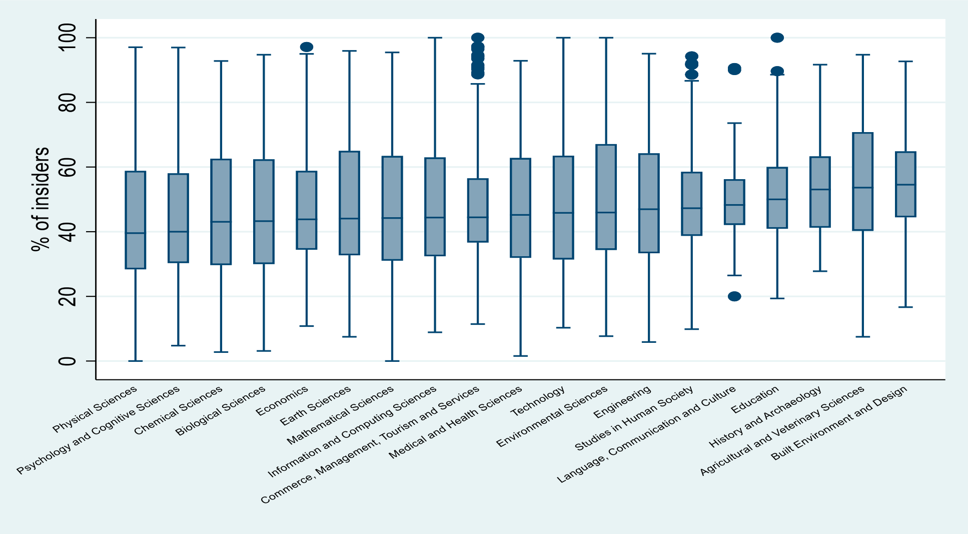

Figure 4. % of insiders by discipline

Note: Only Leiden Ranking universities that were established before 1998 with at least 30 authors in the respective discipline. Only disciplines with results for at least 30 universities.

Conclusions

This paper demonstrates how bibliometric data can provide valuable insights into the institutional mobility of researchers. The empirical analysis reveals noticeable differences along the north versus south and west versus east geographical dimensions. The gulf between universities in Central, Eastern, and Southern Europe on the one hand and universities in North America, Western, and Northern Europe on the other is striking, pointing to systemic differences in how labor markets for researchers operate in the respective areas. Most developing countries fall between the two extremes, but there is significant variation within them. The findings also show that differences between universities and national research systems are most important, while disciplinary differences might be only marginally important.

The main findings on cross-country differences are broadly consistent with the growing body of empirical literature on geographical mobility of researchers, such as the MORE3 survey in Europe conducted by IDEA Consult, WIFO and Technopolis (2017) and the bibliometric analysis of mobility between European countries and the United States (Science Europe, 2013). Nevertheless, evidence on (a lack of) institutional mobility, or more specifically academic inbreeding, has been limited to qualitative analyses, surveys of particular contexts and/or case-studies of individual countries (Inanc and Tuncer 2011, Morichika and Shibayama 2015, Tavares, et al. 2015, Yudkevich et al. 2015, Horta and Yudkevich 2016 and Seeber et al. 2016), whereas broad comparative evidence based on harmonized data has been lacking. In this regard, the approach developed in this paper opens up new avenues for quantitative research as well as policy analyses on this topic.

O Factor: Open-Open citation measure

Devika P. Madalli

Documentation Research and Training Centre, Indian Statistical Institute, Bangalore (India)

Abstract

Measures such as Impact factor and H-Index are used to reflect the impact of scientific publishing and authors' productivity. There have been many arguments in support of and against these measures: whether they truly taking all factors into consideration and whether they must be used as the bottom-line in deciding worth of published content and authors who contribute content. However, measures such as Impact factor and H-Index and other indices continue to used, rather overwhelmingly, as measures of quality and productivity. The other facet the quality paradigm is the question of quality of Open content. Open access advocates endeavour to entice academicians and researchers to publish in open journals and other open resources. Academicians are hesitant to publish in open access journals because open access publishing has still not attained the status that commercial published journals have. Here we address the question 'How to establish quality of Open Content?' We introduce the concept of 'Open Content Metrics (OCM)' as counterparts of the measures of quality and productivity already established for commercially published journals. We introduce the concept of O–Factor (OF) as a measure to reflect what we refer as Open-Open citation. Data and illustration to calculate OF are provided.

Introduction

Measures of scientific productivity and outputs are important indicators that reflect the progress of science. Citation index is used as a means to attribute to authors their contribution and Impact factor as a means to measure the impact of a journal. These provide a mechanism to assess the impact of a researcher in the scientific community. There are several arguments for and against the appropriateness of such measures (Garfield, 1955; Kelly and Jennions, 2006; Ayris *et al.,* 2018), but measures such as impact factors continue to be used and quoted as indicators for quality of research. Proponents and advocates of open content, work towards making content openly available with appropriate licenses that foster the sharing of knowledge, thus hoping to free it from the commercial publishing cycle. However open content is often discarded with a common rather unfair remark that 'All' Open Content is of poor quality. Academics and researchers who are better judges of quality know that there is good and bad in Open content just as is the case with commercially published content. The main reason being that it is academicians and researchers who produce content but it is also true that the 'same' academics work as peer reviewers to ensure 'quality' of content whether in open access and or in commercially published journals. Other reasons for this are many and are deemed as out of the scope of the present discussion. To sum up, the discussion of open versus commercial journals often culminates in a common unfounded insecurity that open access content lacks in quality. To prove or disprove the argument may be the subject of prolonged discussions but the present work is based on the premise of the Open Access Principles (Madalli, 2011) that state: ***'Knowledge unto those that produce knowledge'*** *and* ***'Scholarship is the same; priced or open'.***

In view of the above, it is important to concentrate on measures that can be applied to Open Content and we refer to such measures as 'OCM – Open Content Metrics'. Open Content metrics are meant to encompass all measures that establish productivity, quality, use and reuse of Open Content. The focus of this paper is to deliberate upon the impact of open access journals and open content and to introduce the concept of 'Open Authors'. 'Open authors' is a term referred to authors publishing in open access journals. The significance of the proposal lies in establishing impact of the Open content and providing the right impetus for researchers and authors to consider being ‘Open Authors' without any concerns or constraints.

Quality and Measures of scientific publishing

There have been several critical studies (Seglen, 1997; Linde, 1998) explicating the pitfalls of the conventional methods of quantifying scientific literature output like the impact factor. Some of the most common pitfalls are enumerated below:

- The overall impact of a journal as quantified by its impact factor is not a marker of the quality of the individual articles of that journal.
- Impact Factor is highly domain-specific, and, thus it is unsuited to be used as a standard to gauge research output across domains.
- It is also plagued by quantitative pitfalls like the number of references attributed or the number of self-citations, which introduces noise in the final calculation of the metric
- Impedances like the language, visibility and the length of the articles within a journal also affects its impact factor, which should ideally not be a concern.
- Due to its dependence on the dynamics of a specific domain, Impact Factor might show undue inflation/deflation in its measured value.
- Also, impact factor cannot be said to be absolutely foolproof as there are byways through which it can be subjected to quantitative manipulation and misrepresented.

Carpenter, Cone and Sarli (2014) elucidate the various upcoming methods of measuring scientific and research output, specifically highlighting the importance of more granular, document-specific metric measures such as counts reflecting events like views, downloads, tags, recommendations and annotations which are taken into consideration in the altmetrics approach. They argue that such measures, as opposed to the conventional methods to gauge scientific outputs, can effectively reflect the inceptive sway and provide a much broader perspective as regards the research importance of a journal and its constituent articles. They also point out that there may be a chance of co-existence amongst the conventional and the next-generational metrics. Barnes (2015) takes a more nuanced approach while considering altmetrics as an innovative new tool in measuring scientific impact. He reviews various pieces of evidence indicating much more timely impact assessment provided by altmetric indicators as well as their wider coverage compared to the traditional metrics. Bornmann (2014) discusses the benefits and pitfalls of alternative metrics of measuring scientific output in an illustrative and engaging way. The major benefits of such alternative metrics are listed to be broadness, diversity, speed and openness.

The above discussion from literature evidence that 1) There are many measures being considered and applied to gauge quality and productivity in scientific publishing. 2) That none are perfect and 3) That devising metrics and methodologies towards measuring productivity and impact of scientific content is an ever emerging domain by itself, with newer modes of publishing and use and reuse of content in novel ways.

Hence while research is required to arrive at the best measures, the academic and scientific world continues to use Impact factor and H, G (and similar) indices as measures to reflect quality. It is necessary to establish measures for open content hosting resources including Open journals to establish themselves as an equally good opportunity to publish. In the sections that follow we introduce the concept of O-factor as a measure of impact of Open access journals.

Data Collection

Collecting data about Open Authors is most challenging in the present situation where commercial citation indices make no distinction about open authors and open content and that of commercial content. Given this constraint, in the first instance, we selected Google Scholar (GS) as our citation database to collect citation data. To identify information whether a given author has published in open access we proceed to the next step. GS provides citation information and other bibliographic information. For finding the citation information of an article cited by Open Access journals we used the citation information link in GS where we checked which sources have cited the article and collected only those citations given by open access journals. However, there were a few problems to be addressed:

- GS indexes different types of resources including scholarly journals as well as web-based resources. So, when we searched for an article, we found the citation count was more compared to Scopus because it collects citation information from all the resources like websites, slide-share, etc.

- Next problem was, GS collects citation from different languages including English, so when we analyze the citation information, it is difficult for us to identify whether the cited document is from open access journal or from other resources.

To overcome these problems, we have used Scopus for our study. To validate our concept we have considered an Open Access (OA) journal, 'Journal of Medical Library Association (JMLA)' from Directory of Open Access Journal (DOAJ). This title is a random selection and with an aim to validate our idea and illustrate O factor as one measure within OCMs to establish the impact of Open Content.

To collect citation-related information, we have used the search keyword "Journal of Medical Library Association" and restricted the datasets to the year 2016 and 2017 because we are trying to find the impact factor and O-factor for the year 2018. Based on the above query we found 142 articles from Scopus for the years 2016 and 2017.

Then, we searched each article in the Scopus database and collected citation count as well as the citation given by the OA journals. As is obvious, this is done by manual verification. For our study we only considered five fields viz. article title, year of publication, source of the article, cited by and cited by OA journals.

One of the problems we faced during collecting the citation information from Scopus was, some of the articles which we collected did not provide complete citation information i.e., it had citation count but did not provide information about who cited those articles.

***Table-1: Excerpt of Citation* Information of Journal of Medical Library Association (JMLA) for 2017 and 2016**

Data Analysis

Based on the data collected from Scopus in table 1, we have calculated IF and O-Factor with the help of three year IF formula which was given by Garfield (Garfield, 2006), namely:

Computing the Impact Factor (IF)

Impact factor of a journal is calculated taking into consideration citations received recently which is defined as 'in the two years that precede the year of calculation of its IF'. This is devised to assess the Impact as well as to maintain the current status that helps the current ranking of journals.

IF = Total number of citations received by journal for the previous two years/
Total number of articles published in previous two years

Computing the O factor (OF)

We introduce the notion of 'O' factor (OF), which one of OCMs. OF is derived by computing citations received by an open access journal. O factor for an open access journal is defined as:

'the total number of the citations received by articles in the journal by open authors divided by the total number of articles published in the open access journal in the preceding two years of its publication'

In a given year 'y' OF of an OA journal is computed as

$$OF_y = C_{y-1} + C_{y-2} / P_{y-1} + P_{y-2}$$

where
OF is the Open Impact Factor
y = the year for which impact factor is calculated
C = citations received
P = total no. of publications in the journal in a given year (y-1, y-2 ... so on)

Illustration

In our illustration, for the JMLA we found that the total number of citations received in the year 2016 and 2017 was 311 (see Appendix I for full data).
The total number of articles published in the year 2016 and 2017 was 142.

So, the Impact Factor of JMLA for the year 2018 is

$$IF= 311/142=2.19$$

For finding O-Factor (OF) of JMLA of 2018,

$$OF_{2018} = C_{2017} + C_{2016} / P_{2017} + P_{2016}$$

where
OF is the Impact Factor
y = the year for which impact factor is to be calculated = 2018
C = citations received from open access journal only = 107
P = total no. of publications in the journal in the year 2016 and 2017 = 142
so,

$$\text{O-Factor}_{2018} = 107/ 142 = 0.75$$

Findings

From the above analysis, we found that IF of JMLA is 2.19 and the O-Factor of JMLA is 0.75. The result shows that IF is more than the O-factor but if we consider the total number of citations received from OA journals, it was around 36% of the total citation received from all the journals. The other finding is, the concept of O-Factor is new and there are many constraints to find the O-Factor of a journal at present. For instance, if a journal publishes 1000 articles in two years then getting all the required information to calculate O-Factor is a very difficult task. It is hoped that OCMs and methodologies for deriving OCMs will be refined and will be used as commonly as IF, H index and other measures in future.

Limitations

The concept of OCM is nascent and literature reveals very scant information on efforts to work out measures for open content. Popular citation indices do not distinguish between commercial content and open content and there are no indicators for articles published in Open access journals or other open resources. It takes manual effort to identify first which open access journals and authors have gained citations, and second whether the citation is referring to openly published content or commercial content or a mix of both. For the purpose of illustrating OF, we have used data from Scopus but we do not make a presumption to what extent Scopus covers open access content. We have just used one journal, 'JMLA' and collected data for the specified 2 years to demonstrate the methodology. Data as well as findings may vary rather drastically by the domain, title of publication, country of publication and other such factors.

Significance and Conclusion

As discussed, and illustrated above, there are ways to establish 'Quality' by existing and accepted norms of measuring the impact of scientific publishing. The existing and accepted measures have their pitfalls as evidenced within this paper but to establish the worth of open content and encourage authors to consider being "Open Authors" it is necessary to establish measures that work as indicators for their productivity. Such measures will also enable open access journals to be listed and considered administratively for the purposes of career advancement in academia on par with so-called "Ranked journals", which of course has been the crux of the matter of the reason why authors are hesitant to publish in Open access journals. The notion of 'Open Content Metrics - OCM' is nascent and needs the attention of academia, researchers and open access advocates to bring out effective methodologies and measures in favour of open content. There is no doubt that qualitative indicators such as usage patterns of open access journals and journals articles as such have their merit. The latest metrics such as altmetrics that take into consideration social media resources along with others are also important in reflecting use and reuse of resources. OCMs ideally would encompass all such measures that establish 'quality' of open content.

Article Processing Charges based publications: to which extent the price explains scientific impact?

Abdelghani Maddi[1] and David Sapinho[2]

Abstract

The present study aims to analyze relationship between Citations Normalized Score (NCS) of scientific publications and Article Processing Charges (APCs) amounts of Gold Open access publications. To do so, we use APCs information provided by OpenAPC database and citations scores of publications in the Web of Science database (WoS). Database covers the period from 2006 to 2019 with 83,752 articles published in 4751 journals belonging to 267 distinct publishers. Results show that contrary to this belief, paying dearly does not necessarily increase the impact of publications. First, large publishers with high impact are not the most expensive. Second, publishers with the highest APCs are not necessarily the best in terms of impact. Correlation between APCs and impact is moderate. Otherwise, in the econometric analysis we have shown that publication quality is strongly determined by journal quality in which it is published. International collaboration also plays an important role in citations score.

Introduction

Since the start of the 21st century, scientific community has witnessed an unprecedented rise in the Open Access (OA) movement (Björk, 2004; Chi Chang, 2006; Sotudeh and Estakhr, 2018). OA is seen as a good means of ensuring better dissemination of knowledge and more equity between actors, faced with the issue of paying subscription fees (Prosser, 2003; Tananbaum, 2003; Solomon and Björk, 2012; Cary and Rockwell, 2020).

However, OA does not necessarily mean "free", and raises the question of business model underlying scientific publication. For institutions, it may even generate new costs: in addition to the subscription fees, they are increasingly led to pay costs of OA publication (Maddi, 2020). This concerns a part of Gold OA publications which are based on the "author-pays" business model (Rizor and Holley, 2014; Sotudeh, Ghasempour and Yaghtin, 2015). Thus, authors pay the "Article Processing Charges" (APCs), usually via their institution, to allow open access to the publication (Asai, 2019; Khoo, 2019; Bruns, Rimmert and Taubert, 2020; Copiello, 2020). The APCs have increased significantly over time. This rise has been estimated at three times faster than it would be if indexed to inflation (Khoo 2019). The trend appears to be stronger in more frequently cited journals, as highlighted for Biomed Central journals (Asai 2020), medical and specific OA journals (Asai 2019). These findings would also suggest that large subscription journal publishers tend to set higher APCs. Nevertheless, there is no evidence to date that the introduction of APCs for a given journal reduced its publications volume (Khoo, 2019). In other words, once able to pay an APC, authors give little emphasis to their amount. The APC-based publishing model is being more and more integrated by academic institutions that aspire to switch to an economic model excluding subscription fees. Thus, APCs are now a considerable burden on "total cost of publication" for institutions, reaching 10% in 2013 (Pinfield, Salter and Bath, 2016).

[1] Corresponding author : Abdelghani Maddi, Observatoire des Sciences et Techniques, Hcéres, 2 Rue Albert Einstein, Paris, 75013, France, T. 33 (0)1 55 55 61 48.

While many studies have described relationships between OA publications and citation level (Gumpenberger, Ovalle-Perandones and Gorraiz, 2013; Zhang and Watson, 2017; Piwowar *et al.*, 2018), only few have focused on the amount of APCs, with heterogeneous findings. On one hand, APCs based journals have been regarded, in general, more cited than other OA journals (Björk and Solomon, 2012) , on the other hand, it was concluded that both categories have, on average, similar performances with some disciplinary differences (Ghane, Niazmand and Sabet Sarvestani, 2020). Another study analyzed the relationship between APCs and scientific impact of publications using respectively DOAJ and Scopus data (Björk and Solomon, 2015). On a set of 61,081 publications and 595 journals, authors showed that there is a moderate correlation (0.4) between the two indicators at the journal level (APCs and impact). Correlation is greater (0.6) when data is weighted by the volume of articles for each journal (article level), suggesting that publishers take quality into account when pricing their journals. Likewise, authors are also sensitive to journal quality in their submission choices.
The present study aims to analyze relationship between citations normalized score of scientific publications and APCs amounts. To do so, we use APCs information provided by OpenAPC database (https://treemaps.intact-project.org/) and citations scores in the Web of Science database (WoS). Database covers the period from 2006 to 2019 with 109,141 publications (March 1, 2020). Among these publications, 83,752 match with the WoS database using DOI. Our database contains 4,751 journals with a contrasted number of publications per journal. These journals belong to 267 distinct publishers.
To the extent that large, high impact publishers/journals may request high APCs, it is expected that quality will be strongly correlated with the APCs. The latter would therefore explain the publications visibility.

Data

APCs data

APCs data has been extracted from “OpenAPC” database. It is an initiative that involves 231 institutions worldwide (5 from North America, 255 from Europe and 1 from East Asia) that publish data sets on fees paid for OA journal articles under an open database license. At the beginning of March 2020, the database contains 109,141 publications and 6,941 journals.
Each publication in this database is only assigned to the institution that declared, skipping, therefore, other collaborating institutions. For more details about Open APC database see: https://treemaps.intact-project.org/page/about.html

OST data

The data about citations scores and disciplinary assignation of publications has been extracted from the french Observatoire des Sciences et Techniques' (OST) in-house database. It includes five indexes of WoS available from Clarivate Analytics (SCIE, SSCI, AHCI, CPCI-SSH and CPCI-S) and corresponds to WoS content indexed through the end of March 2019. See https://clarivate.com/webofsciencegroup/solutions/webofscience-platform/.

Final database

The database used for analysis includes several information about publications from the two data sources:

- From the APC data : institution that declares the publication, APCs amounts, journal in which they are published, country of the journal, publisher of journal and a flag indicating whether journal is hybrid. By matching the "OpenAPC" database to that of OST.

- From the WoS-OST in-house data : we estimate the impact of publications by calculating the following indicators :
    - Normalized Citations Score (NCS) at article level: the NCS of a given article was calculated by dividing the number of citations received by the average number of citations in the same disciplines and the same year (Waltman *et al.*, 2011).
    - Mean Normalized Citation Score (MNCS) at journal and publisher level: the MNCS for a given publisher was calculated as the weighted average of the NCS scores, based on all the articles of journals that it publishes. In the case of the OpenAPC database, the selection was restricted to OA articles only.
    - Mean Normalized Impact of Journals (MNIJ) at journal and publisher level: For a given journal, the MNIJ is calculated as the average number of citations per article in a given discipline for a given year, normalized by the number of citations per article in the same discipline and the same year at the global level. The overall MNIJ of a journal (all disciplines combined) is obtained by calculating a weighted average of the MNIJs by discipline.
- Finally, international collaboration was measured by number of countries involved in publication.

The two datasets were merged on the basis of DOI, resulting in a sample of 83,752publications.

Method

Spearman correlation test and regression analysis are performed to highlight the relationships between amount of APC and citations.

Dependent variable and model choice

The dependent variable is the logarithm of Normalized Citations Score (labelled Log (NCS)) received by each publication during the period 2006-2019. To retain the zeros, we have added 1 to the NCS before making the logarithmic transformation. Log (NCS) is a continuous variable with a lower boundary at zero and an upper boundary at infinity. Thus, a left censored Tobit regression model is used to account for the disproportionate number of observations with zero values, because a significant proportion of the observations in our sample are zeros. Tobit regressions avoid inconsistent estimates from OLS regression.

Explanatory variable

In this study, we seek to analyze to what extent the amount of APCs have an incidence on the number of citations received by OA scientific publications. Our explanatory variable is therefore the amount of APCs by publication.

Control variables

Journal impact and number of countries per publication are added as control variables. This choice was driven by the literature that shows that citations depend on journal quality and international collaboration (Maddi, Larivière and Gingras, 2019; Maddi and Gingras, 2021). The hybrid status of a journal was also observed, using a dummy variable.

Results

In this section we present the main results. First, we characterize the APCs data, namely: evolution of the average amount paid by institutions, characteristics of the top 20 producing publishers and then those of the most expensive one. Secondly, we present the correlation tests results between the amount of APCs on the one hand and the MNCS and MNIJ indicators on the other hand. Finally, we present results from regression.

Overview of APCs data

Figure 1 shows the evolution of APCs average by publication in all "OpenAPC" database, and using a constant data set of publications from journals of 2006-09 period (79 journals). As we can see, the average amount has doubled between 2006 and 2019, going from 1,000 euros to almost 2,300 euros per publication. This is explained in particular by the new journals that have been indexed into OpenAPC database after 2009, which significantly increases the APCs average. Overall, APCs have increased significantly even for old journals (2006-09) from 1,000 to 1,800 euros on average.

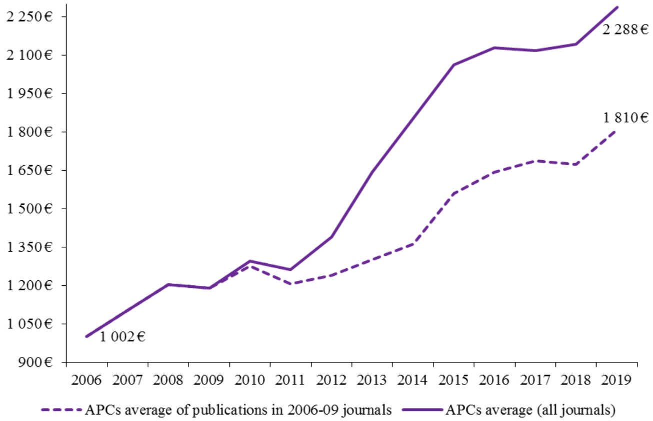

Figure 1: APCs Average per publication, total and with constant journal set

With all reservations that we can make on the Open APC database, we can hypothesize that this increase is notably due to a rise in demand for OA publication. As is well known in economics, increase in demand systematically leads to an increase in prices. Publishers are therefore taking advantage of this enthusiasm for OA to increase their prices.

Figure 2 describes the distribution of publications in the OpenAPC database, in relation to the amount of APCs, by discipline.

First, it highlights contrasting gold open access publication practices. This finding is similar to that observed from the WoS data base for OA publications in previous studies (Maddi, 2020; Maddi, Lardreau and Sapinho, 2021). However, the distribution is quite different than that of all the publications where the weight of engineering or chemistry, for example, is higher (OST, 2019). Thus, nearly 50% of the publications in the OpenAPC database are in Fundamental biology and Medical research, with respectively 23,466 and 19,669 publications. These two disciplines account for only 30% of publications in the WoS database (and 42% of Gold open access). The least present disciplines are mathematics, computer science and humanities. This result is largely explained by the overall size of these disciplines (see OST, 2019).

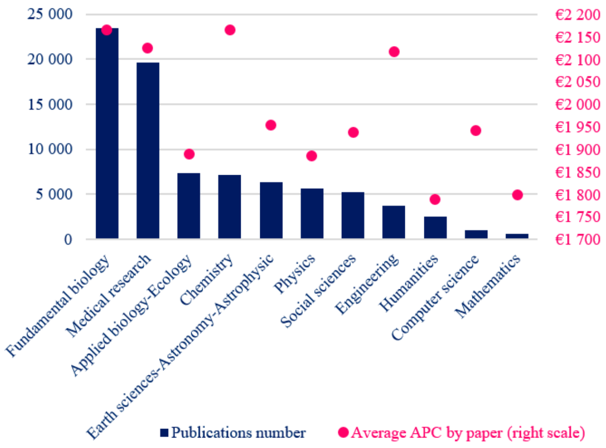

Figure 2: publications number and average APC by discipline

The average amount of APCs by discipline varies from € 1,800 (Mathematics and Humanities) to € 2,150 (Fundamental biology and Chemistry). The difference is therefore not significantly high depending on the discipline.

Figure 3 shows the distribution of publications in the OpenAPC database (top 20 countries) as well as the corresponding average APC amount per country.

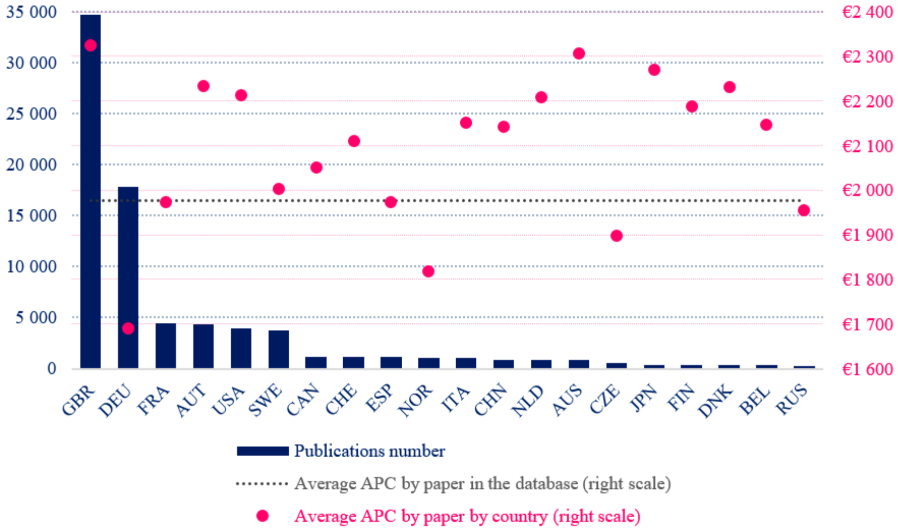

Figure 3: publications number and average APC by country (Top 20 countries in OpenAPC database)

The UK accounts for 40% of the OpenAPC database publications with almost 35,000 articles (fractional count), followed by far by Germany with 17,779 articles. France comes in third position, with 4,450 publications, followed closely by Austria, the United States and Sweden. This distribution shows that the OpenAPC database is biased in favor of European countries. The scope of our results is therefore limited in particular to European countries. When it comes to the average amount of APC per country, the UK also comes first with an average APC of

2325 euros. In contrast, Germany, the second producer country in the OpenAPC database, has the lowest average APC per paper (1690 euros), followed by Norway with average APCs of 1817 euoros.

Table 1: top 20 producing publishers: publications numbers, APCs average, MNIJ and MNCS

Publisher	# publications	APCs average	MNIJ	MNCS
Springer Nature	14103	1 992 €	1,75	1,29

Ovid Technologies (Wolters Kluwer Health)	715	3 215 €	1,41	1,82

Table 1 shows that more than half of publications are concentrated on the top 5 publishers. With a few exceptions, APCs are lower for large publishers than for the overall average. The MNIJ is higher than the world average for almost all publishers. Likewise for the MNCS. Furthermore, Table 1 shows that for some publishers, impact of publications (MNCS) is much higher than that of journals (MNIJ). This is particularly the case for the publishers "Informa UK Limited" and "BMJ". Explanation can be found in the fact that the majority of journals for these publishers (respectively, 87 and 93%) are either closed or hybrid. As demonstrated in the literature, OA publications are more cited than non-OA ones. Consequently, MNCS of publications indexed in OpenAPC database would be systematically higher than the average impact of journals in which they are published.

Table 2 shows that among the largest publishers, only Elsevier BV is listed in the top 20 most expensive ones (20th position), that are mostly American. We can also note that both impact of publications and impact of journals are high. Some exceptions can be made, especially for "MyJove Corporation" publisher with an average amount of 3081 euros for a very low impact. Similarly, "The American Association of Immunologists" charges for expensive APCs, while the average impact of journals and publications is at the level of the world average.

Table 2: top 20 most expensive publishers: publications numbers, APCs average, MNIJ and MNCS

Publisher	# publications	APCs average	MNIJ	MNCS
American Society for Nutrition	47	4 761 €	2,34	2,32

Correlation test

We performed a Spearman correlation test on four variables at publisher level: publications number (pub_nbr), APCs average (APCs_avg), MNIJ and MNCS. The results are presented in figure 4.

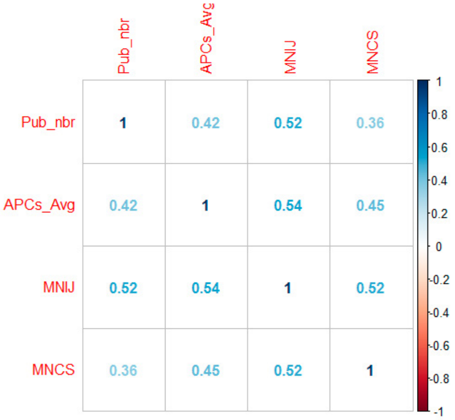

Figure 4: Spearman correlation matrix

All coefficients are significant at 5%. We observe that the number of publications is more correlated with the MNIJ (0.52) than with the MNCS (0.36). This means that within the OpenAPC database there are small publishers whose publications have high citations scores and large publishers with low citations scores. We also note that the number of publications per publisher is moderately correlated with the amount of APCs. This would mean that there is no evidence of relationship between the size of publisher and the amount of APCs.

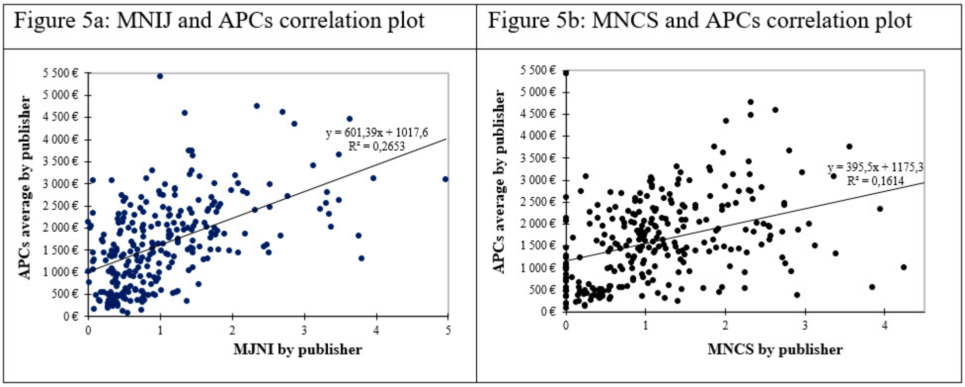

Figure 5a: MNIJ and APCs correlation plot

Figure 5b: MNCS and APCs correlation plot

Figure 5: APCs average per publication

Figure 3 shows correlation plots between on the one hand MNIJ and APCs (figure 5a), and on the other hand the MNCS and the APCs (figure 5b). The correlation between MNIJ and the amount of APCs is much higher (0.54 against 0.45). This shows that publishers take the quality into account when pricing their journals. However, this prices does not necessarily translate into impact. As long as the APCs are only moderately correlated with the MNCS.

Regression results

Table 3 summarizes Tobit regression results for explaining NCS by the amount of APCs. Regression was carried out in two stages. First, only the explanatory variable was integrated (*Log APC* per publication - model 1). Then, control variables were added (model 2).

Table 3: Tobit maximum likelihood estimation for log NCS

		Model_1		Model_2	
Variables_type	Variables	Coefficient	Pr(>|z|)	Coefficient	Pr(>|z|)
Explanatory	$Log\ (APCs)$	0.22***	$<2.22e^{-16}$	0.012***	$5.25e^{-05}$
Control	$Log(journal\_impact)$	-	-	0.471***	$<2e^{-16}$
	$Log(countries\_nbr)$	-	-	0.100***	$<2e^{-16}$
	Is_hybrid	-	-	0.204***	$<2e^{-16}$
Model statistics	Wald-statistic	2667	$<2.22e^{-16}$	$1.238e^{+04}$	$<2.22e^{-16}$
	Log-likelihood	$-8.063e^{+04}$	$<2.22e^{-16}$	$-7.607e^{+04}$	$<2.22e^{-16}$
	#publications	83,753			
	#Left-censored	11907			
	#Uncensored	71846			
	#Right-censored	0			

****Significant at 1%*

Table 3 shows that when control variables are not taken into account, the amount of APCs strongly impacts citation score (model 1). Once control variables are integrated, the APCs amount impact drops significantly. However, it can be seen that the amount of APCs has a positive impact on citations. Another interesting result is the impact of hybrid journals. Thus, if the journal is hybrid, citations score is higher. In other words, OA articles published in hybrid journals are generally more cited than OA articles published in 100% APCs journals. This is to be expected, given that not all well-established journals in the market have adopted a fully OA business model (Traag and Waltman, 2019). On the other hand, the main large publishers have massively integrated the hybrid model from 2013 (Besancenot and Vranceanu, 2017). In contrast, many fully OA journals are recently created journals that still have not built such a strong reputation for quality (some might even be aiming for average-level reputation and impact if this maximizes income – see (Traag and Waltman, 2019)). Hybrid journals are therefore more likely to be, at moment, in a virtuous circle where they receive higher quality manuscripts than fully OA journals, which translates to higher NCS of the published articles.

Conclusion and discussion

Through this article, we seek to analyze relationship between APCs and academic impact. Based on a large sample of 83,752 publications our study empirically verifies the belief that if we pay dearly for publication, impact of publication would necessarily be high. This belief stems from the fact that an author or an institution may think that all publishers who charge a high price for APCs and indexed in international databases like WoS, necessarily have a high academic quality. Our results show that contrary to this belief, paying dearly does not necessarily increase impact of publications. First, large publishers with high impact are not the most expensive in terms of APCs. Second, publishers with highest APCs are not necessarily the bests in terms of impact. Correlation between APCs and impact is moderate.

Otherwise, in the econometric analysis we have shown that publication quality is strongly determined by journal quality in which it is published. This result agrees with several studies which show it empirically (Waltman and Traag, 2017; Maddi, Larivière and Gingras, 2019). International collaboration also plays an important role in citations score. This result is also consistent with literature (Larivière *et al.*, 2015).

Another interesting result relates to the impact of hybrid journals versus 100% APCs journals. The regression results indicate that if the journal is hybrid, the NCS is stronger than if it is fully open. This result is consistent with the study of (Schönfelder, 2020) on the same database (OpenAPC) which showed that journal's impact and hybrid status are the most important factors for the level of APCs.

Our results have several implications for public policy and authors choices when it comes to submit their publications. First, the strong interest for OA had an immediate effect on the publishing market. Prices of OA publications have increased exponentially. This increase is disproportionate to the academic impact. The impact of publications for which authors have dearly paid is no better than that of publications with low APCs. Impact may even be lower. We also showed that some publishers are taking advantage of OA movement to demand high APCs, while their academic impact is very low. Finally, our results suggest that, for authors, APCs should not be used as an indicator for journals selection for submission. For institutions, for efficient management, it is important to be attentive to journals quality before granting funds for OA publication.

Abstract

Research fronts (RFs) represent the most dynamic areas of science and technology and the topics that receive higher attention in a specific field. Their identification has become the focus of global scientific and technological competition. In this study, we performed an analysis of the In-Cites research fronts in a case study for the scientific output of the Carlos III University of Madrid. This research in progress has two objectives: a) to quantify the alignment of the research output of UC3M in the different fields with the RF and b) to test if papers aligned with RFs receive more citations per document than those not aligned. The ultimate goal of this research is to assess the usefulness of RFs as an orientation for the establishment of research priorities at the institutional level for the university.

Introduction

Research Fronts (hereafter RFs) have been an increasingly relevant object of research in scientometrics. The literature on this topic grew steadily in the last century and has received wide attention over the last two decades (Szomszor, Pendlebury & Rogers, 2020). RFs have been labeled 'the footprint of the scientific communities' (Fajardo-Ortiz et al., 2017). RFs have become of interest for several audiences (Small, Boyack & Klavans, 2014). Nevertheless, there is no widely accepted definition detailing the specific attributes of research fronts and emerging research topics and technologies. As Rotolo, Hicks & Martin (2015, p.1827) point out 'the lack of consensus over definitions is matched by an eclectic and ad hoc approach to measurement'. Their definition of a research front includes, as Wang (2018) summarizes, five attributes: radical novelty, relatively fast growth, coherence, prominent impact and uncertainty and ambiguity. Wang's work proposes, develops and applies four criterions: growth (rapid increase in yearly publications), novelty (novel atthe early stage of its emergence), scientific impact (prominent volume of citations) and coherence (number of within-cluster citations divided by the total number of publications). A closely related topic to RFs, that of 'emergence' (in the case of emerging technologies) has been defined by Small, Boyack & Klavans (2014) as participating from two key features: novelty and growth. Some authors have underlined (Li & Chu, 2017) the relatedness between RFs and the dynamic and multi-dimensional conception of research activity.

Different studies have developed quantitative methods that can be used to identify and characterize RFs and their evolution over time. There is an extensive corpus of research using citation networks as a methodology for the identification of RFs. Mainly, as pointed by Shibata et al. (2009) research on the topic presents two approaches: one related to time-based indicators (i.e. future citations are predicted by current citations) and the other based on the detection of emerging clusters of densely connected papers. Both involve methods such as direct citation or bibliographic coupling. However, these approaches present some limitations: citation bias depending on authors' citing motivations (e.g. citation of their colleagues); it takes longer for fields with smaller scales or developing slowly (Shibata et al., 2008) and the fact that higher citation frequency does not necessarily imply greater quality (Marrone, 2020). In recent years, different approaches using text mining methods have been generalized. These include techniques such as Latent Class Analysis (LCA) or Latent Semantic Analysis (LSA) (Marrone, 2020). As an example, the burst term detection has become popular to explore dynamics and new trends (e.g. the Kleinberg burst detection algorithm). However, as pointed by Li & Chu (2017) these techniques are reliant on stochastic models which are particularly sensitive to the initial conditions. Another approach is the set of topic-modeling methodologies (Marrone, 2020). While these attempts allow discovering meaningful categories called 'topics' that can be used to understand how research fields change over time, such methods present some caveats such as the inconsistency in the terminology, which may reduce their usefulness or the ability to name unlabeled topics. Mapping and visualization techniques on the identification of the RFs (e.g. Chen, 2006) have also gained popularity in recent years. Previous studies identifying RFs were developed in a wide variety of fields such as engineering (Shibata et al., 2009), medicine or health-related research (Schwechheimer & Winterhager, 2001), technology (MacDonald & Dressler, 2018), or scientometrics (Anegón, Contreras & Corrochano, 1998), among others. However, to the best of our knowledge, not many approaches focused at an institutional level as we presented in this case study.

Clarivate Analytics counts with two products that provide information on RFs. On the one hand, InCites, which a customized research evaluation tool allowing institutional benchmarking on output, citation, collaboration, influential work and the discovery of areas of opportunity. Research Fronts are one of its components. On the other hand, Essential Science Indicators (ESI) provides data on Highly Cited Papers (articles in the top 1% of citations in the same field and year) and Hot papers (articles in the top 0.1% of citation frequency in the most recent bimonthly period for the same field and year). The filtering options include research fields, authors, institutions, countries and regions and research fronts. The RFs at the ESI interface can also be filtered by research fields and they are provided as a set of five strings separated by semicolon. These strings are the result of the "analysis of frequently occurring keywords or phrases in the titles of the paper" (Clarivate Analytics, 2021). In total, the interface provides 11,769 research fronts for 22 fields. We provide an example as an endnote[i]. The output also contains the number of highly cited papers, hot papers or both (named 'Top Papers' in the filtering options) in (it is to say, being the articles that conform the RF) the RF, cites to highly cited papers and cites per highly cited paper as well as the mean year. The identification and definition of the RFs (Clarivate Analytics, 2021) is based on single-link clustering of highly cited papers via normalized co-citation. Co-citation frequency is divided by the square root of the product of the citation frequencies of the two (initial) papers, aggregating other pairs that share common papers. The measure of association applied is the number of times pairs of papers have been co-cited.

The main attributes of the RF provided by Clarivate Analytics are high impact (since they are calculated on HCP) and currency (due to the yearly basis of the calculation and updating of the RFs). As Clarivate Analytics (2021) put it, one of the practical applications of RFs is to *"(...) assist in identifying areas where important work is being done and where the scientific community is focusing its attention*". This theoretical use of the RFs counts with its practical counterpart in their use for the identification of strengths and areas of opportunity for institutions in the product In-Cites, as well as in the reports produced in collaboration with the Chinese Academy of Sciences, in its seventh installment in 2021 (Clarivate Analytics and CAS, 2021).

Taking into account the prior practical uses of the RF our first objective is to quantify the alignment of the research output of UC3M in the different fields with the RF. Such alignment might be useful for decision making at the University concerning areas of attention since both, scientific impact and currency of research are desirable features of the research output of the University. For the above rationale to be of practical use we need to prove that, beyond HCP and for the 'regular' output of the university in the various fields (on which the RFs are defined), there is a positive relationship between citations and alignment. This might seem plausible at first, but the association between a greater scientific impact and the alignment with the RF, albeit obvious for the HCP, could take a diversity of values for non-HCP papers in various fields or even not be present at all, thus requiring empirical contrast. For this reason, the second objective of this research is to analyze if there is an association (causal or otherwise) between the alignment with RFs and citations for a set of articles from UC3M that are not HCP.

Data and methods

Dataset

The workflow used in this study is summarized in Figure 1. We downloaded all the registers (articles only) of the UC3M at the Web of Science's Core Collection for the years 2015-2019. For this purpose, we used the OG (organization enhanced) field and retrieved only the articles included at the Social Sciences Citation Index (SSCI), Science Citation Index (SCI) and Arts and Humanities Citation Index (A&HCI). We selected these databases because they encompass most of the publications registered in the three major branches of knowledge. In parallel, we collected all the literal descriptors of the RFs available at the 2020 Essential Science Indicators interface, by research area as in the case of the example provided in the introductory section.

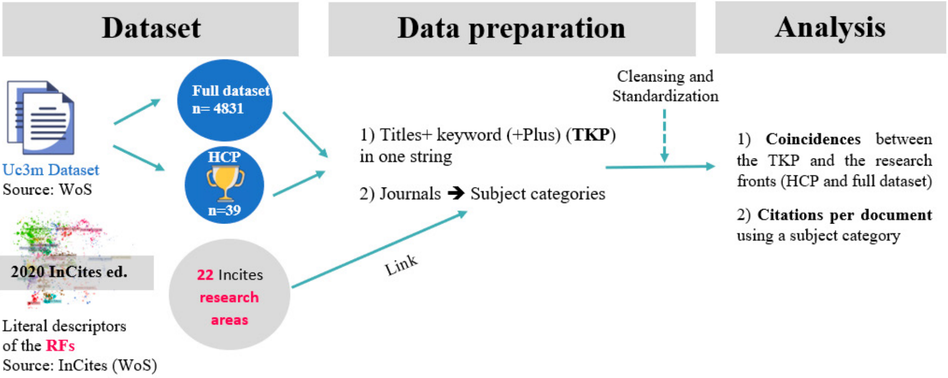

Figure 1. Workflow used in this study

Data preparation

1) In this step, we merged the titles, keywords and keywords plus (TKP) into a single string for each article. We also removed from the matching process all the coincidences of single terms *(Cleansing and Standarization),* given the greater likelihood that these terms are void or spurious in terms of their relationship to the strings defining each research front. This was intended to provide a more conservative and robust measure of the alignment of the documents with the research fronts.

2) We linked each subject category in which the journals of our dataset are classified to one of the 22 In-Cites research areas (not all WoS journals are classified in an ESI field). For this purpose, we used the list of journals in each In-Cites category and identified the frequency of their WoS category, using the maximum frequency of coincidence as rule of attribution of a WoS category to an In-Cites category. If an article's journal is classified in two subject categories that belong to the same In-Cites classification, the article was counted as one whole publication classified in that single research area. In the case of a journal classified in *n* subject categories that were mapped to different In-Cites categories, we calculated a direct fractional score using the formula 1/n, where n is the number of different research areas associated to the subject categories. We then summed the fractional scores for each of the 22 research areas. That value is the number of contributions per research area.

Analysis

The analysis is conducted in two steps.
1) In a first step we calculated the number of coincidences between the TKP and the RFs. We searched, for each RF definition the coincidence of terms from the contributions' merged titles, keywords and keywords plus in the same field. In example, we found that an article in the area of Economics contained the string 'corporate social responsibility', which is one of the four terms of one of the research fronts in that field. The result of this process was the number of coincidences between each article's TKP and the RF in their own research area for the overall output of the UC3M-
2) We also calculated the citations per document using the fractional counting method. In a final step, we compared the citations per document using an In-Cites category scheme between the documents with at least one coincidence with the associated research area's RF and those without coincidences. We tested the existence of statistically significant differences in their median citations using Mann-Whitney's U test.

Results

Table 1 illustrates the median citations of the articles with and without coincidences with the RFs by In-Cites discipline. In all cases but Neuroscience & Behavior the median citations is greater in the case of articles with RF coincidences and in five of them these are statistically significant (p-value=.05).

Discussion and conclusions

The results do not allow establishing a causal relationship between RF alignment and citation potential, but yes a positive association. The results evidence a greater impact of RF-aligned research over non RF- aligned papers: this does not immediately follows from the definition of the RF (which are extracted only from HCP), but rather suggest the existence of a continuum of alignment between papers and RFs beyond the boundaries of the HCP set. If this continuum exists, the 'distance' or 'alignment' with RF seems to be non-independent from the existing citation count and possibly from the citation potential of scientific literature. Although the data is not fully developed yet, preliminary comparisons of citations per document by field of knowledge show that UC3M output in several fields is below the median for the public Spanish University System. This might also correspond with a lower alignment of its research lines with the RFs in the case of UC3M. Despite the lack of proven causality, the clear association between alignment and impact underlines the usefulness of taking the descriptors of the RFs as potential points of reference for decision-making concerning the prioritization of research lines, resource allocation, and economic incentives (Chen and Guan 2011).

Table 1. Descriptive statistics for the contrast of medians between the articles aligned and not aligned with the RF at UC3M.

	N. Articles with coincidence with RF	*N. Articles without coincidence RF*	*% aligned with RF*	*Median citations (coincidence)*	*Median citations (no coincidence)*	*Bilat. Sig.*
Engineering	573	951	37.60	2.5	2	0.003
Computer Science	211	454	31.73	2.33	1.5	0.001
Physics	172	882	16.32	3	3	0.707
Mathematics	146	503	22.50	2	1.33	0.004
Materials Science	131	280	31.87	3	2.5	0.168
Chemistry	129	330	28.10	3	2	0.003
Social Sciences, General	111	283	28.17	2	1	0.023
Economics & Business	94	314	23.04	3.5	2	0.001
Clinical Medicine	54	46	54.00	3	2.17	0.219
Neuroscience & Behavior	27	20	57.45	3.5	4.08	0.647
Environment/Ecology	22	67	24.72	3.67	2.5	0.066
Psychiatry/Psychology	15	27	35.71	5	2	0.168

Note. Biology & Biochemistry, Geosciences, Pharmacology, Agricultural Sciences, Immunology, Space Sciences, Plant & Animal Science and Molecular Biology and Genetics count with 7 or less articles with coincidences. These values are considered too low to allow extracting useful conclusions and for that reason are not included in the table.

This research presents some limitations that the authors intend to overcome in the near future. HCP considered in this study are not limited to a given time period, which might imply a form of bias in the analysis of the RFs alignment (an HCP from 2012 might present spurious alignment with current, 2019 RF). In addition, these results can be considered valid for the UC3M outputs, but further research implies the necessity of testing the congruence of these results with other institutions of different types (technical, generalist, established and new universities). It has not been possible to establish a causal relationship between citations and alignment with RFs and this might limit the usefulness of the conclusions for the university, albeit RFs are systematically used for similar objectives in Clarivate Analytics' In-Cites. In this sense, despite already taking into account some of the main sources of variability in citations (the same institution and most lecturers and their output divided by fields of knowledge), we expect to isolate other intervening sources of variability maximizing the *ceteris paribus* scenario in further research. Concerning the methodology used for counting the coincidences, the authors acknowledge that more sophisticated procedures have been developed and tested for text-based relatedness measures, such as those detailed in section 3.2 of Waltman et al (2020). In this first approach, we used a simpler methodology in terms of co-occurrence in order to serve as a proof of concept, but further developments would imply the use of the aforementioned measures and procedures when applicable. Finally, we only counted coincidences as a dichotomous variable: an article presents a coincidence with a RF if two or more terms coincide. The degree of alignment of an article with a RF could vary substantially taking into account the number of coincidences for a single paper (i.e. paper 'a' presents 1 coincidence whereas paper 'b' presents four coincidences', both with the same RF). That gradation ought also to be addressed in further research.

Abstract

We examined research papers from the Russian Federation during the 14 years, 2006-19, in chemistry, physics, mathematics, and biomedicine, that were covered in the Web of Science (WoS) Science Citation Index – Extended. We saw a modest expansion in physics, chemistry, and mathematics which are traditional Russian strengths. However, following directives from VV Putin, biomedical research is now also being encouraged. We compared the mean numbers of Total Citations (TC) to papers from different years with their usage counts in the WoS. U1 shows the numbers of usages in the last 180 days, and U2 gives the count since 2013. These "altmetrics" provide an alternative means for research evaluation, and can give an indication of the papers' interest and utility to other researchers earlier than citation counts. Usage counts (U2) are mostly higher than TC for recent years. Russian physics papers are the most cited, but chemistry papers receive more usage counts. Biomedical research has expanded, more than the other subject areas of our study, but it is still not well cited.

Introduction

Traditional scientometrics, as originally defined (Nalimov & Mulchenko, 1969) meant "the quantitative methods of research on the development of science as an informational process". It involves the counting of papers, and citations to them from other papers, and their classification in various ways. The production of the world in particular subject areas, of individual countries, of research institutions (such as universities), of research groups, and even of individual scientists, can all be counted, and compared with those of others in order to assist the process of research evaluation. More recently, with the rise of social media and many other types of document, the concept of citations has been widened to include these citations, which are often referred to as "altmetrics". Altmetrics is "the study and use of scholarly impact measures based on activity in online tools and environments" (Priem *et al*, 2012). Also called Scientometrics 2.0, this field complements journal citations with impacts in social networks such as views, downloads, "likes," blogs, Twitter, Mendeley, CiteULike (Mingels *et al*, 2015). Research by Thelwall *et al* (2016) focused on medical publications (332,975 articles in 45 fields) indexed by Scopus in 2009. This study demonstrated a strong correlation between citations and Mendeley readership counts across all medical fields. According to the authors' opinions, altmetric indicators should be used as a substitute for classical metrics. The field has spawned many learned articles, and even a new journal, the *Journal of Altmetrics Research*, which was founded by the late Judit Bar-Ilan in 2019.

In fact, there are two related fields, *webometrics* and *altmetrics*. The former is used to refer to references and other parameters that are found on the World Wide Web. These new research areas have provided some interesting insights into the world of scientific publishing, but they suffer from the disadvantage (from a scientific point of view) that they are essentially transitory, and so their findings cannot easily be repeated at a later date, which is a core requirement of scientific research. A significant growth of altmetric research, based on Web of Science data (WoS), was observed during the previous three years (Kousha *et al*, 2020, Fang *et al*, 2020). The peculiarity of classical citations metrics and altmetrics indicators were investigated in comprehensive bibliometric analysis conducted by Chi *et al* (2019) on two subfields of chemistry: analytical chemistry (C1) and organic chemistry (C3). Three types of indicators (Capture, Citation, and Usage Counts) were selected and extracted from the following platforms: WoS, Scopus, Mendeley, EBSCO, and CrossRef. The dataset of 39,736 papers in analytical chemistry (C1) and 27,531 papers in organic chemistry (C3) indexed by the WoS in 2013 was investigated. DOI identifications were used to match the dataset with PlumX. The results of the study showed significant correlations at different levels among various altmetric indicators. A high correlation was observed among classical citation indicators on the platforms that were studied.

However, not all these new indicators suffer from this lack of reproducibility. There are, in fact, several good alternatives to the counting of citations in the serial literature. One of the first to be exploited was the reference section of patents. These were found to be an indication of the scientific underpinning of the inventions, and they included not only other prior patents, but also scientific papers from journals and conference proceedings. It was found that if a patent had many non-patent references, it was likely to be valuable (Harhoff *et al.*, 1999). Another finding was that the research cited in this way was often basic rather than applied (Narin & Olivastro, 1998). Another form of citation that has been examined for some years, but has not been widely used because there is no convenient database, is the way the mass media, and in particular newspapers, publish stories about research. These are particularly frequent in medical research, and allow scientists' discoveries to be appreciated by the general public, and also by policy makers, and other scientists, who may give more academic citations to the cited papers as a result of this publicity (Phillips *et al*, 1991; Lewison *et al.,* 2008).

For the last two decades (Grant, 1999; Grant *et al*., 2000), the references on clinical practice guidelines have been used to show how medical research can be translated into clinical benefit through the recommendations that they provide, and which will increasingly be used to guide, and sometimes to determine, medical care. The references are usually chosen as a result of a careful search of the literature, and many potentially eligible papers are discarded because their methodology is not regarded as sufficiently rigorous. Recently, the process of collecting these references has been automated by Minso Solutions AB in Boras, Sweden (Eriksson *et al*., 2020; Pallari *et al*, 2021) so that a research funder, or a performer, can see which of their papers have been cited in this way. This process tends to strongly favour clinical work rather than basic research; it thus can help to redress the balance because counts of citations in journal articles usually benefit the latter (van Eck *et al*., 2013).

In September 2015, the Web of Science (WoS, © Clarivate Analytics) introduced two new indicators of research impact. They are designated as U1 and U2. U1 counts the numbers of "usages" of a paper in the last 180 days, and U2 counts the numbers since 2013. "Usage" means that the person who has searched for a paper in the WoS has either attempted to download the full text, or has saved its record in a bibliographic reference manager (such as EndNote) or some other downloadable format. This is a new field of altmetrics, and it has led to several investigations that have attempted to compare these usage measures with citation counts (Markusova *et al*., 2018; Chi & Glänzel, 2019; Lewison, 2020). The results have been somewhat inconclusive because they are measuring different behaviours. In principle, a researcher would first identify a paper of interest by way of its title, then read the abstract (normally easily available), perhaps obtain a full text, especially if it is Open Access (OA), and then finally read the paper and cite it in a subsequent research paper of her own.

In this paper, we have examined Russian research production in four major fields: chemistry, mathematics and physics, the traditional areas of strength in Russian science, and one to which increased attention is now being given, namely biomedicine. Evaluation of research is now playing a greater role in the Russian Federation. Two presidential Decrees have concerned research. The first, #599 in May 2012, set a goal "that the Russian share of research productivity (RO) has to reach 2.44% of the global RO, and five Russian universities have to be among the top hundred universities included in one of three world ranking systems in 2015". There are further ambitious goals established in the Decree N 204 published in December 2018 (http://static.kremlin.ru/media/acts/files/0001201805070038.pdf). These would use research to propel the Russian economy into the top five of the world by 2024. The decree also established seven strategic priorities, and for the first time (Starodubov *et al.*, 2019) one of them was medicine. We will use different indicators to see if the Russian research system is responding to these challenges, and in particular, data on Total Citations (TC) and the two usage counts (U1 and U2) for Russian papers published during 2006-19.

Methodology

We downloaded the bibliographic details of all papers in the WoS with an address in Russia in the years 2006-19 in six subject categories (SC) by WoS classification: mathematics, 20 sub-fields of biomedicine, and two major sub-fields in each of chemistry and physics. These were inorganic & nuclear and physical chemistry, nuclear physics, and particles & fields. [The search was restricted to the Science Citation Index - Expanded (SCI-E). Because of the history of the science structure in Russia, which is focused heavily on hard science, there are only a small number of Russian social sciences and arts & humanities journals compared with natural sciences that are indexed in the WoS.] We then determined the number of papers each year in these six subject areas, and for each paper, the total number of citations to the date of retrieval in July 2020 (TC), and the values of U1 and U2 (see above). In total, we compiled data on 485,505 papers, which formed our database.

The main indicators for analysis were:

- The number of publications;
- The number and percentage of records that had at least one U1 value >= 1, one U2 value >= 1; and received at least one citation (TC)
- The mean number of citations (TC) per year;
- The mean number of U1 and U2 counts per year;
- The number and percentage of highly cited records;
- The percentage of OA publications in 2013. (Our hypothesis was that access to full-text publications could have an impact on usage counts.)

By way of example, mean values of TC, U1 and U2 were calculated as the quotient of total citations and usage counts to July 2020 (when the papers were identified and their details downloaded to file) divided by the number of papers published in a given year.

In order to see whether the research evaluation targets set by President V.V. Putin were met, or approached, we also determined the numbers of all papers in the SCI-E, and those in chemistry, mathematics and physics, and those in the defined subfields of biomedicine. These could then be compared with the respective totals with an address in the Russian Federation.

We made a detailed examination of the distribution of TC and U2 usage counts for the 2014 Russian papers in biomedical research (n = 6672). These papers were divided into individual groups with the same numbers of citations, or U2 counts, 0, 1, 2,3... Then the sum of citations and U2 counts for each group was calculated. These sums, as percentages of the respective totals, were then plotted on the ordinate axis of a graph, the abscissa being TC or U2. Not all values of TC or U2 were represented, and the gap between values, unity for small ones, became much larger for high values.

Results

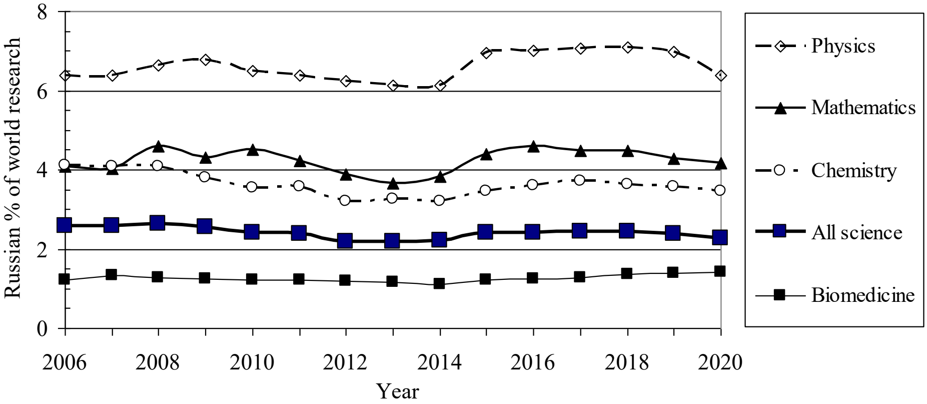

Figure 1. Russian research productivity in the Science Citation Index - Extended, 2006-20, in all science and in four major fields (integer counts), percentages of the world totals.

The first analysis was of Russian production in the four major fields, plus all science, and the comparison with world production is shown in Figure 1. Here Russian production is given as integer counts, *i.e*., full credit is given for each paper that contains at least one Russian address. It is clear that the target of Russia publishing 2.44% of world science was met easily for the three traditionally strong fields but not in biomedicine, where the average was only 1.26 %, though it did increase to 1.41% in 2020. There was a small but definite increase in all the percentages in 2015, mostly following a gradual decline from about 2008. But it has been followed by further small declines in the last two years. The Russian presence in all science has hovered around the target figure of 2.44%. It was slightly higher in 2006-09, but has since declined and dropped to 2.26% in 2020.

Among the 161 Russian journals indexed by SCI-E there are 41 journals in physics. Historically these journals are of high quality, six of them belonging to the top two citation quartiles (JCR, 2019). Russian science is moving rapidly towards open access (OA), which will improve its likelihood of being cited. Only 9% of its papers in 2006 were OA, but 15.4% were in 2013, and 28% were in 2020. However, the corresponding figures for the world were 20% in 2006 and 40% in 2020, because many of the major research funders in the USA and Europe are insisting that publications with their support should be OA, and are providing money for author publication fees (anon, 2008; Widener, 2018).

We turn now to the effects of Russian research in the six subject areas, two each in chemistry and physics, mathematics and biomedicine. The graphs, Figures 2 to 7, show the mean values of total citations (TC), and the two usage measures, U1 and U2. [The values of U1 are quite small, so 10 x U1 has been plotted so as to make them more visible, and any variations with time more obvious.] In all six graphs, mean U2 reaches a peak for papers published in 2013, because papers published earlier have "lost" some of their usage counts from their early years, when they normally attract the most interest. In the subsequent years, the curves of mean values of TC and U2 parallel each other. For most of the years, values of U2 exceed those of TC, indicating that scientists download more papers than they cite, as would be expected.

However, in mathematics and in physics: particles & fields, the two curves are almost superimposed, suggesting that for these fields a sight tends to lead to a cite. The lack of cites following a download is greatest for the two chemistry subject areas, where the ratio of U2 to TC is more than two for papers from 2012, and increases to four for 2016-17 papers, and six for the ones published in 2019. However, this may simply indicate that chemistry citations are much slower to appear than they are in other fields of science.

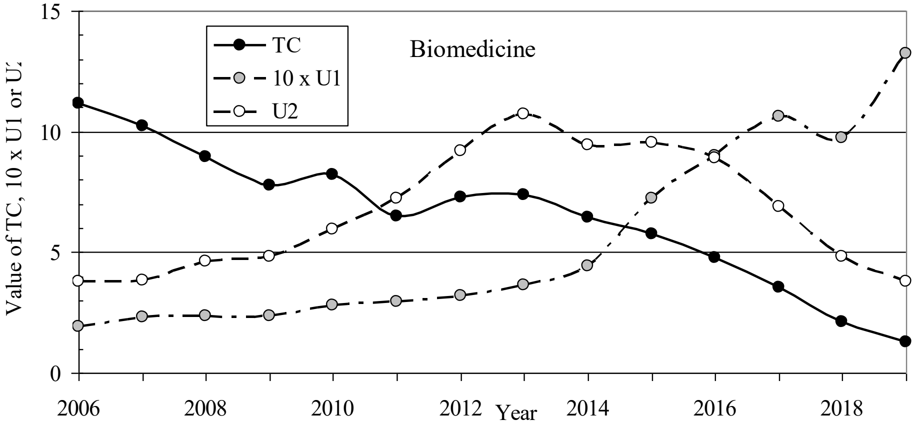

Figure 2. Mean values of total citations (TC) and usage counts U1 (multiplied by 10) and U2 for Russian biomedical papers in the WoS published in different years, 2006 to 2019.

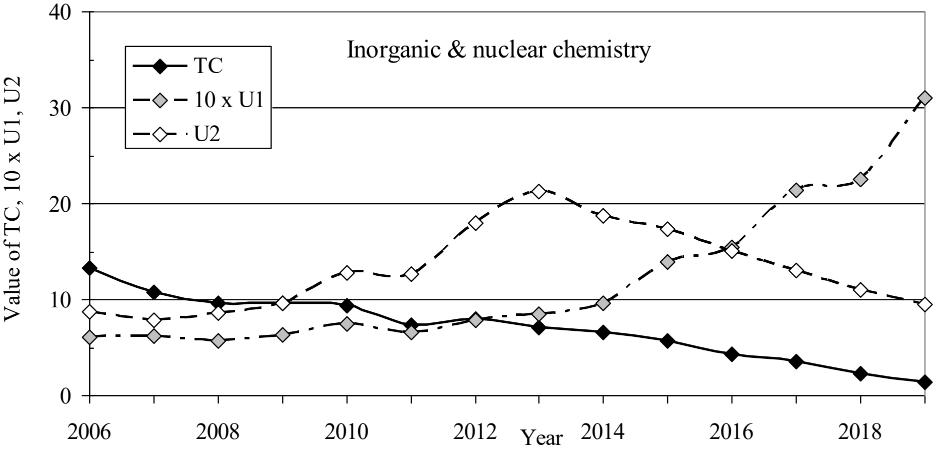

Figure 3. Mean values of total citations (TC) and usage counts U1 (multiplied by 10) and U2 for Russian inorganic & nuclear chemistry papers in the WoS published in different years, 2006 to 2019.

The values of U1 rise steadily for the most recent papers in biomedicine and both subject areas in chemistry, but not for mathematics and physics, where the peak occurs for 2017 papers. This indicates that in these subjects the maximum usage does not occur for papers in their first year, but takes two to three years to build up, as happens for citations. Chemistry papers receive a lot of usage in their first year, much more than those in physics (means are between one and two) and especially in mathematics (mean value below 0.3). This confirms what is known about this subject, that papers take a long time to emerge (some require many months to be checked by reviewers), and take even longer to have an impact.

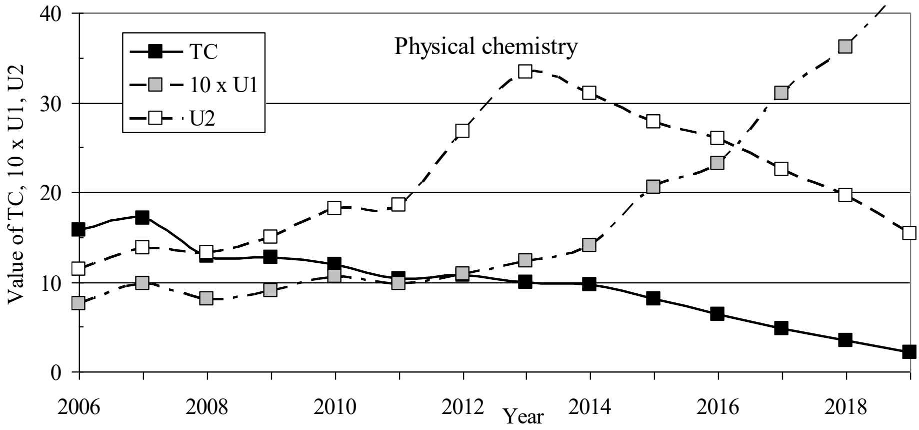

Figure 4. Mean values of total citations (TC) and usage counts U1 (multiplied by 10) and U2 for Russian physical chemistry papers in the WoS published in different years, 2006 to 2019.

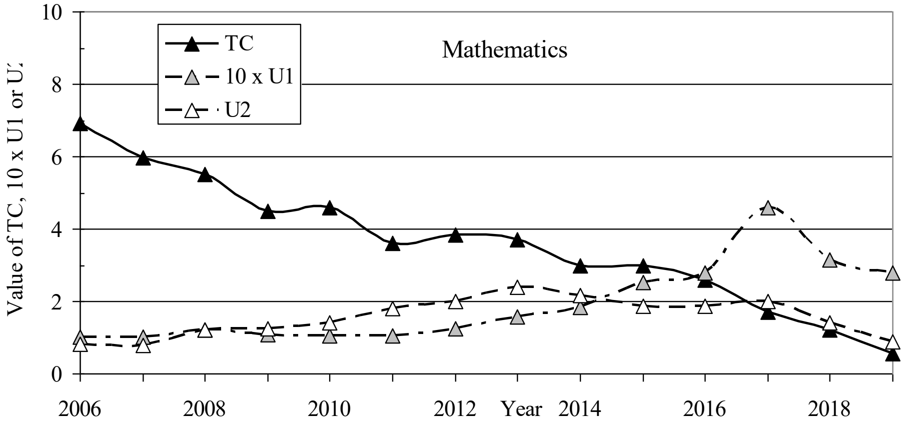

Figure 5. Mean values of total citations (TC) and usage counts U1 (multiplied by 10) and U2 for Russian mathematics papers in the WoS published in different years, 2006 to 2019.

It is very clear from these graphs that the most cited papers of these six groups were those in the two subject areas of physics. This held true for papers in all publication years, as Table 1 shows. There are several possible reasons for this, apart from the generally accepted high standing of the subject in the Russian Federation. One is that there is a high level of international collaboration: 59% of physics papers are collaborative compared with 32% for all Russian research productivity (RP). A consequence is that physics has a much higher share of highly-cited articles (ones in the top 1%), namely 1.12%, compared with just 0.66% for our dataset (InCites, 2015-19).

Table 1. Mean total citation (TC) scores for Russian papers in six subject areas in four years.

Year	Phys, P&F	Phys, Nucl	Chem, Phys	Chem, I&N	Biomed	Maths
2006	33.6	42.2	15.8	13.3	11.2	6.9
2010	22.0	14.4	11.9	9.4	8.2	4.6
2014	15.5	13.3	9.6	6.6	6.5	3.0
2018	8.2	4.3	3.5	2.2	2.1	1.2

Table 2. Mean usage count (U2) for Russian papers in six subject areas in four years.

Year	Phys, P&F	Phys, Nucl	Chem, Phys	Chem, I&N	Biomed	Maths
2006	3.1	6.1	11.4	8.7	3.8	0.8
2010	5.2	5.8	18.2	12.8	6.0	1.4
2014	10.0	13.1	31.0	18.8	9.4	2.1
2018	8.9	7.2	19.7	11.1	4.8	1.4

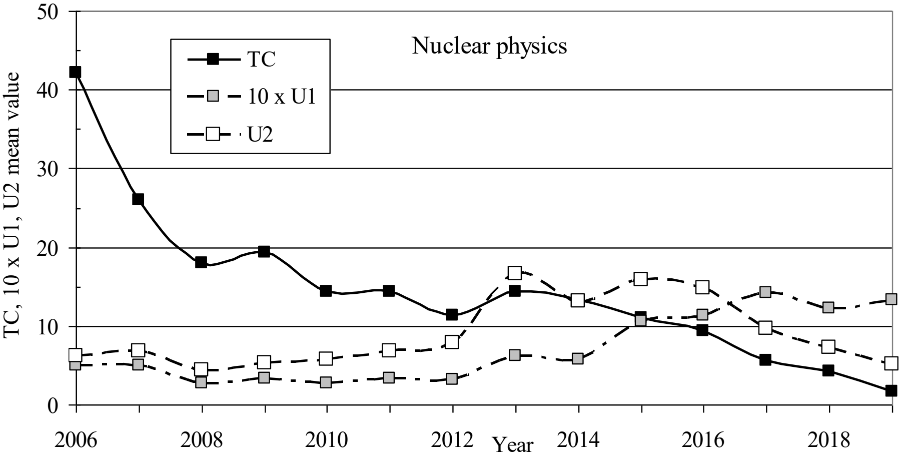

Figure 6. Mean values of total citations (TC) and usage counts U1 (multiplied by 10) and U2 for Russian nuclear physics papers in the WoS published in different years, 2006 to 2019.

On the other hand, the mean usage counts for the physics papers tend to be lower than for the chemistry papers, as seen in Table 2. This might be owing to an archive on high energy physics that has been operating since 1991 and is very popular among specialists (https://arxiv.org/archive/hep-th) (Chumachenko *et al.*, 2020). It is also noteworthy that in 2013, 42% of Russian particles & fields papers were published in OA journals, compared with the average of 15% for all Russian science publications. As mentioned above, the users of physics publications do not show a significant interest in very recent literature compared with users of research in other disciplines because the values of U1 peak in 2017 rather than in 2019. The height of the peak in U1 in 2017 for particles & fields (Figure 7) is 4.4, which is much the highest for the six disciplines studied here.

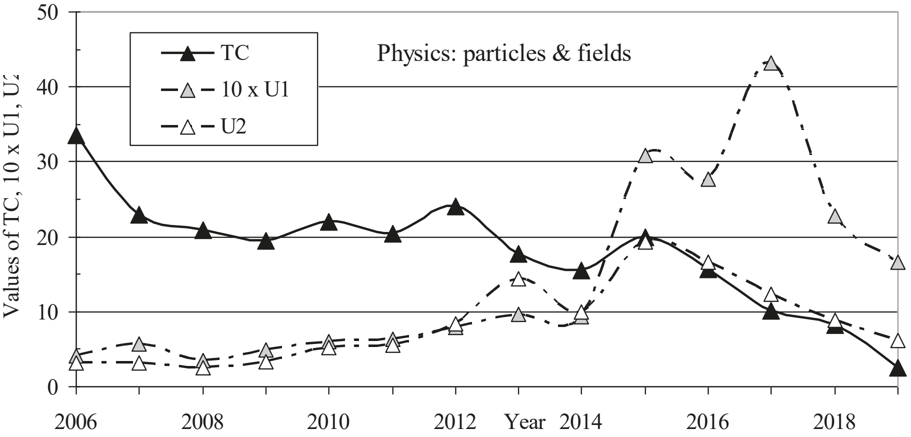

Figure 7. Mean values of total citations (TC) and usage counts U1 (multiplied by 10) and U2 for Russian physics: particles & fields papers in the WoS published in different years, 2006 to 2019.

The highest values of U2, in the peak year of 2013, are much higher for the two chemistry subject areas than for the other four, see Table 2. Researchers would have had to depend on abstracts, or to search for full-texts in the National Library because the OA percentages were only 3.6% in physical chemistry and 5.1% in inorganic & nuclear chemistry, far below the corresponding values for nuclear physics (25%) and particles & fields (42%). And a check on 12 chemistry papers with the highest U2 counts showed that they were closed access, with the full text only available through the journal publisher.

Mathematics has also been seen as a great Russian scientific strength, and Figure 1 shows that the Russian presence in the field is almost twice that of its presence in world science. However, its average TC score is much lower than that of the other five disciplines, see Table 1. The same is even more so with respect to U2, and this is perhaps surprising because the share of OA journals was relatively high at 23% in 2013.

As mentioned above, one of the strategic priorities selected by the Russian government is speedy development of “high-tech medical care and personalized medicine and health-saving technology”. The current pandemic showed the necessity of improvements in social medicine improvement in every country. The speedy development of the Russian vaccine “Sputnik-V” aroused great attention around the world. The creation of this vaccine is a tribute to many Russian scholars’ contributions to virology. It followed the development of an oral polio vaccine by Soviet microbiologists Professors K.M. Chumakov and M.I. Voroshilova. This saved the lives and health of millions of children in Africa in the 1960s (Kramer, 2020).

Biomedical research, although still only a small part of the overall Russian research portfolio, has been relatively successful in responding to this directive. The Russian percentage presence in the world has risen over the 14-year study period from 1.23 to 1.41%, or by 8%, see Figure 1. This may seem modest, but it contrasts with an increase of only 3% in physics, and *contractions* of 11% in all science and 14% in chemistry. Russian biomedical research accounted for 15% of all its scientific production in the WoS in 2019, and 23% of our database of Russian papers. However, it is still not well cited compared with the more traditional strong subjects, see Table 1. A consequence is that the leading Russian biomedical journals had very low citation Impact Factors: *Kardiologie* (0.13) and *Gematologiya i Transfiziologita* (0.06) in 2019. A recent study of cancer research in Eastern Europe (Begum *et al.*, 2018) revealed that the papers from Russia received fewer five-year citations on average than those of many other East European countries such as the Czech Republic, Estonia, Hungary, Poland, Slovakia, Slovenia and Ukraine.

The plot of the sums of TC and U2 values for the 6,672 biomedicine papers is shown in Figure 8. It shows that the two indicators are closely related. Only 14% of Russian publications in 2014 were OA, compared with a world average of 37% in that year.

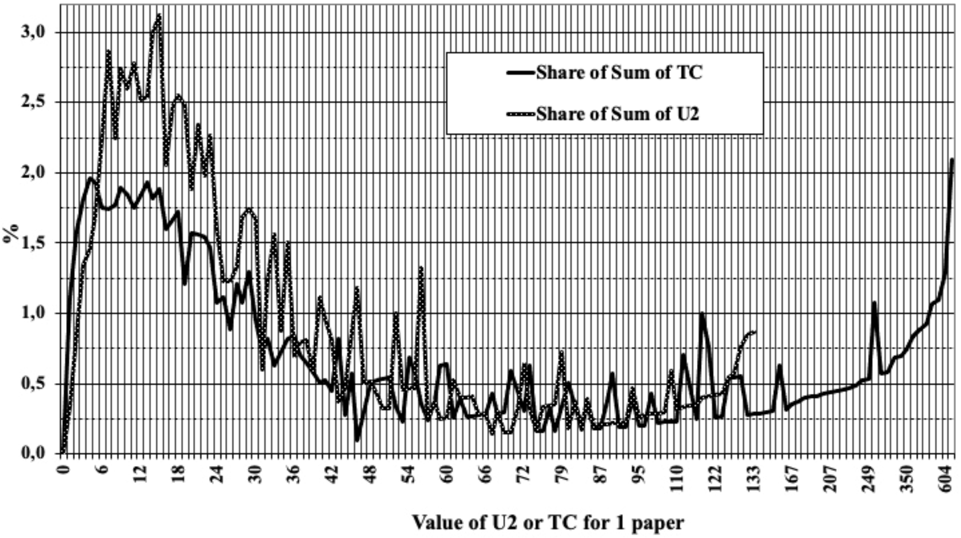

Figure 8. Share of sum groups with the same TC or U2 value for Russian biomedical research papers in 2014 in the SCI-E of the Web of Science.

Discussion

Our analysis of total citations (TC) and of counts of usage since 2013 (U2) showed a similar trend in both with time for all the subject areas that we studied except for mathematics. For the biomedical papers published in 2014, relatively few (15%) were effectively ignored by WoS readers and had U2 = 0, but many more (36%) were not cited between 2014 and 2020. It is notable (Fig. 8) that the TC distribution has risen because of the highly-cited articles (HCAs). In the whole dataset for 2014 there were 203 HCAs, and 28 of them were on biomedicine. The HCAs had a big influence (22%) on the total number of biomedical citations, but the highly-used articles (those among top 1%) made only a small contribution to the usage total (6.7%). Among these papers only one was published with domestic collaboration. It was in the Russian journal *Acta Naturae* (with an Impact Factor of only 1.36) which has been assigned to the Q4 journal group in the subject category Cell Biology. One article in particular (Makarov *et al*., 2014) received 484 citations (to July 2020), but only 82 usage counts. On the other hand, another one, the review article (Surmenev *et al.,* 2014) had the most usage counts (486) and also had many citations (389). Most (78%) of the HCAs were published with US co-authors and their percentage in OA journals was 84%.

The similarity of the two sets of data in Figure 8 provides evidence that the two indicators, TC and U2, are closely related. After 2013, the mean value of U2 is substantially higher than TC. This suggests that this altmetric indicator could attract attention to a publication at least a year before it attracted a significant number of citations.

There are some limitations to this analysis. The biomedicine dataset is restricted to one year, and subject categories were grouped into broad areas by formal criteria. We plan to continue our analysis, investigating the influence of time-span on usage metrics. Another interesting objective of our future work is to identify hot research topics with altmetric data for Physical Chemistry.

Conclusions

We analysed a dataset of 485,505 publications, whose authors have at least one affiliation in Russia, that were indexed in the SCI-E in 2006-2019. Our objective was to explore the relationship between usage metrics (as an example of altmetrics) and classic citation metrics. Our results demonstrate a similar pattern between total citations (TC) and usage counts (U2) since 2013 in all the disciplines that we studied and in total Russian research production, except for mathematics. Chemistry, Physical, and Chemistry, Inorganic & Nuclear, have the highest values of the altmetric indicator U2 (33.4 and 21.2 respectively) in 2013 compared with any other disciplines that we studied.

The biomedicine group (6,662 publications) revealed a significant difference between the percentage of publications that did not attract any attention (15%) and the percentage of uncited publications (36%) in 2014. The share of the TC distribution has been rising because of the highly-cited articles (HCAs). It is remarkable that 28 HCAs (0.42% of the total) received 22% of all citations and 8% of the U2 counts. Only one HCA was published without international collaboration.

Since 2013 the usage count U2 values have been substantially higher than the citation score TC values. This suggests that this altmetric indicator could draw attention to a publication at least a year before it could attract a significant number of citations. Our data show that access to OA journals has an unexpected impact on usage counts U2: their values are significantly higher if the user needs to request a full-text copy from the publisher.

Altmetric indicators are now being used by many members of the Russian science community as an essential science indicator. U2 and TC do not contradict each other, but they do measure different aspects of behaviour.

Acknowledgments

We are grateful to the Russian Foundation for Basic Research (grants 20-07-00014 and 20-010-00179) for financial support, and to Clarivate Analytics for the opportunity to use their data.

Abstract

Unlike other academic bibliographic databases, Google Scholar intentionally operates in a way that does not maintain coverage stability: documents that stop being available to Google Scholar's crawlers are removed from the system. This can also affect Google Scholar's citation graph (citation counts can decrease). Furthermore, because Google Scholar is not transparent about its coverage, the only way to directly observe coverage loss is through regular monitorization of Google Scholar data. Thus, few studies have empirically documented this phenomenon. This study analyses a large decrease in coverage of documents in the field of Astronomy and Astrophysics that took place in 2019 and its subsequent recovery, using longitudinal data from previous analyses and a new dataset extracted in 2020. Documents from most of the larger publishers in the field disappeared from Google Scholar despite continuing to be available on the Web, which suggests an error on Google Scholar's side. Disappeared documents did not reappear until the following index-wide update, many months after the problem was discovered. The slowness with which Google Scholar is currently able to resolve indexing errors is a clear limitation of the platform both for literature search and bibliometric use cases.

Introduction

Academic bibliographic databases, and especially those that generate citation graphs, usually implement document inclusion policies that rarely allow records of documents to be removed once they have entered the system. In a bibliographic database that is intended for literature discovery, coverage stability is a desirable property, if we assume that users intuitively expect a system to retrieve the same documents over time given the same query (in addition to new documents that also meet the search criteria). This property is especially critical for some literature search use cases such as those carried out for systematic reviews, where reproducibility of the process is essential (Gusenbauer & Haddaway, 2020; Haddaway & Gusenbauer, 2020). In a citation index, the disappearance of a document would affect the citation counts of all its cited documents, impeding some types of citation analysis.

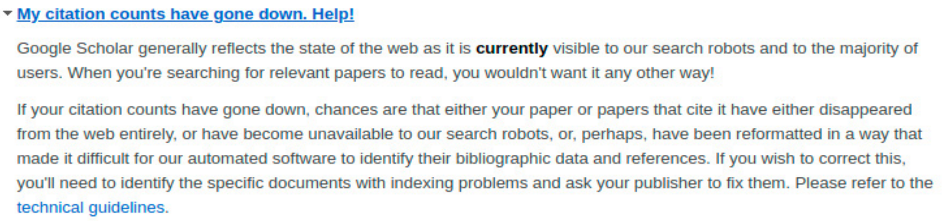
Google Scholar continues to be widely used for literature discovery, and sometimes as a data source for research evaluations. Some reasons for this are its comprehensive coverage, and that it is free to access. However, unlike other analogous tools, Google Scholar intentionally operates in a way that does not maintain coverage stability (Delgado López-Cózar et al., 2019). Instead, Google Scholar mirrors the general-purpose Google search engine, and subordinates the continued inclusion of documents in its index to their ongoing availability on the Web (as well as their continued abidance to Google Scholar's technical guidelines). Its documentation declares that this approach was chosen to provide a current reflection of the academic web at any given time (Google Scholar, n.d.-b).

As a result of this policy, coverage in Google Scholar not only increases when new documents indexed, but can also decrease when indexed documents become unavailable to Google Scholar's crawlers. To learn whether documents have stopped being available on the Web, Google Scholar carries out two complete recrawls of its index approximately every year (Google Scholar, n.d.-a). If Google Scholar's crawlers are not able to access a document during one of these recrawls, it is removed from the index.

In some cases, documents that have been removed are still findable in Google Scholar, because they are available from other sources on the Web which Google Scholar also indexes, or because they are cited in other works indexed in the system (in these cases, the document is kept as a *[CITATION]-type* record). However, in other cases, and usually after one of these major index recrawls, documents stop being findable in Google Scholar altogether, with the added consequence that citation counts of the documents that they cite also suffer a decrease (provided that cited reference metadata was available for the removed documents).

If we consider Google Scholar merely as a gateway, a digital *non-place* (Augé, 1995) through which users navigate to the places where academic documents can be accessed, rather than as a data source in its own right that could serve as a record of the inherently cumulative academic knowledge and the interactions that occur between academics, then the decision to not display information about documents that are no longer accessible is understandable (if an airport loses a flight route, it does not make sense to for it to keep displaying information about it). Furthermore, under this point of view, decreasing citation counts may not be an overly concerning issue, as their purpose would only be to serve as one of the parameters that is used to rank documents in a search, a purpose for which a certain amount of inaccuracies in citation counts can probably be tolerated.

However, Google Scholar is perceived as a bibliographic data source by many users, which makes decreasing coverage problematic. For example, researchers sometimes report author-level indicators calculated by Google Scholar in research evaluation processes (hiring, promotion, grant applications…), and seeing these figures decrease overnight and without explanation can be a cause of concern and confusion to them. Probably it is the number of questions about this phenomenon that has led Google Scholar to include a clarification in its help pages about why this occurs (Figure 1).



▾ My citation counts have gone down. Help!

Google Scholar generally reflects the state of the web as it is **currently** visible to our search robots and to the majority of users. When you're searching for relevant papers to read, you wouldn't want it any other way!

If your citation counts have gone down, chances are that either your paper or papers that cite it have either disappeared from the web entirely, or have become unavailable to our search robots, or, perhaps, have been reformatted in a way that made it difficult for our automated software to identify their bibliographic data and references. If you wish to correct this, you'll need to identify the specific documents with indexing problems and ask your publisher to fix them. Please refer to the technical guidelines.

Figure 1: Extract from Google Scholar help page that explains why citation counts of documents sometimes decrease in this platform

The issue of decreasing coverage in Google Scholar is compounded by the fact that there is no public information on the sources that are covered by this search engine. Therefore, users have no way of knowing when certain collections of documents are removed from the index, opening the possibility to situations in which users may decide to rely on this platform based on assumptions regarding its coverage that no longer hold true.

This lack of transparency means that the only way to directly observe coverage loss is through regularly monitoring Google Scholar data: recording states of the index at regular intervals. This makes this phenomenon difficult to analyse, as extracting data from Google Scholar is very time-consuming (Else, 2018), and it is difficult to anticipate which documents are going to be dropped by Google Scholar and when. Because of this, few studies have empirically documented this issue.

In November 2017, while carrying out an annual update of a directory of Spanish academic journals covered by Google Scholar Metrics (an annual product released by Google Scholar that calculates a 5-year h-index for journals), Delgado López-Cózar & Martín-Martín (2018) noticed that the number of available Spanish journals in this product had sharply decreased compared to previous years, breaking the general growing trend observed since 2012: while the 2016 edition of the directory contained 1,101 Spanish journals, in the 2017 edition only 599 journals could be found (Delgado López-Cózar & Martín-Martín, 2019). Journals from all fields disappeared, but Law journals were particularly affected, going from 156 journals in 2016 to 35 journals in 2017. Because Spanish law journals do not yet have a strong presence on the Web, we turned our attention to the largest bibliographic database that focuses on academic content published in Spain: Dialnet. This database is still the only window through which many journals published in Spain are visible on the Web, and therefore was considered likely to be involved in this *blackout* of Spanish scientific production in Google Scholar. After searching content available from Dialnet in Google Scholar and comparing the results to previous web domain analyses that we had carried in the past (Delgado López-Cózar et al., 2019), it was confirmed that most of the content from Dialnet had disappeared at some point from the search engine. This analysis was published in the Spanish LIS-focused mailing list *Iwetel,* where Dialnet's Technical Director confirmed that they had been aware of this issue since June 2017. Apparently, Google Scholar had detected that the metadata of a small batch of old records from Dialnet were inconsistent with metadata for the same documents found in other web sources, and decided to remove most of Dialnet from its index under suspicion of providing incorrect metadata. Dialnet promptly fixed this issue, but its records did not return to Google Scholar results until the following complete recrawl of the index was made public in January 2018. Thus, users interested in this content and who knew it to be covered in the past were unknowingly underserviced by Google Scholar for more than half a year. In this case, the issue was more difficult to detect because Dialnet did not contain cited reference metadata that Google Scholar could access and use in its citation graph, and therefore citation counts were not affected. This episode revealed that despite its known errors and limitations (Orduna-Malea et al., 2017), Google Scholar subjects its data to certain quality-control measures. This is, to our knowledge, the first empirically documented case of a large coverage fluctuation in Google Scholar.

In 2019, the editor of the journal *Astronomy & Astrophysics* denounced an apparently similar case (Forveille, 2019). In March 2019 the journal was notified by several researchers that citation counts to documents of this journal had decreased "by an order of magnitude" in their personal Google Scholar profiles. The editor contacted Google Scholar, who acknowledged the error and promised to remedy it. However, this would not be visible in the platform until the next complete recrawl of the index. This resulted in a sharp decrease of the h-index of this journal in the 2019 edition of Google Scholar Metrics, which was computed after Google Scholar was made aware of the issue, but using the yet uncorrected index: while the 2018 edition displayed an h5-index of 115 for this journal, in the 2019 edition this figure dropped to 52. Given the inherent resistance of a high h-index to small random changes in the underlying citation counts (probably the reason why Google Scholar favors this indicator), this signalled a very significant drop in coverage of documents in this field.

The large drop in Astronomy & Astrophysics documents in Google Scholar was also noticed by Martín-Martín et al. (2018, 2021). Analysing a collection of citations to a sample of highly-cited documents from all subject areas collected in 2018 to compare relative differences in coverage in Google Scholar, Scopus, and Web of Science, they found that Google Scholar was able to find 98% of the citations found by Web of Science, and 97% of the citations found by Scopus. Additionally, 30% of all citations were only found in Google Scholar. In 2019 the data was collected again using the same sample of highly-cited documents, but the citations to Astronomy & Astrophysics documents obtained from Google Scholar had radically changed (unlike in other subject categories, where relative differences among data sources remained mostly the same as in 2018): Google Scholar was only able to find 60% of all Web of Science citations, and 60% of all Scopus citations. Since the citation data extracted from Web of Science and Scopus in 2019 contained the same citations that were extracted in 2018, plus the new citations included in these systems between the two points of extraction, this large difference also signalled a significant drop in coverage in Google Scholar.

The datasets extracted from Google Scholar for Martín-Martín et al. (2018, 2021) provide us with an opportunity to analyse this case in more detail. Therefore, the goal of this study is to document this case, to try to find out the cause of this sudden drop in coverage to documents in the field of Astronomy & Astrophysics, and to check whether this issue was resolved in subsequent recrawls of Google Scholar's index.

Methods

The datasets extracted from Google Scholar and analyzed in Martín-Martín et al. (2018, 2021) were used. These datasets contain the lists of citing documents to a sample of 2515 highly-cited documents from 2006 that Google Scholar released in 2017 with the name *Google Scholar Classic Papers* (GSCP). In this product[1], Google Scholar displayed the top 10 most cited documents published in 2006 in each of 252 subject categories. For more information about this product, see Orduna-Malea et al. (2018).

Since in this study we are particularly interested in the coverage of Astronomy & Astrophysics documents in Google Scholar, only the 10 highly-cited documents in this field in GSCP (Table 1), and the list of citing documents in Google Scholar for each of these documents, are analyzed here.

The list of documents that cite each document in Table 1 was extracted from Google Scholar in three different occasions: April-May of 2018, May-June 2019, and April 2020. To do this, a custom scraper was used (Martín-Martín, 2018).

The metadata extracted from Google Scholar for each of these citing documents was enriched by complementing it with metadata available in the HTML meta tags of the webpages where Google Scholar found these documents, and the metadata available in CrossRef's and arXiv's public APIs. A DOI was found for 79% of the citations in the 2018 dataset, 76% of the citations in the 2019 dataset, and 77% of the citations in the 2020 dataset.

Citations across the three datasets were matched based on (in this order) Google Scholar's internal document identification codes, the URLs of the webpages were Google Scholar found the citing documents, the DOIs of the citing documents, and a combination of title and author similarity, in a similar way as described in Martín-Martín et al. (2018, 2021):

1. For each pair of datasets, A and B and a seed highly-cited document X, all citing documents with a document id (Google Scholar ID, URL, and DOI) that cite X according to A were matched to all citing documents with a corresponding document id that cite X according to B.
2. For each of the unmatched documents citing X in A and B, a further comparison was carried out. The title of each unmatched document citing X in A was compared to the titles of all the unmatched documents citing X in B, using the restricted Damerau-Levenshtein distance (optimal string alignment) (Damerau, 1964; Levenshtein, 1966). The pair of citing documents which returned the highest title similarity (1 is perfect similarity) was selected as a potential match. This match was considered successful if either of the following conservative heuristics was met:
    1. The title similarity was at least 0.8, and the title of the citing document was at least 30 characters long (to avoid matches between short, undescriptive titles such as "Introduction").
    2. The title similarity was at least 0.7, and the first author of the citing document was the same in A and B.

First, citations in the 2019 dataset were matched to citations in the 2018 dataset. The result of that matching was in turn matched to the citations in the 2020 dataset.

Results

A simple observation of the citation counts reported by Google Scholar over the years for the 10 highly-cited documents in the field of Astronomy & Astrophysics in GSCP already reveals a large fluctuation (Figure 2).

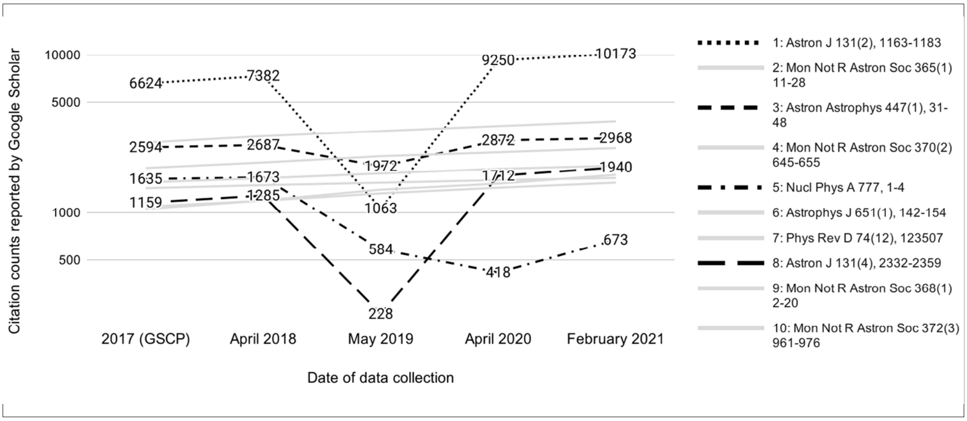

Figure 2: Citation counts reported by Google Scholar over the years to the 10 highly-cited documents in the field of Astronomy & Astrophysics in GSCP.

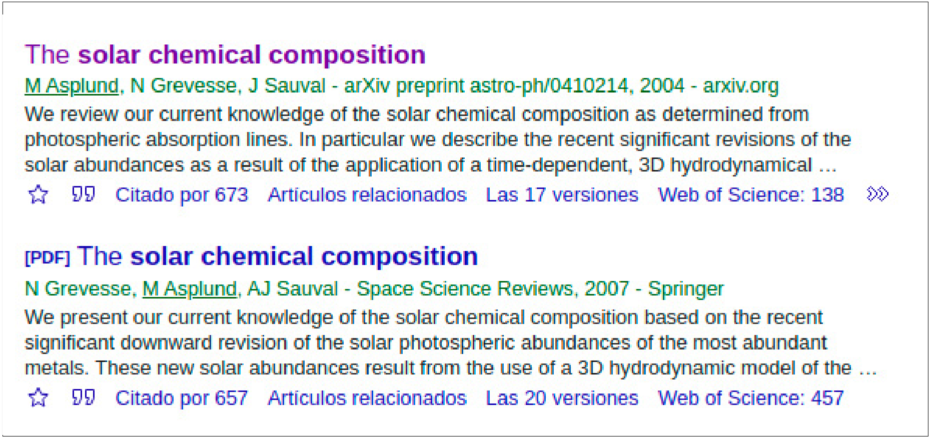
Four of the 10 documents suffered a sharp decrease in citations in 2019. In the most extreme case (document #1), the citation count in 2019 had decreased by 6,319 citations respect to the count reported in 2018. It is important to note that this document was published not in the journal *Astronomy & Astrophysics*, but in *The Astronomical Journal*, published by IOP Science. Indeed, of the four documents that show a drop in citation counts in 2019, only one was published in *Astronomy & Astrophysics* (document #3). There is a second article from *The Astronomical Journal* with decreased citation counts in 2019 (document #8), and another one published *Nuclear Physics A* (document #5). This shows that *Astronomy & Astrophysics* was not the only journal to be affected by the drop in coverage in 2019, which is expected, since whichever documents disappeared from Google Scholar likely cited articles from various journals in the field.

Six of the ten documents (#2, #4, #6, #7, #9, #10), however, do not show clear signs of a coverage drop: their citation counts grew each year. Four of these documents were published in *Monthly Notices of the Royal Astronomical Society* (Oxford University Press), one in The Astrophysical Journal (IOP Science), and one in Physical Review D (American Physical Society). This does not rule out the possibility that they lost citations in 2019, only that the growth/loss balance was positive. Nevertheless, this suggests that some documents could have been more affected than others.

Of the four documents that clearly lost citations in 2019, three of them seem to recover them by 2020 and continue receiving citations in 2021. This suggests that the coverage loss was indeed temporary, and that citations were recovered at some point between summer of 2019 and spring of 2020, probably after the second complete recrawl of the index in 2019. One of the documents (#5), however, does not recover the amount of citation counts that were reported in 2017 and 2018, even by 2021. After closer examination of this document, titled "The solar chemical composition" and published in *Nuclear Physics A*, it was discovered that there are actually two documents with the same title and the same authors, published in two different journals (Figure 3). We believe it is probable that in 2017 and 2018, these two documents were incorrectly merged into one record (combining the citations of the two), and that in 2019 they were separated, as they remain in 2021. Since this is a different kind of Google Scholar error than those we are documenting here, this document and its citations were excluded from further analysis in this study.

We analysed the list of documents that cited each of the nine highly-cited document according to Google Scholar at three points in time: 2018, 2019, and 2020. In 2018, 21,907 citations were extracted. In 2019, 15,042 were extracted, while in 2020, 25,195 citations were found in Google Scholars to these nine documents. Of the 21,907 citations found in 2018, 8,840 (40%) were missing in 2019. In 2020, however, 96% of the citations available in the 2018 dataset had reappeared.



The **solar chemical composition**

Figure 3: Two documents with the same title and authors, published in different journals. It is possible that Google Scholar incorrectly merged these two records into one (combining citation counts) in 2017 and 2018, and separated them in 2019. Screenshot taken on 14/02/2021.

To find out exactly which documents caused the decrease in citation counts, the citations found in 2018 to each of the nine highly-cited documents were grouped by the publisher of the citing document, and by whether or not the citation was also found in 2019 and 2020 (Figure 4). Missing documents are mostly concentrated in document #1, #8, and #3, while the other six documents are affected to a much lower extent.

Missing documents in 2019 are distributed across many of the largest publishers in the field (Figure 4). They are also distributed across all publication years. Therefore, because we know that these large publishers did not actually disappear from the Web in 2019, and it is unlikely that they concertedly modified the metadata of their documents or their crawler access rules so as to not comply with Google Scholar's technical guidelines, it is likely that the error originated at Google Scholar's side. The exact cause of the error is, nevertheless, unknown.

There are several possibilities as to why some citations from 2018 are still missing in the 2020 dataset: some may correspond to documents that did actually disappear from the web (particularly those in the category "Other", in which some of the documents are hosted in less stable websites). Some others may correspond to duplicate records found in 2018 that were subsequently merged.

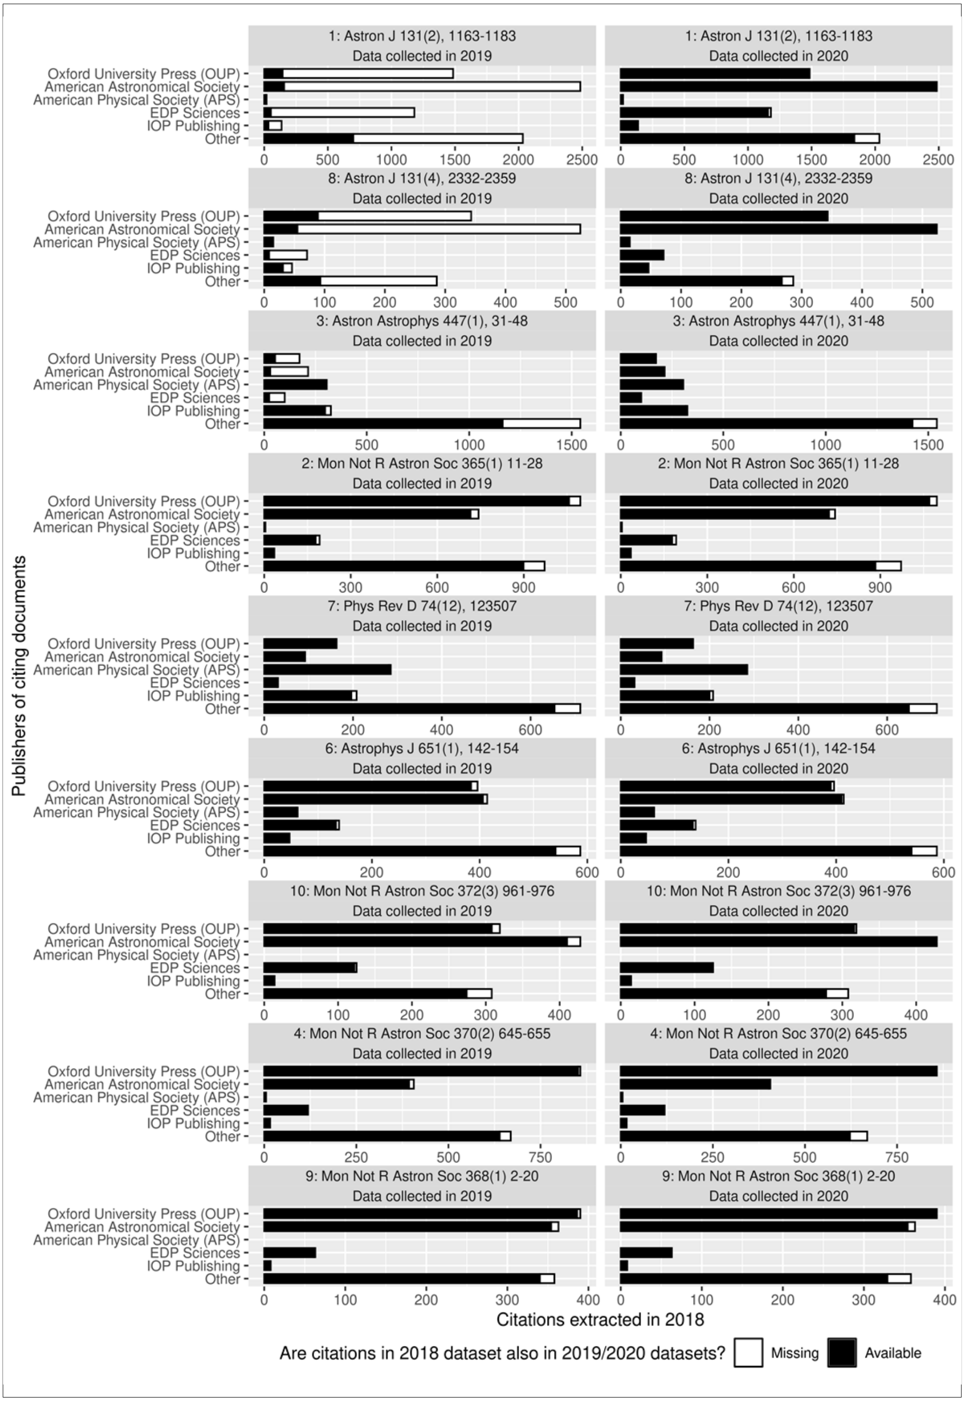

Figure 4: Citations found in 2018 for each of the 9 highly-cited documents, grouped by publisher of citing document and by whether or not the citation was found in 2019 and 2020.

The citing documents that were present in the three datasets (data extracted in 2018, 2019, and 2020) came with citation counts of their own, which provides us with an opportunity to gauge to what extent each publisher was affected by the loss in coverage in 2019 using a larger sample than the 10 highly-cited documents in GSCP. In this regard, documents published by EDP Sciences (publisher of the journal *Astronomy & Astrophysics*) were severely affected by the loss of coverage (Figure 5), followed by documents published by the American Astronomical Society, which were affected to a much lower extent. Out of the 724 documents published by EDP Sciences that were available in the three datasets, 404 of them (58%) reported at least 10 citations less in the 2019 dataset than in the 2018 dataset, whereas out of the 2,604 documents published by the American Astronomical Society present in the three datasets, 141 (5%) reported at least 10 citation less in the 2019 dataset than in the 2018 dataset. In the rest of publishers, lower citations in the 2019 dataset than in the 2018 dataset were even more uncommon.

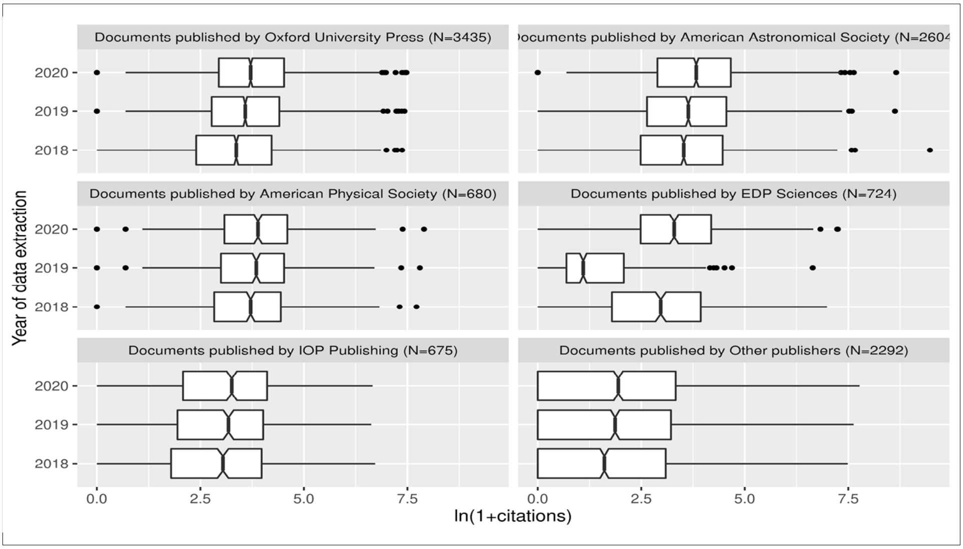

Figure 5: Distribution of (log-transformed) citation counts of citing documents in 2018, 2019, and 2020, grouped by publisher.

Discussion and conclusions

The results confirm that this is another case of a large coverage fluctuation in Google Scholar. The only other documented case of a coverage fluctuation at a similar scale is the one that affected Dialnet in 2017 (Delgado López-Cózar & Martín-Martín, 2018). Some similarities and differences between the two cases are drawn here:

- In the case described here, the effects were quickly reported by researchers who noticed drastic drops in citation counts in documents of the area, especially in the journal *Astronomy & Astrophysics*. On the other hand, in the Dialnet event, the effects of the coverage drop did not draw much attention until a few months after the coverage drop, when many Spanish journals were found to have disappeared from Google Scholar Metrics (although Dialnet's managers declared to be aware of the issue from the beginning). Dialnet records do not provide citation data, which could explain why the effects on the surrounding network were less noticed.

- In the case described here, we have only ascertained that a large number of citation connections were dropped by Google Scholar, causing sudden and sharp decreases of citation counts in other documents. It is not clear whether the citing documents also became unavailable in document searches, as in the Dialnet event. If this was the case, it would mean that users interested in Astronomy and Astrophysics content during 2019 who expected Google Scholar to have a comprehensive coverage of this field (based on previous experiences with the platform) could have been unknowingly underserviced for a period of 6 to 9 months.
- In the event that affected Dialnet, the managers of this database explained that the problem was caused by a small batch of old records with an incorrect author order. Google Scholar detected the difference in metadata between Dialnet and other sources that covered the same documents, and decided to quarantine metadata from Dialnet until the issue was resolved. In the case studied here, the direct cause of the issue has not been made public by either Google Scholar or the affected journals.

Although there are reports that Google Scholar sometimes contacts content providers when an issue like this arises (Delgado López-Cózar & Martín-Martín, 2018), the slowness with which it is currently able to resolve this kind of issues is a clear limitation of the platform for literature search use cases as well as for bibliometric use cases.

This case highlights the tension that is created when design choices that make sense in some scenarios, such as continued online availability as an inclusion criterion in general purpose search engines, are applied to more restricted domains, like academic literature search, where users might have different expectations (i.e. for content to be stable and to grow over time). These assumptions are further reinforced when other services in which stability is also to be expected (journal rankings, author profiles) are built on top of the original data.

Anurag Acharya, chief engineer of Google Scholar, once declared that, unlike the case of searches in the general Google, "the world of research is global", which was the reason why Google Scholar decided to implement a relevance ranking that does not take into account data from a user's previous searches (ALPSP, 2015). Events like the one documented here make the case to also consider the expectation of coverage stability and continued growth as one of the properties that characterises academic literature searches and therefore one of the principles that should guide the design choices of academic search tools.

Abstract

We analyze the Brazilian production and diffusion of scientific literature on COVID-19 in 2020, to assess what was the protagonism of this country during this event. All documents were obtained from Web of Science and considered under bibliometric and altmetric analysis. We used the production and citation indicators crossed with other variables like author, institutional affiliation, impact factors, funding organizations, research areas, etc. A total of 2,703 articles were found, mostly published in December and in English, having received 10,190 citations, with an average of 3.77 citations per document, a value lower than that found for other countries. Ten journals concentrated publications, being only one of those not Brazilian. São Paulo University was the most producing institution. Analyzing the top 100 most cited articles with an altmetric tool, the average Altmetric Attention Score (AAS) was 392.22. From the 40,062 mentions on social media, 94.8% came from Twitter, mainly by general public (78.6%). The top 10 articles with the highest AAS concentrated 79,5% of all attention; eight of them were original investigations. We propose a content analysis to verify which specific topics are attracting greater interest from the general public, but not so much from the scientific community.

Introduction

The new coronavirus emergence caused a rapid and massive growth in research at a fast pace, ending in a scientific race. The challenge was to rapidly identify relevant, accurate, and robust research. COVID-19 effects were widely discussed in digital social media, so science produced a mediatic public debate in real time. The response of scientific communities to epidemics such as H1N1, Zika, Ebola, MERS, and SARS, showed increased production immediately after the outbreak declaration by WHO. For COVID-19, the official pandemic declaration generated a blast in scientific publications.

Brazil has become a major player in global science, although it is currently suffering a severe crisis affecting its scientific community. The country is part of the group of nations that leads publishing on COVID-19. Several authors have analyzed this publication with traditional bibliometrics, or during short periods of time, but these studies do not show the conversation between science and society, expressed by the interaction between bibliometric and altmetric indicators. In this work, we will characterize the COVID-19 Brazilian production using one full year of bibliometric indicators and will cross this result with altmetric indicators within social media.

As a result, this article shows the most relevant characteristics of the Brazilian COVID-19 production and dissemination to society through social media during 2020.

Context

Since the emergence of the new coronavirus much knowledge has been mapped. The rapid spread of the COVID-19 across the globe has caused the number of investigations related to the disease to grow, also at a very fast pace, setting an unprecedented scientific race (Torres-Salinas, 2020).

The challenge for scientists – especially at the beginning of an epidemic – is to identify relevant research results in a short amount of time, when the availability of accurate and robust clinical, laboratory, and epidemiological data is essential to guide decision-making in a timely manner, especially concerning public health issues (Xu et al., 2020). Therefore, demands for speed and efficiency in the dissemination of scientific results impose an additional challenge to the scientific communication system (Larivière, Shu & Sugimoto, 2020; Torres-Salinas, Robinson-Garcia & Castillo-Valdivieso, 2020).

The outbreak has highlighted the relevance of data sharing, developments, and research results in a faster (and more open) way than the traditional scientific communication system (Larivière, Shu & Sugimoto, 2020). In this race imposed by the pandemic, the response from editors has been efficient, as scientific journals are giving priority to works related to COVID-19 (Horbach, 2020), reducing the average publication time, making available articles in preprint (not yet peer-reviewed) and open access, like in other historical public health crises, such as the Zika virus outbreak in Brazil (Araujo et al., 2017).

COVID-19 effects are vividly discussed in digital environments like platforms and social media such as Twitter (Chen, Lerman & Ferrara, 2020; Melo & Figueiredo, 2020), so this is the first time that a pandemic can be described, debated, and investigated by the scientific community in real time and online, by means considered conventional (journal articles) in association with social media (Boetto et al., 2020).

Initiatives such as those undertaken by publishers and the strengthening of interaction on social networks around scientific research go toward Open Science, a comprehensive term that involves sharing practices in open access, but also calls for greater transparency and valuing the participation of nonscientists and non-specialists in the production and dissemination of knowledge, constituting a "new scientific practice" (Oliveira & Silva, 2016).

Studies analyzing the response of the scientific community to international public health emergencies, such as H1N1, Zika, Ebola, MERS, and SARS, showed that the number of scientific publications increased immediately after the outbreak was declared by WHO (Haghani et al., 2020; Zhang et al., 2020). In the case of COVID-19, it was no different. The official declaration of the pandemic generated an unprecedented growth in scientific publications from different areas of knowledge (Brainard, 2020).

Brazil, although suffering severe financial and infrastructure cuts affecting its scientific community (Norte, 2020; De Negri et al., 2020), still is part of the group of countries that leads publishing on COVID-19, since the beginning of the outbreak (Bernardes & Dorado, 2020).

Several authors have presented analyzes on COVID-19 publication using traditional bibliometric indicators (Chahrour et al., 2020; Figueredo et al., 2020; Oliveira et al., 2021; Silva et al., 2020). However, these studies do not show an association between bibliometric and altmetric indicators, from the perspective of Brazilian scientific production on COVID-19, nor do they undertake an analysis of the impact and diffusion of these publications using altmetrics.

Within this context, this study analyzes Brazilian COVID-19 production and dissemination of knowledge, identifying the most relevant characteristics of this domain, to provide an overview of the impact of this literature in social media during 2020.

Methods

This is a case study about Brazil's scientific publication behavior during the first year of the COVID-19 outbreak. We used both bibliometric and altmetric indicators, to identify the diffusion and impact of Brazilian academic publications related to the new coronavirus. Traditional bibliometric indicators can be complemented with altmetrics. Bibliometrics allows analyzing the dynamics of publications during a certain period of time, while altmetrics let us apprehend people's interaction on the social web around research products and assess the wider impact of science following online activities and tools (Baheti & Bhargava, 2017; Piwowar, 2013; Priem et al., 2010; Williams, 2017). The combination of methods allows updating the concept of scientific influence (Barros, 2015). Alternative metrics are important for the analysis of emerging online conversations of global importance, such as COVID-19, since they have indicators of scientific production, dissemination, and appropriation beyond the academic environment and its typical channels of dissemination (Borrego, 2014; Williams, 2017).

Scientific articles, published between January 2020 and December 2020, were collected from the Web of Science (WoS) Core Collection database (Clarivate Analytics, Philadelphia, PA, USA) on January 25, 2021. Descriptors were "COVID-19" and "SARS-CoV-2". WoS includes some of the finest and more robust databases about the health area; its results are comparable to SCOPUS database, but in the case of Brazil we found 20% additional documents. All articles were analyzed using descriptive bibliometrics to have a profile of their main characteristics in production and citations. The results were organized following selected variables: author, institutional affiliation, journal, journal impact factor (JIF), language, document type, publication data, citation level, access, funding organizations, and research areas.

The top 100 articles with the highest citation were analyzed using the Bookmarklet for Researchers (Altmetric, London, UK) altmetric tool, which provides, among other data, the Altmetric Attention Score (AAS). We assumed that, following Lotka’s production principle and Merton’s Matthew Effect, that less than 5% of all publishing authors and papers, would accumulate the majority (more than 70%) of citations or “visibility”. AAS weights the attention driven by a scientific article in social media, reporting a compound indicator reflecting the number of mentions and shares in news, documents about public policy, blogs, contents at Twitter, Facebook, Wikipedia, Reddit, references in videos, and Mendeley readers, all packed into an index.

Results

The search in WoS returned 2,703 records that received a total of 10,190 citations, an average of 3.77 citations per document. It was possible to observe that most papers were published in December 2020 (312; 17.5%) and September 2020 (275; 15.5%), as seen in Figure 1.

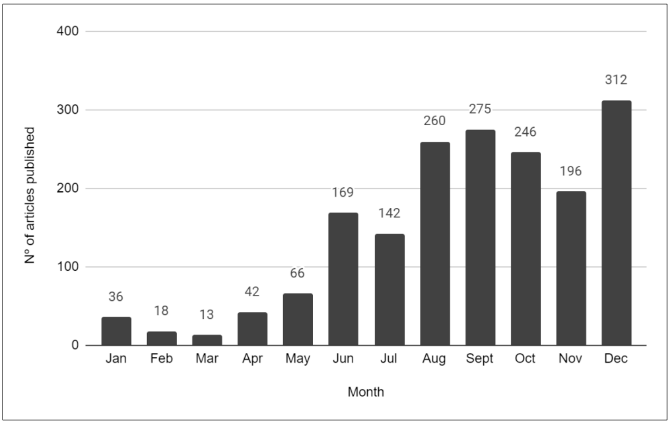

Figure 1. Number of articles authored/co-authored by Brazilian researchers on COVID-19 published per month, during the year 2020 (Source: WoS, 2021).

Most frequent documents were original articles 1,458 (53.9%), followed by letters 413 (15.3%), editorials 391 (14.5%), and review articles 390 (14.4%). Most documents were in English (2,381; 88.1%), followed by Portuguese (294; 10.9%). The number of institutions/authorships reported in WoS as involved in the production of these documents was 5,010. University of São Paulo (USP) stood as the most productive institution with 583 articles (21.6%), followed by the Federal University of São Paulo (UNIFESP) with 222 (8.2%), and Oswaldo Cruz Foundation with 216 (8.0%). Table 1 highlights the 10 most producing institutions.

Table 1. The most productive institutions of Brazilian authors/co-authors who published articles on COVID-19 in 2020 (Source: WoS, 2021).

Institution	*Country*	*Articles*	
		n	*% of 2,703*
University of São Paulo	Brazil	583	21.6
Federal University of São Paulo	Brazil	222	8.2
Oswaldo Cruz Foundation	Brazil	216	8.0
Federal University of Rio de Janeiro	Brazil	179	6.6
University of Campinas	Brazil	142	5.2
Federal University of Minas Gerais	Brazil	138	5.1
Federal University of Rio Grande do Sul	Brazil	105	3.9
University of London	England	90	3.3
Federal University of Bahia	Brazil	85	3.1
Federal University of Pernambuco	Brazil	85	3.1

Institutions/funding agencies for research were mentioned 2,105 times in 623 articles. From these, 1,339 mentions were about Brazilian institutions. The Brazilian National Council of Scientific and Technological Development (CNPq) was the most prevalent, with 400 (19.0%) mentions, followed by the Coordination of Superior Level Staff Improvement (CAPES), with 318 (15.1%), and São Paulo State Research Support Foundation (FAPESP), with 174 (8.7%) occurrences. About 77% (2,080) of the records did not contain any data regarding research funding.

A total of 15,359 researchers were counted, among Brazilian and foreign authors and co-authors. The most productive author/co-author published 19 articles, while the majority, 12,668 (82.5%) published only one article. The 10 most productive Brazilian researchers are shown in Table 2.

Table 2. The most productive Brazilian authors/co-authors who published articles on COVID-19 in 2020 (Source: WoS, 2021).

The geographic distribution of retrieved publications shows the collaboration of Brazil with 134 countries. The spread of international collaboration includes the US in 461 documents

(17.0%), England in 244 (9.0%), Italy in 218 (8.1%), Spain in 183 (6.8%), and Canada in 151 (5.6%).

Table 3. Characteristics and components of the top 100 most cited COVID-19 articles published by Brazilian authors with the highest Altmetric Attention Scores, 2020.

Characteristic	*Value*
Altmetric Attention Score, median (range)	392.22 (1–6889)

Physics & Mathematics	2 (2.5)
Environmental Sciences	1 (1.3)
Interdisciplinarity	1 (1.3)
Virology	1 (1.3)

There were 122 research areas identified. Half of them (67; 54.9%) were related to human health; recurrent topics were “Public Environmental Occupational Health” (335; 12.4%), “General Internal Medicine” (309; 11.4%), “Infectious Diseases” (139; 5.1%), “Neurosciences Neurology” (112; 4.1%), and “Science Technology Other Topics” (112; 4.1%).

The articles were distributed in 991 scientific journals, with an average of 2.73 articles per journal; 898 (96.6%) were international and 93 (9.4%) Brazilian. Of the 10 journals with the highest number of publications, only one was not Brazilian: CLINICS, 74 (2.7%); Cadernos de Saúde Pública, 68 (2.5%); Revista da Associação Médica Brasileira, 68 (2.5%); Ciência & Saúde Coletiva, 58 (2.1%); Revista da Sociedade Brasileira de Medicina Tropical, 47 (1.7%); Arquivos Brasileiros de Cardiologia, 46 (1.7%); Revista de Administração Pública, 43 (1.6%); Revista Tecnologia e Sociedade, 34 (1.2%); PLOS ONE, 28 (1.0%); and Vigilância Sanitária em Debate: Sociedade, Ciência & Tecnologia, 27 (1.0%). The number of journals that published a single document was 613 (61.9%).

As for the altmetric analysis of the 100 most cited articles, most of them were published in biomedical journals (62/79; 78.5%); however, compared to other journals, the Science of the Total Environment published the largest number of articles (6/100; 6.0%). All articles were open access; only 49.0% were original investigations, and 43.0% of the studies were considered Brazilian because they presented the majority or the totality of authors from Brazilian institutions. To analyze the real contribution of original investigations from Brazil, we cross-referenced how many studies were of this type against how many were Brazilian – by the criteria above –, resulting in 57.1%. The medians of AAS, citations per document, and JIF were 392.22, 58.5, and 11.487, respectively (Table 3).

A total of 40,062 mentions on social media platforms were found. The highest number of mentions for the selected articles was found on Twitter (37,965/40,062; 94.8%). The geographic analysis of the tweets showed that US (36.0%), United Kingdom (15.0%), and Brazil (12.0%) had the highest number of mentions. The demographic analysis of all tweets showed that 78.6% were from members of the general public, 10.4% from scientists, 8.7% from professionals (doctors, other health professionals), and 2.3% from scientific communicators (journalists, bloggers, editors). Altogether, there were 39,980 mentions of Mendeley, most of which were identified as coming from undergraduate students (5,212; 13.0%), researchers (5,023; 12.6%), and master's students (4,575; 11.4%) (Table 3).

Table 4. Top 10 COVID-19 articles published by Brazilian authors in 2020 by AAS and its position in the ranking of the 100 most cited articles according to WoS, Jan./2021.

Article	*Source*	*JIF*	*AAS*		*Citations*	
			n1	*#*	*n2*	*#*
Cavalcanti et al., 2020	N Engl J Med	74.699	6.889	1	110	12

JIF = Journal Impact Factor; *AAS* = Altmetric Attention Score; *n1* = score value; *n2* = times cited; # = ranking position.

The top 10 articles with the highest AAS concentrated 79,5% of all registered attention; eight of them were original investigations; and four of them were considered Brazilian studies by the criteria described above. The article with the highest AAS (6,889) addressed the use of

Hydroxychloroquine with or without Azithromycin in patients with mild to moderate COVID-19 (Cavalcanti et al., 2020) and was published in the New England Journal of Medicine (JIF 74.699). Despite occupying the 1st position in the ranking of articles that received the highest index of attention in social media, this article was only in 12th position among the most cited. The article by Emanuel et al. (2020) was the most cited and performed well among those who had higher AAS, occupying the 3rd position among articles published by Brazilian authors/co-authors. None of the journals with the highest AAS were Brazilian and 70.0% had JIF ≥ 30.0 (Table 4).

Discussion

Through this study, it was possible to verify the characteristics of Brazilian scientific production on COVID-19 and to apprehend its visibility through different kinds of indicators, such as citations and AAS.

Although the number of articles registered (2,703) is below that produced by the five most productive countries on this theme in the same period – USA (21,975), China, (9,766), UK (9,265), Italy (7,958), and India (6,146) – (Ahmed et al., 2021), yet Brazil stands out as the largest producer in research on COVID-19 in Latin America, followed by Mexico, Colombia, Chile, and Argentina (Costa et al., 2021; Espinosa et al., 2020).

The number of original investigations found in this study (53.9%) was similar to what Ahmed et al. (2021) found (57.8%) with a larger sample of documents and countries. Most of the articles were published during the second half of 2020, a relatively short time considering the lack of available data on the disease – since the first cases of COVID-19 in China were reported on December 31, 2019 – and the lack of investments in science and technology faced by Brazilian scientists.

According to De Negri et al. (2020), the inexpressive investment in science and technology, when compared to other countries, and the lack of a Brazilian strategy for research and innovation are facts that hinder the production of initiatives that face the crisis in a skillful way. In 2020, only two bids for research funding on the new coronavirus were launched by the Brazilian federal government in the amount of approximately US$ 10 million, with results released only in July of that year. In terms of comparison, only in the USA, more than US$ 6 billion was allocated exclusively to COVID-19 research. Still, we found that 623 studies (23,0%) reported some source of funding.

Even with severe budget cuts to the Brazilian universities experienced in recent years (Oliveira, 2020), the University of São Paulo still managed to stand out as the most productive institution, appearing among the 20 organizations that most published studies on the new coronavirus in the world (Bernardes & Dorado, 2020). Likewise, the most productive authors/co-authors found in this study were researchers from the University of São Paulo, a result also found by other studies that pointed out researchers from this university among the 10 most productive about COVID-19 (Gregorio-Chaviano, Limaymanta & López -Mesa, 2020; Torres Pascual & Torrell-Vallespín, 2020).

This study also shows the collaboration between scientists from Brazil and others from 133 countries for developing research on COVID-19 in multicenter studies, such as the evolution and spread of the disease (Candido et al., 2020), pharmacodynamics (Cavalcanti et al., 2020; Sterne et al., 2020) among others. This demonstrates a significant ability to articulate collaborations, in such a short time, with researchers from several countries who share a common objective, which is to mitigate the pandemic effects on the global population.

Among the research areas identified, "Public Environmental Occupational Health" (12.4%) and "General Internal Medicine" (11.4%) stood out, showing a focus on problems in the care and treatment of patients, as well as concerns about aspects of the environment and occupational health of professionals working on the front lines of this disease combat, being both multidisciplinary areas.

The results showed that English (88.1%) was the predominant language of publication. This finding reveals the concern to disseminate their studies through a language that is accessible to a greater number of researchers, which allows a wide dissemination of information. Moreover, articles in English receive more citations than those published in other languages, as higher visibility may indirectly impact the scientific community (Di Bitetti & Ferreras, 2016).

The 2,703 articles analyzed in this study received 10,190 citations, with an average of 3.77 citations per document, a value lower than that found for other countries, such as USA (8.84), China (25.62), UK (9.18), Italy (9.00), and Spain (6.43), but similar to that found for India (3.47) (Ahmed et al., 2020).

The publication of 90.6% of articles in international journals, mainly of great visibility and impact, demonstrated a positive trend in terms of research quality, in addition to the interest of Brazilian researchers in journals with the most varied scopes. In contrast, the nine journals with the largest number of publications on COVID-19 were of Brazilian origin, a result that differs from the study by Figueredo et al. (2020), who found only three Brazilian journals out of 10 with the largest number of articles published on COVID-19.

In the past year, many studies on the COVID-19 pandemic were published in scientific journals and disseminated on social media platforms, providing information and guidance on the epidemiology and characteristics of the disease, on the clinical management of patients and the development of ways of treatment and vaccines, all in real time not only for scientists and health professionals, but also for academics, mediatic, and the general public. Traditionally, articles considered to be of high relevance can be identified by counting citations received; however, this method is not always feasible to identify the impact of a publication, especially in a rapidly spreading pandemic, such as COVID-19.

When measuring the online attention received by the 100 Brazilian articles with the highest number of citations, it was found that 78.6% of all mentions on Twitter (37,965/40,062) were from members of general public, 10.4% from scientists, and 8.7% from professionals (doctors, other health professionals), showing that Brazilian articles on COVID-19 had more repercussions in the nonscientific public than in the scientific community.

Tornberg et al. (2020) investigated the correlation between AAS and citation count, suggesting an alignment between the interests of academics and the general public. In the present study, when comparing the 10 most cited articles with the 10 highest AAS, it was found that only the first three cited were among the 10 most mentioned on social platforms. A hypothesis to be considered about this would be to analyze the subject addressed in the article, which may arouse greater interest in the general public and in the press but is not so relevant to the scientific community. For example, the article with the highest AAS (6,889) addressed the use of Hydroxychloroquine with or without Azithromycin in patients with mild to moderate COVID-19 (Cavalcanti et al., 2020), a subject of great repercussions in Brazil and was widely explored by the media due to the recommendation of the use of this drug by nonspecialists in the health area, such as the then Brazilian and American presidents (*Like Trump...*, 2020). This analysis may represent an opportunity for future studies.

Conclusion

This study investigated aspects of the production, dissemination, and use of knowledge about COVID-19 produced by Brazilian authors, thus contributing to the assessment of the current state of science, as well as the impact of research in scientific community and social web. As COVID-19 still is a current topic and considering the time frame used, it is reasonable to infer that the documents retrieved in this research reflect the Brazilian scientific production and are relevant, as they were cited by other authors in their research and aroused the attention of the scientific community, but mainly of the general public. To understand the reasons for this phenomenon, we propose a content analysis to verify which specific topics are attracting greater interest from the general public, but not so much from the scientific community.

It is expected that the findings presented here will stimulate new studies on the Brazilian scientific production related to the current pandemic of COVID-19, as a way to demonstrate its relevance and the imperative necessity of investments in science even in times of political and economic difficulties.

Co-Patents: What do trends reveal? An assessment of European innovation systems

Abstract

Concepts like 'innovation systems', 'open innovation' and innovation ecosystems all direct our attention to the importance of collaboration and spillovers for understanding innovation dynamics. In this paper we analyse the extent to which co-patents, i.e., patents owned jointly by two or more independent entities, signal a growing trend (1980 – 2015) and whether growth is situated alike across countries, technological fields and type of actors. We rely on EPO data for a set of 43 European countries. Our findings provide insights on two levels. First, a detailed assessment of the type of actors involved in co-patenting activities reveals a considerable amount (28%) of 'false positives', i.e., co-ownership of patents by actors being part of one and the same (consolidated) entity. Second, when analyzing the patterns resulting from deflated indicators, our findings reveal that co-patents are becoming more common albeit highly differentiated across fields, countries and type of actors. An outspoken increase is observed for science intensive fields as well as for governmental agencies and universities. While universities and public organizations tend to opt for more entrepreneurial behavior of a collaborative/sharing kind, this is much less the case for firms.

Introduction

Innovation and technological progress have since long been acknowledged as vital for the long term survival and growth of the firm (Baumol, 2002; Schumpeter, 1939) and as critical driving forces in enhancing social welfare. Numerous scholars have emphasized the importance to adopt a more comprehensive view to fully grasp the innovative capacity of (national) innovation systems (Freeman, 1987, 1994; Lundvall, 1992; Nelson, 1993; Mansfield & Lee, 1996; Mowery & Nelson, 1999; Dosi, 2000). The notion of 'innovation system' and more recently of 'innovation *eco*system' (Adner, 2017; Audretsch et al., 2019; Jacobides et al., 2018; Shipilov & Gawer, 2020; Xu et al., 2020) has gained wide acceptance amongst scholars and policy makers as a guiding framework to understand and model innovation systems on a more aggregated level. Within these models, not only a variety of actors (besides firms and entrepreneurs, also governmental and scientific actors, including universities and public research organizations) figure prominently; also the importance of collaboration and spillovers is being stressed.

From 2000 onwards, the concept of cooperative innovation has gained popularity, especially after Chesbrough (2003) coined the notion of 'open innovation'. Open innovation practices imply the "use of *purposive* inflows and outflows of knowledge to both accelerate internal innovation and expand the markets for external innovation." (Chesbrough, 2003; 2006b). Besides sourcing from outside, open innovation at the same time implies that inventive output from within the firm should have the opportunity to outflow into the market through a variety of channels (Belderbos et al., 2010; 2014). These mutual knowledge flows have become cornerstones of the modern literature on economic development (Belenzon, 2012).

Chesbrough's (2003) mentioning of purposefulness seems crucial for pinpointing such collaborative dynamics, by going beyond mere (potentially 'accidental') knowledge spillovers. As a relevant indicator of R&D collaborations, considerable attention has been devoted to investigating patents, which provide readily available information on such collaborations, including the technological nature, location, number and names of the individual inventors, as well as of the applicants, i.e., the owners of the underlying IP rights. Consequently, several attempts to capture 'open innovation' through patents have been made. Whereas a majority of recent work relies on co-inventorship to reflect the (geographic) scope of the collaborative process (i.e. Kogler et al. 2017; Morescalchi et al., 2015; Wanzenböck et al., 2014), yet another option resides in considering co-owned outcomes, i.e. co-owned patents as an indicator of joint R&D efforts (Arora et al., 2016; Walsha et al., 2016; Belderbos et al., 2014; Giuri et al., 2007; Chesbrough, 2006a; b) While it can be noted that not all collaborations will result in patents, let alone, co-owned patents, it is nonetheless correct to assume that co-patents do result from some form of collaborative efforts, involving a multitude of different actors (Belderbos et al. 2014). Actually, co-ownership also signals the intention of the entities to stay involved in further market exploitation efforts related to the underlying technology (Belderbos et al., 2014). As such they reflect 'joint' or 'open' business strategies, rather than joint inventive efforts.

In this paper, we systematically map and analyze the extent to which co-patents – patents owned jointly by two or more independent entities – indeed signal a growing trend; and we evaluate and compare growth patterns (time period 1980 – 2015) across countries, technological fields and type of actors (sectors). Before analyzing the occurrence of co-patent activity (over time and across fields, countries) we first address a risk of biased measurement of collaboration in technology when considering jointly owned patents. Numbers may become inflated due to patents that are jointly owned by different departments of one and the same organization, rather than by independent entities. This paper sets out by deflating the indicators accordingly. Next, we use the correct (deflated) indicators on technological collaboration, to evaluate patterns over time. We thereby distinguish between the variety of actors (firms, individuals, universities, governmental agencies) populating the innovation system. By analyzing the sectors engaged in co-patenting, and the occurrence of technological collaboration across technology domains and countries, we are able to shed light on whether the tendency to adopt more collaborative practices is indeed widespread across European innovation systems and/or more situated within specific parts (type of actors) of innovative ecosystems.

As such, we contribute to and complement previous work on co-patenting and more generally, on assessing trends in the involvement of multiple actors in R&D collaborations. In particular, the decline of science in corporate R&D, as recently signalled by Arora et al. (2017) is a point of interest. Arora et al. (2017) observe that large corporations are becoming more reluctant to invest into their own internal scientific capabilities while at the same time relying more on outside collaborations in this respect. The question arises whether indicators signalling co-ownership (of patents) reflect such 'division of labour' trends; is co-ownership between firms and universities and/or public research organizations becoming more prevalent recently?

Data and methodology

To investigate the presence of co-ownership in patenting, data has been retrieved from the PATSTAT.2018b database, which provides exhaustive information on patent data, i.e. patent grants and applications to the European Patent Office (EPO), along with details on the applicants, priority years, applicant countries and technology fields (EPO, 2018). In a first step, information on the applicant(s) has been used to distinguish between patent applications filed by a single applicant from jointly filed patent applications implying two or more applicants that (seemingly) represent independent entities. In a second step, this information was used to highlight co-patenting trends over time, for different actor-combinations (sectors) and technological fields. For both, we considered all patent documents with priority years between 1980 and 2015 and included a set of 43 European countries[i], rendering a total patent count of 1.558.354 patents (including both single-and co-owned).

Deflating co-patent counts

Co-patents are identified as patents with more than 1 applicant. All applicants have been harmonized according to the name harmonization algorithm developed at KU Leuven. This procedure already distinguishes between different departments within organisations (for details on the procedure, see Van Looy et al., 2006; Eurostat 2011). Closer inspection of co-patenting partners however revealed the presence of 'false positives': co-applicants that are in reality different departments, business units, subsidiaries etc. of one and the same organisation, rather than independent entities. Examples of seeming co-applicant pairs include 'NOVARTIS' patenting with 'NOVARTIS ERFINDUNGEN VERWALTUNGSGESELLSCHAFT', 'UNILEVER UK' co-patenting with 'UNILEVER NL', 'SCHLUMBERGER TECHNOLOGY co-patenting with 'SCHLUMBERGER HOLDINGS' or 'SERVICES PETROLIERS SCHLUMBERGER, and 'PHILIPS ELECTRONICS' with different country-specific subsidiaries, i.e. 'PHILIPS ELECTRONICS UK', 'PHILIPS DEUTSCHLAND' or 'PHILIPS NORDEN'. If one defines co-patenting as collaboration between truly independent entities, then the inclusion of such cases leads to an overestimation of the co-patenting phenomenon and inflated co-patenting statistics. To correct for this, we calculated Levenshtein distance (LV) measures between all co-patent applicant names. A human rater decision tree was designed, based on LV threshold values and sector allocation results (based on the sector allocation algorithm developed at KU Leuven, see Eurostat 2011). After inspection of pairs according to the designed procedure, we observe the following difference in Table 1 between the inflated and deflated co-/ single patent count, suggesting a total of 'false positives' amounting to approximately 28%.

Table 1. Number of co-patents before and after removal of false positives.

	Co-Patents	*Single owned Patents*	*Total Patents*	*Co-patent shares (%)*
Inflated count	117.866	1.440.488	1.558.354	7,56
Deflated Count	85.397	1.472.957	1.558.354	5,48

In Figure 1, we present the deflated and inflated co-patent share over time, showing the systematic overestimation of the co-patenting phenomenon. Furthermore, we observe considerable variability of the trend, albeit with seemingly more consistent increases since the 2000s, from a comparatively lower level.

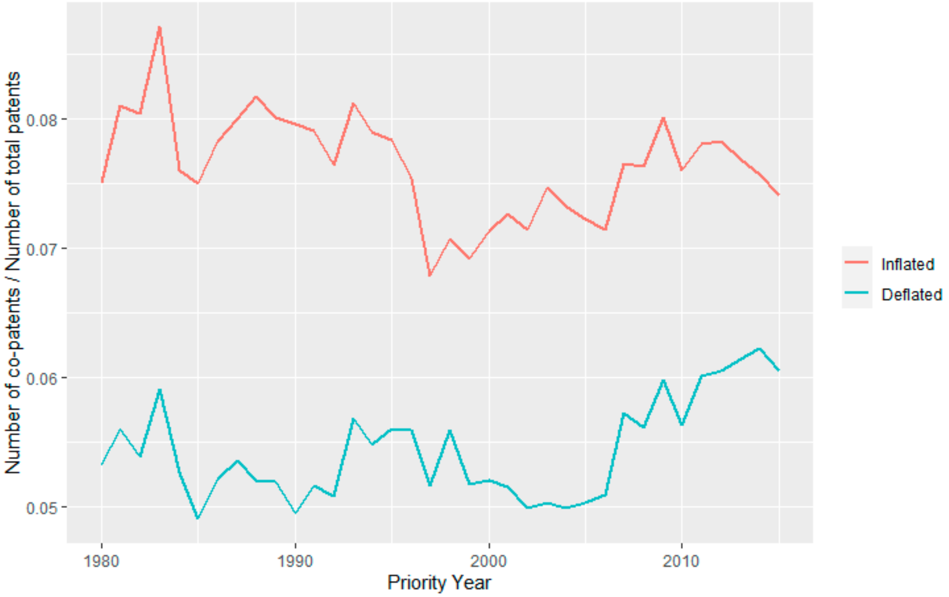

Figure 1. Comparison of inflated vs. deflated co-patent application shares.

Identification of co-patent trends

To provide a differentiated view of co-patent trends, we utilize the *deflated* co-patent count and explore the resulting patterns across fields, countries and type of actors. For technology fields, we rely on the technology classification provided by Fraunhofer (FhG), which assigns IPC patent classes to 35 broad technology fields, such as Telecommunications, Semiconductors, Biotechnology or Pharmaceuticals. Furthermore, we exploit the country and sector information related to the patent applicants. For each patent, we define whether the patent is (co-)owned by companies, individuals, universities and/or governmental institutions, whereas all other categories have been aggregated to "other" sectors (including hospitals and ambiguous legal entities). In cases of multiple assignments (i.e., one patent belonging to multiple technology fields, to multiple sectors, and/or to applicants in different countries), we made use of the full patent count, i.e., counting the patent with 1 for every technology field/ applicant country/ sector. When considering sector combinations at the individual patent level, we limit our analysis to cases of maximum two different sectors (i.e., company-university), whereas more complex constellations (i.e., company-university-government) are assigned to "other". We then explore some basic trends, and additionally perform an analysis of covariance (ANCOVA) to identify if and to what extent, co-patenting is country- and technology-field specific. The ANCOVA allows to evaluate whether the means of a dependent variable are equal across different levels of categorical independent variables, while statistically controlling for the effects of other continuous variables (covariates). Applying a minimum threshold of 105 out of 1260 (35 *FhG_class**36 *Prio_year)* possible occurrences with at least 1 co-patent, we limit the analysis to a subset of 25 applicant countries (*Applt_ctry*) and all 35 technology fields (*FhG_class*) as categorical variables and estimate their effect on the share of co-patents (*Co-pat_share*), while controlling for the application year (*Prio_year*).

Analysis and results

Observing the co-patenting trends over time by utilizing the deflated co-patent counts, reveals a highly differentiated picture of co-patenting as a phenomenon. Figure 2 shows a u-shaped evolution of co-patenting, with a downward trend until the mid-1990s and a considerable upward trend thereafter.

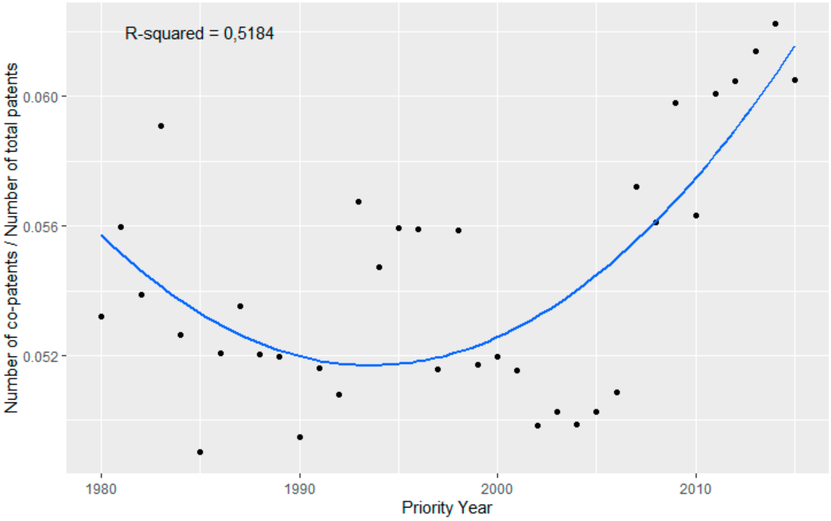

Figure 2. Evolution of deflated co-patent share (total share).

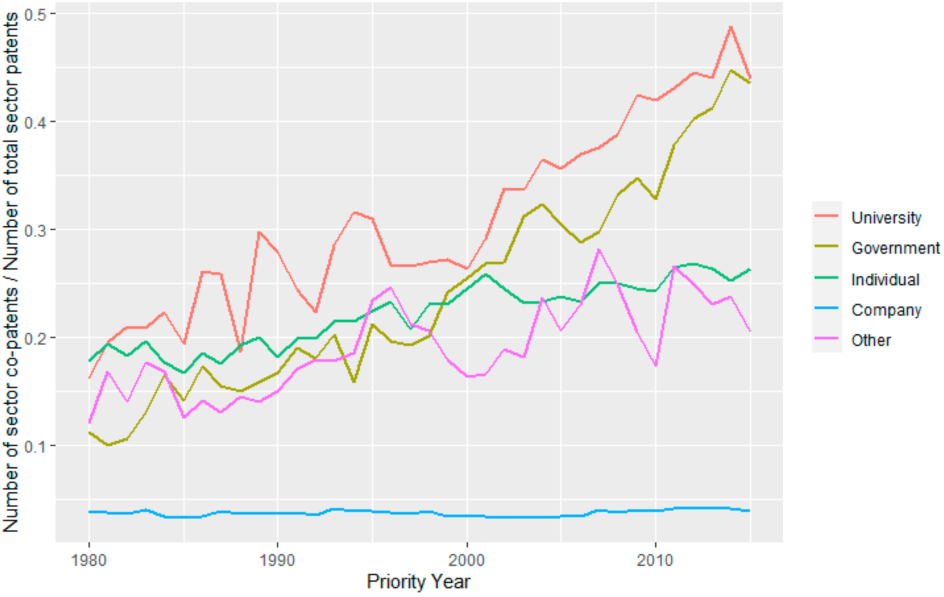

Figure 3. Comparison of deflated co-patent application shares within sectors.

Figure 3 provides an overview of the co-patent application shares within different sectors over time. While co-patenting for companies (as a share of total patents filed by companies) remains stable at a comparatively low level (<5%), co-patents filed by universities and governments (as a share of total patents filed by universities and governments respectively) display a sharp increase, growing from around 16% and 11% in 1980 to around 44% in 2015. This observation is furthermore confirmed in Table 2, showing a strongly growing trend in terms of co-patent counts and shares for all sectors, while a decreasing, albeit non-significant downward trend in shares for companies.

Table 2. Time evolution of deflated co-patent application shares/ counts within sectors.

	Co-patent	*Application Year*
University	Share (%)	0.937**
	Count	0.911**
Government	Share (%)	0.965**
	Count	0.924**
Individual	Share (%)	0.930**
	Count	0.736**
Company	Share (%)	0.267
	Count	0.969**
Others	Share (%)	0.774**
	Count	0.850**

** $p \leq 0.01$

Going beyond the single entity view, in Figure 4 and Figure 5 we disaggregated the results to investigate co-patenting sector pairs. While the numbers of co-patents have grown considerably over time, this growth seems to have been largely driven by sector pairs in which universities and governmental agencies – rather than companies – figure as co-owners.

Observing the relative share of co-patent sector pairs (among the total co-patents), the combination company-company has steadily decreased from around 41% in 1980 to 29% in 2015. Similarly decreasing trends can be observed for co-patents filed by individuals, and at a lower level for company-individuals. On the other hand, combinations involving universities or governments have all increased, most prominently for government-university co-patents, with a visible surge especially after around the year 2000 (from ~2% to around 13% in 2015).

Following this, in Figure 6, we observe a decreasing *share* from ~91% of private-private combinations in 1980 to ~52% in 2015, whereas public-public combinations have increased their share from <1% to ~20%. Similarly, public-private combinations have increased from around 7% to around 22%. Taken together, these trends suggest that the relative increase in co-patenting is predominantly driven by actor combinations that involve public domain actors.

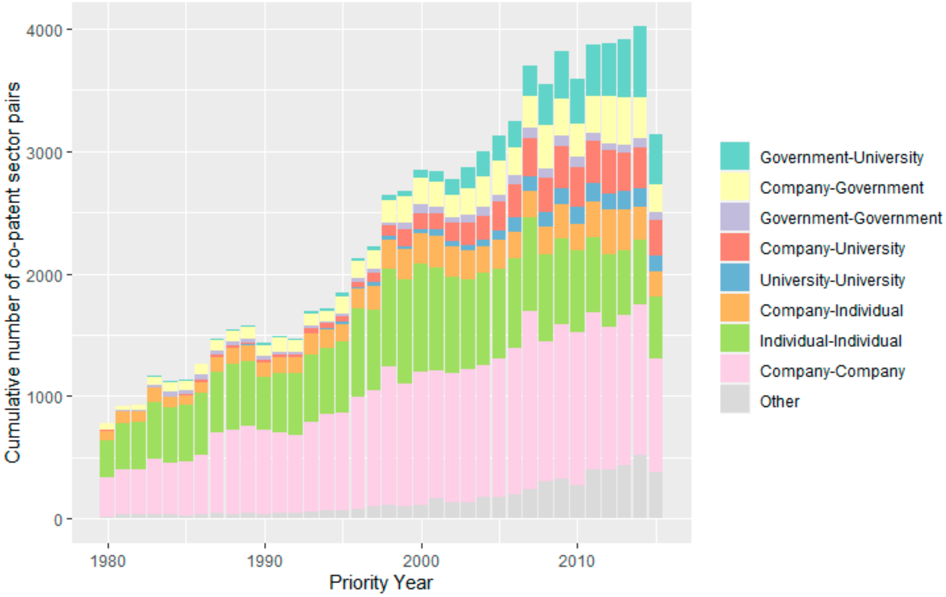

Figure 4. Distribution of deflated co-patent sector pairs.

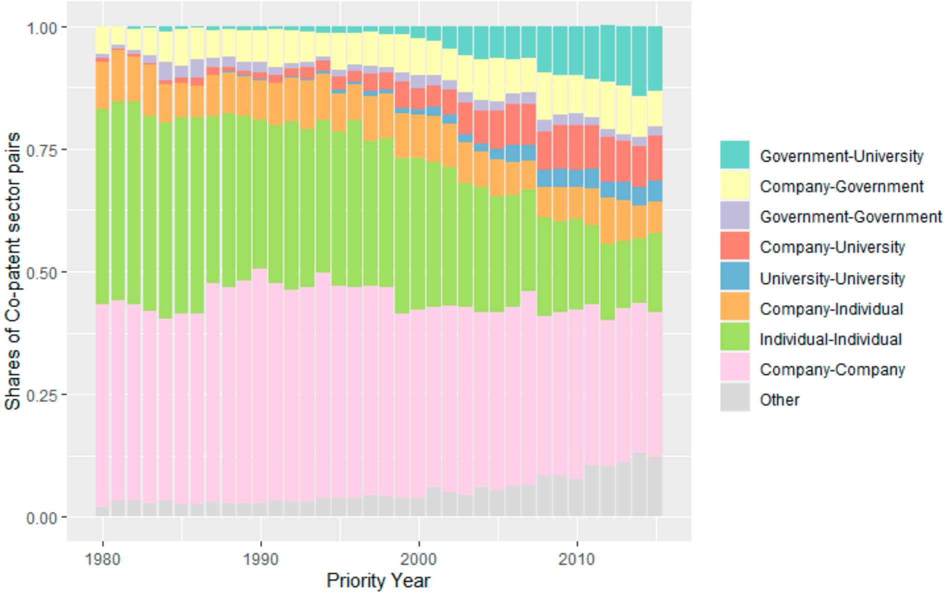

Figure 5. Relative distribution of deflated co-patent sector pairs.

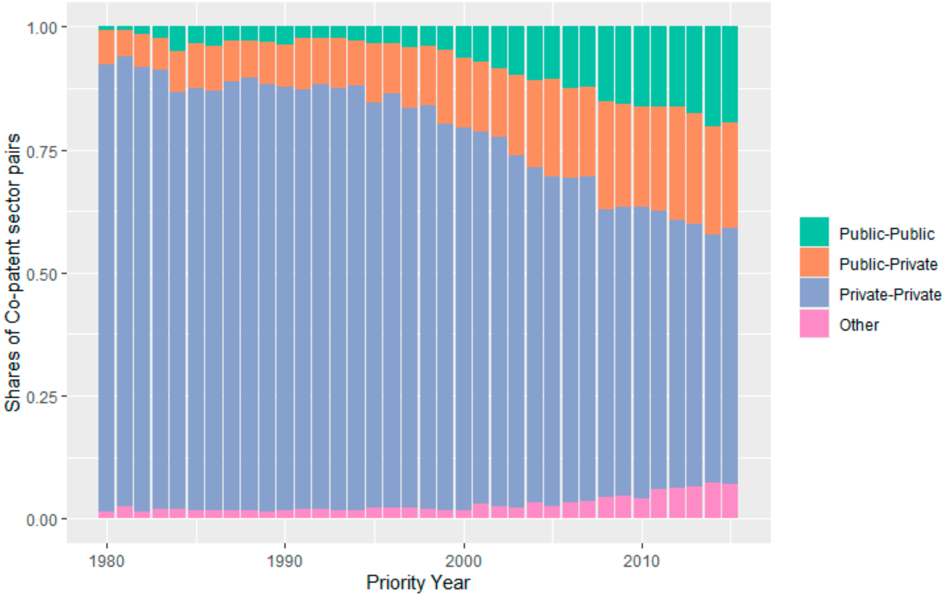

Figure 6. Relative distribution of deflated co-patent sector pairs (public-private).

Turning to the technology fields, an overview of the share of co-patents in each field is provided in Figure 7. The technology fields with the lowest co-patenting rates (below or around 4%) are Telecommunications (3), Digital Communication (4) and Handling in the Mechanical Engineering area (25). The median co-patent share for all technology fields is ~6%.

In contrast to that, we find comparatively high co-patenting shares for four technology fields ranging from 12% to 15%, involving Micro-structure and nano-technology (22), Analysis of biological materials (11), Biotechnology (15) and Pharmaceuticals (16). These results indeed suggest a high field-heterogeneity of the co-patenting phenomena. In particular, the shares of co-patenting seem to be higher for science-intensive fields.

Observing the relative growth dynamics over time in Figure 8, reveals further interesting insights. First, we note considerable year-to-year variability, in particular in the 1980s, where some fields have relatively low patenting rates (i.e., only 18 patents in the field Analysis, Measurement and Control Technology (7) in 1981, or in the 1990s after the first introduction of Micro-structure and nano-technology patents with a yearly patent count of 19 to 52 between 1992 and 1996), leading to a rather large variation of co-patent shares at the beginning of the observed timeframe. Second, we also observe steady growth patterns, in particular for Pharmaceuticals, which initially had a relatively low co-patenting share. Overall, we observe co-patenting rates reaching 10 to 15% by the end of the 1990s in those science-intensive four fields as mentioned above. In addition, after the year 2000, we observe another surge in co-patenting shares, closer to or exceeding 20% until 2015, clearly distinguishing these fields from all others.

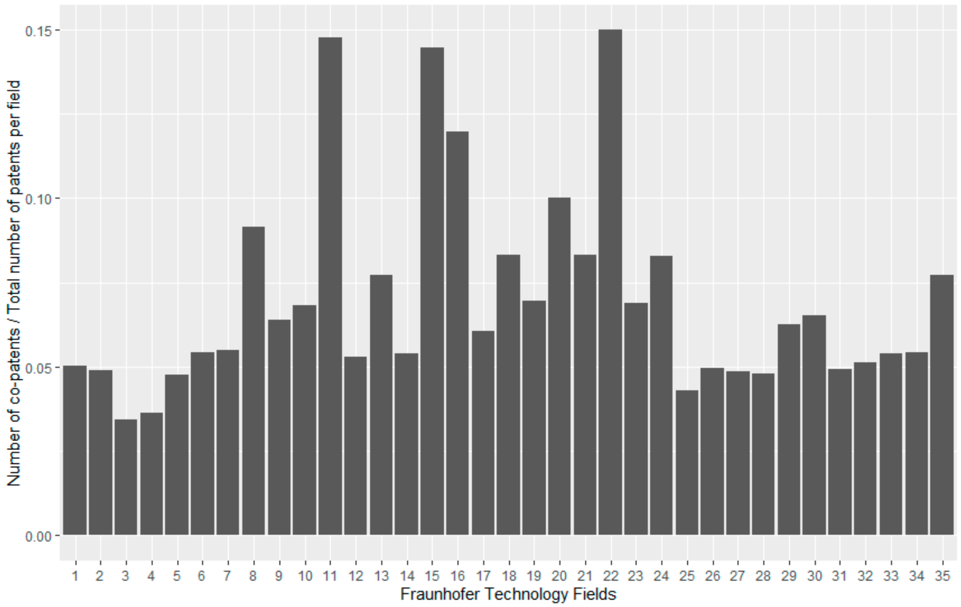

Figure 7. Comparison of co-patent applications by technology fields.

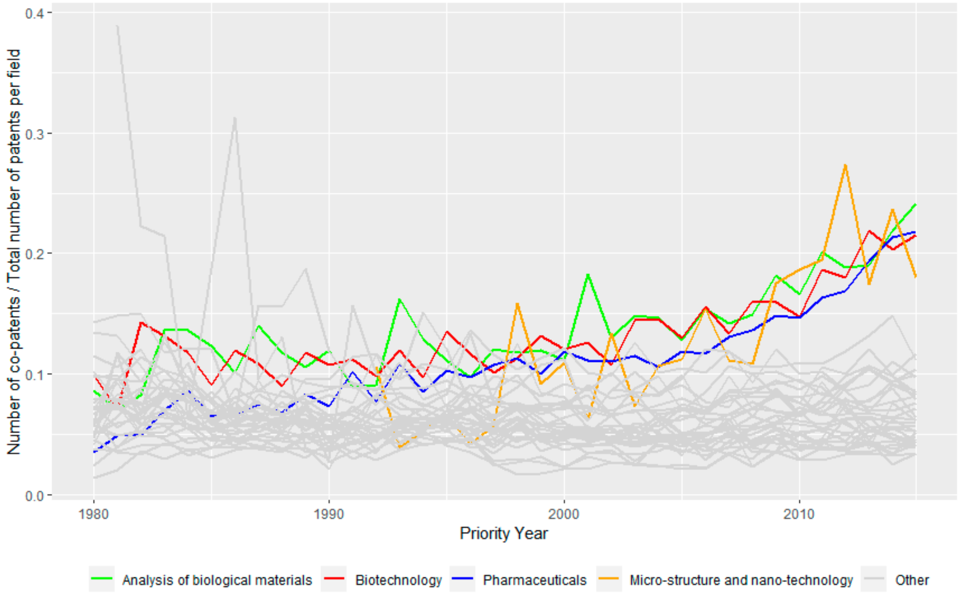

Figure 8. Comparison of co-patent applications by technology fields over time.

In addition, we aimed to identify if and to what extent, co-patenting is also country specific (besides domain/field specific). As can be seen in the ANCOVA output in Table 3, co-patenting varies significantly across countries and technological fields. In particular, we find a strong country-dependence, which explains by far the largest part of the model fit as compared to individual influences of the application year and the technology field.

Table 3. ANCOVA.

Discussion and conclusion

In this paper, we aim to contribute novel insights to the phenomenon of and literature on R&D collaborations and its role within (national) innovation systems. As such, we systematically mapped and analyzed the extent to which co-patents, i.e. patents owned jointly by two or more independent entities signal a growing trend, and whether and to what degree this growth is differentiated across countries, technological fields and type of actors. By relying on patent applications to the EPO for a set of 43 European countries, over the time period 1980-2015, we provide several contributions.

First, from a methodological point of view, we highlight the need to carefully consider data consolidation concerns, when relying on existing information on co-owned patents in patent databases. By defining co-patents strictly as those jointly owned by independent entities, and thereby excluding joint applications of different departments or subsidiaries from one and the same consolidated entity, our results reveal a considerable amount of 28% 'false positives' for our dataset. Not only does this represent an overestimation of the 'true' phenomenon of co-patenting; trends derived from 'deflated' figures present themselves as opposite to the ones obtained from the 'raw' data/indicator (see Figure 1).

Second, when analyzing trends based on the deflated indicator, we indeed observe a growing importance of co-patenting as a tangible output of R&D collaborations. At the same time this trend is highly differentiated across fields, countries and type of actors. While increasing trends are particularly present for some science-intensive fields (such as pharmaceuticals, biotechnology or nanotechnology) where almost 20% of the patent applications are co-patents by the end of the observed timeframe, most other fields remain situated at stable co-patent shares, below 10%. In terms of countries, we observe even stronger differences, signaling outspoken differences in the configuration and collaborative practices between the respective innovation systems. In particular, the variety of actors populating the innovation system seems to be a driving force, as the relative increase in co-patenting is predominantly stemming from actor combinations that involve universities and/ or governments, ergo entities of the public domain.

These findings resonate with earlier contributions focusing on the presence and impact of co-patenting. Belderbos et al. (2014) advance a distinction between value creation (joint development) and value appropriation (joint exploitation) in R&D collaborations. As such, co-patenting – oriented towards appropriation – is approached cautiously by companies due to looming downward appropriation effects resulting from shared intellectual property (in particular with companies active in similar industries). Consequently, the observation that firms do not increase their (relative) level of engagement in co-patenting practices comes hardly as a surprise. In line with the observations advanced by Arora et al. (2017), we do observe an increasing trend whereby firms co-patent more with universities and public research organizations. Equally interesting to notice – as well as to further analyze and substantiate in terms of antecedents – is the behavior of public actors regarding co-patenting. Our findings reveal clearly that universities and governmental agencies not only become more active in terms of technology development; they tend to combine this entrepreneurial stance with ownership practices of a more collaborative nature. We hope our contribution inspires future research, both in terms of antecedents and consequences of these differentiated practices.

Abstract

Research institutions organize their scientific activities in an increasingly diverse landscape. In matters of global interest, research relies on an ever-more cross-disciplinary background, which reveals intriguing questions concerning the local dynamics vs. global audiences. This paper proposes new methodological tools to assess, from a strategic perspective, the evolution of a given research landscape. It relies on the Global Research Institute of Paris's recent experience, a new interdisciplinary Institute that focuses on globalization topics beyond the usual economic meaning. The Institute relies on a broad and diverse set of research units of the Université de Paris and relates to the broad landscape of social sciences in France. This article charts the evolution of French authors' scientific publications on the Institute's thematic interests in French and English. It focuses on the structural features of the debate, namely the volume and the underlying semantic structure. The paper offers significant evidence to understand knowledge circulation dynamics and links that non-speaking countries' scientific literature builds with the English one.

Introduction

Research institutions build their research agendas in an ever-more international, dynamic, and diverse landscape. Many of these efforts are increasingly cross-disciplinary, either in collaboration or competition. Various institutions are motivated to inform their activities through the analysis of available bibliometric data. Understanding a specific research landscape is critical to steer global and multidisciplinary research agendas (Wallace & Ràfols, 2015, 2018). Different approaches tend to emerge in research areas with an international scope, gathering varied research interests from diverse origins and disciplinary backgrounds. One way of observing these complex groupings is to assess emerging trends over time (Ràfols, Porter, & Leydesdorff, 2010; Zitt & Bassecoulard, 1994). It is possible thus to describe the emerging tendencies and follow their evolution.

However, such an interpretative approach may reveal not so much the strategic choices of authors and affiliated institutions but rather the limitations experienced by researchers in their academic environment (Cruz-Castro & Sanz-Menéndez, 2018). Institutional structures tend to reflect the history of the scientific endeavor (Trow 1999, p.4). These questions are important when considering the emergence and circulation of new thematics. Local interests may differ from those appearing in the global arenas, but research in other languages tends to be overlooked in English literature (Chi 2012). How global transformations of research affect local scientific choices is not only a challenging and interesting question; it is also central to understand the growing globalization processes (Arvanitis & O'Brien, 2019).

We present the work done at the Global Research Institute of Paris (GRIP), a new French Institute that wanted to map, from an institutional perspective, research areas with a global scope. In particular, GRIP wanted to investigate the possible distance between its own strategic choices and those found in the French and international literature.

GRIP is an interdisciplinary institute focussing on globalization beyond its usual economic dimensions. GRIP builds upon the broad and diverse social science landscape inside the perimeter of the Université de Paris. Its interpretation of the concept of "Global Research" bounds to a vast array of research units scattered over Paris and relates to the broad landscape of social sciences in France. The multilingual publishing practices toward diverse audiences in social science research become a privileged standpoint of analysis (Kulczycki et al., 2020).

GRIP chose to concentrate on three thematic areas: Global Citizenship; Circulations; and Technologies, Market Logics and Vulnerabilities. These topics have been chosen through exchanges among academics located in the University, with no previous strategic analysis. It was decided to confront these strategic choices with the topics appearing in the international 'mainstream' publications and native-french publication repositories. The aim was to see if the Institute's topics are different or coherent with the available literature.

Methods and materials

This paper charts published research related to the same notion of Global Research that inspired GRIP's development and in two different languages (French and English). Specific queries were built to capture documents involving each of the Institute's thematic areas. As it remains crucial to situate these interpretations, this research focuses exclusively on French authors. To represent the GRIP's scientific objects and interests, we shared our research queries with a sample of researchers involved in the Institute's thematic areas. In this way, we focused on defining a precise query for each thematic area. After collecting and examining our first harvest of documents, the feedback from these same researchers became an input to fine-tune our queries.

As a result, six different queries for information retrieval were written, one for each research axis in both of the chosen sources. For English documents, information was retrieved from the Web of Science database. Items written in French were accessed from the HAL-SHS collection using the API made available by the platform (CCSD, 2021). HAL-SHS is a mandatory repository for French researchers that has been poorly explored and remains highly relevant since regional databases are an essential source to study social sciences' research output (Engels et al., 2012). In both cases, the fields we retrieved were the titles, abstracts, keywords, authors, and publication years. In WoS, the search strategy was based on the documents' topics. In HAL-SHS, full texts were available and searched; we excluded doctoral thesis and other teaching-related documents. We refined and improved our search strategy by consecutive iterations after analyzing the results in a continuous dialog with the researchers, experts in the field. As a result, we established the following query lines for each language, as shown in Table 1.

In this process, we gathered 1,798 English documents from the Web of Science (WoS) and 4,545 French documents from the HAL-SHS, both between 1980 and 2020. The query aimed at articles, books, book chapters, and research communications in both sources. We processed the two resulting collections with the help of the CorText platform using NLP techniques to obtain a fine-grain meaningful set of 750 terms describing the main semantic features of both collections. These lists of terms were manually curated[i] to eliminate noise and shallow terms in both French and English.

A *Period Detector* script was used to capture the semantic structure. We analyzed the frequency distribution of significant terms over the years and computed the optimal partitions in subsequent periods. We selected only the words with a minimum frequency of eight, 376 terms in French and 351 in English. Periods were computed using the gap statistic method (Tibshirani et al., 2001). As a result, we could improve the stability of differences among subsequent years. In this way, we gain access to the underlying knowledge aggregation process reflected in these documents.

Table 1. Queries used to represent each thematic axis in WoS (English) and HAL-SHS (French).

Findings

This analysis describes the themes related to the scientific interests of the GRIP in French publications in two different languages. We discovered that within these issues, as defined above, more documents were published before 2005 in French (393 documents) than in English (115 docs), and publications grow earlier and faster in French than in English (Figure 1). When comparing both curves, there is a significant time lag between French and English documents. The volume of publications around these issues picks up in French between 2002 and 2003, but only six years later in English, between 2008 and 2009. The French language growth seems to feed

English-language papers, but with a significant time lag. Finally, we observe that the number of published English-language documents stagnates from 2018 and on.

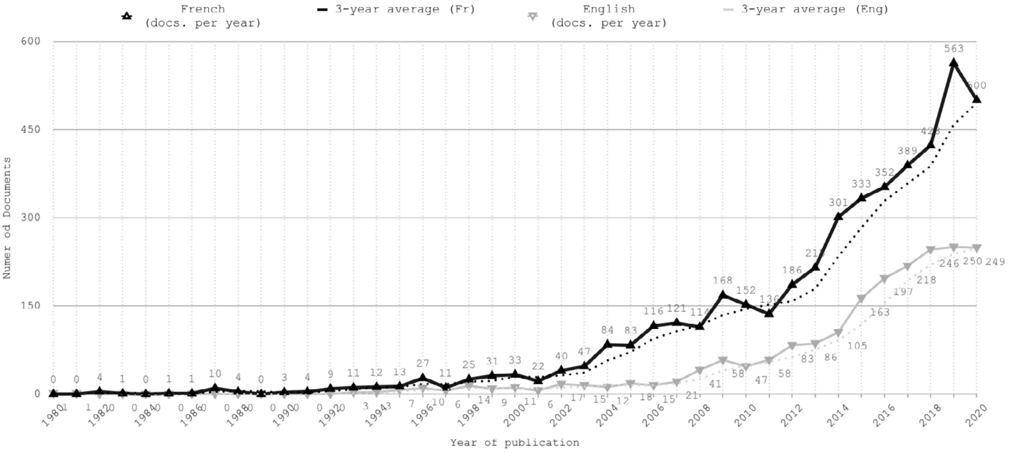

Figure 1. Number of documents representing the Institute's thematic interests in English and French.

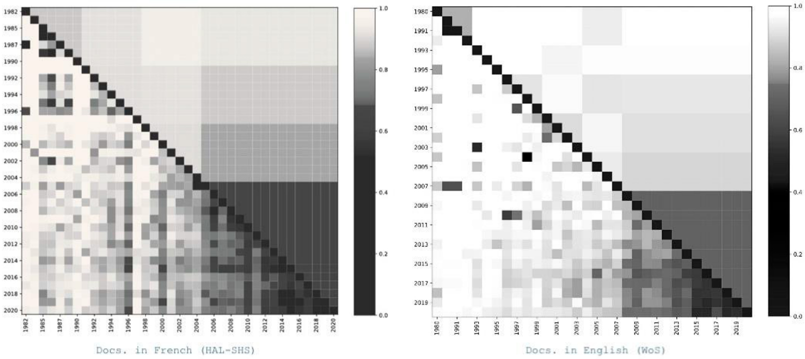

Figure 2. Period detection and significant term correlation between years in French and English.

The underlying semantic structure, summarized in Figure 2, allows us to understand how this growth unfolds. It charts how many terms used in one year resemble the one from the other years in the series. The whiter the cell is, the most dissimilar those two years are. On each graphic's upper right, detected most similar periods are represented by using a homogeneous grayscale. In French, three short periods, between four and eight years of duration, are detected. The fifth and last is the one that covers more time, from 2005 to 2020. It is also the one with documents that resemble the most to each other. In English, the similarity between the papers over the years is more irregular and weak. Here, detected periods are more -six in total- and also shorter. In general, the debate in English is more loose and erratic.

Discussion

Results have shown how similar topics can be addressed at different paces in two different languages. As the volume of documents rises first in French and, later, in English, it is natural to assume that many of the ideas developed in one language get translated and adapted to the other. Our results on the semantic structure of the debate in each language confirm this ‘'natural'' pattern: the production in French has a tighter, firmer, and stronger underlying structure. Topics appear on a longer time frame, a fact we could relate to long prolonged and sustained tradition on these subjects with a steady amount of documents published in the first of the three periods. The last detected period of fifteen years (2005-2020) speaks of a stabilization of the researchers' main concerns interests reflected in Ffrench documents. The delay between French and English-language publications on the same topics relates can be explained by a valorization strategy done by publishing English-language articles or books only after a valorization strategy that takes place after a maturation period that is visible in the French-speaking literature. Matters of interest get first widely discussed in French and then published in English.

We could also use the metaphor of ‘carry publishing’ (as we talk of carry trading in the financial investment business) since we can consider the articles in French as a local investment maturing over time to benefit in the long term by a publication in English on the international arena. It has potential implications for a better understanding of knowledge circulation dynamics and language interaction between English and non-English speaking scientific literatures (Kulczycki et al., 2018). This process takes place over the long term (Gordin, 2015) and relates to both scientific strategic choices and structural social constraints in the production of scientific knowledge (Hanafi and Arvanitis, 2014). The flat slope in publication rate from 2018 and on allows us to assume that these ‘carry publishing’ strategies have limits. Here, novelty appears as an inherent solid constraint since the international interest may decrease over time.

Further research should investigate these publication practices for non-English speakers; the particular case of French is of specific interest since it goes well beyond France (e.g., French-speaking Africa and North-African countries publish more in French than French scientists). How much does the thematic orientation of French documents resemble that of the English ones? What role authors’ choices play in this process? How do research institutions, evaluation standards, and international competition (as reflected in universities’ rankings) impact the publication process?

Conclusions

This research has shown that, on issues of global relevance, language matters. Specific interests can develop in a particular way in specific linguistic and geographic boundaries. These perspectives do eventually migrate to the English language but in a less systematic way. Beyond observing the fact that social sciences publish more heavily in their “national” languages than other scientific domains, little research has been done on the fundamental issue of language (Gordin, 2015; Ortiz, 2008; Kulczycki et al., 2018. 2020).

Our results indicate a maturation process over time, which affects the value given to locally-published scientific research since the English language is predominant in the core-publishing journals (Hanafi, 2011; Keim, 2016). Regarding the method used, a research strategy based on keywords complemented with a dialogue with researchers reveals a strong potential for a strategic-oriented analysis. Since informants may not be fully aware of these language-processing techniques, they might have difficulties providing precise feedback when examining a resulting semantic map. A strong interaction along the analytical process is needed to obtain fine-grained results and build query lines in the data-mining process. Last, the local perspective in our analysis allowed us to link the scientific debates at the national level with those appearing in English journals. It has been possible in the case of France, where local data were available, and because French social sciences also circulate beyond the national boundaries (see, e.g., 'French theory' in the USA). But as national repositories and databases are growing everywhere (see the databases such as Latindex in Latin America, or the new repositories in Asia, China, Russia, India), studying differences between locally published research in non-English speaking contexts and English-speaking international authors will be feasible and will probably reveal specific determinants that go beyond the need to diffuse more widely research results.

RRI projects in the mirror of RRI indicators

Abstract

The Responsible Research and Innovation (RRI) approach encourages societal actors to work together during the whole research and innovation (R&I) process to better align R&I and its outcomes with the values, needs and expectations of the society. In this paper, we monitor the results of the implementation of the concept of responsible research and innovation, primarily from the perspective of the world's largest funding programme – the EU Framework Programme RRI related projects. The analysis is primarily based on data on the funded projects related to RRI under the EU Framework Programmes FP7 and Horizon 2020, in total 85 projects with 845 participants (organisations). For the sake of completeness of the analysis (unified database structure), we used the Clarivate Web of Science database. In total we retrieved 212 papers. We used RRI indicators developed in the MoRRI project for testing project activities. In the context of this paper, we take a closer look at the implementation of the four principles: public engagement, gender balance, open access, and governance.

Keywords
RRI, EU Framework Programme, MoRRI indicators

Introduction

The notion that "soft" values have a role to play at all stages of society's life only took root in the last quarter of the 20th century, and it did not receive its "price tag" until the second decade of the 21st century.

The term “responsible research = RR”, or “responsible innovation = RI”, or “responsible research and innovation = RRI” is not new, and in publications dates back from the 80s of the 20th century (Figure 1).

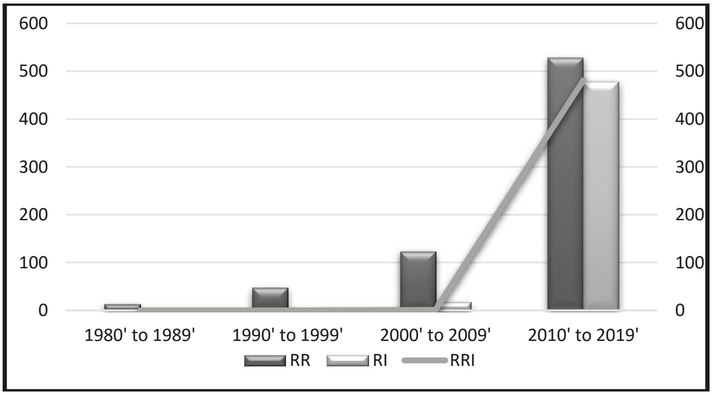

Figure 1. RR, RI, and RRI papers by timeline (WoS as of 01.01.2021)

The concept of RRI gained real impetus after the European Commission started to support it in 2011 (Sutcliffe, 2011, von Schomberg, 2011). As stated by Tim Flink and David Kaldewey (Flink and Kaldewey, 2018), “STI policy discourses in Europe and elsewhere have seen the arrival and uptake of new concepts, models and metaphors, all of which seem to challenge the old idea of an overarching social contract between science and society as well as those socioeconomic narratives of planning that surrounded the linear model of innovation”. This is well illustrated by the linguistic analysis of the basic documents of the EU Framework Programme (FP), which show that allusions to "soft" values did not appear in FP official texts until the seventh year of its operation, since FP3 (1990-1994), and gained real substantive value from FP7 (2007-2014) (Mustajoki, et al, 2020).

RRI may be defined as an ‘on-going process of aligning research and innovation to the values, needs and expectations of society.’

The RRI approach encourages societal actors to work together during the whole research and innovation (R&I) process to better align R&I and its outcomes with the values, needs and expectations of the society. It is like an umbrella that brings together different aspects of collaboration, ensuring the participation of different stakeholders in research and development (R&D), open access to the process and results, gender equality, timeliness in science education, ethics and good governance. As the ambition was to bring together under common denominator practitioners, policy makers, researchers, entrepreneurs and the so-called “aunt Maali” from the countryside, there were difficulties in making the term understandable. Because of that several authors expressed their concern on the risk that RRI will remain a vague set of hopeful 'Keys' which must be incorporated into funding proposals but do not significantly influence the norms, discourses and functions of other institutions in the EU, including those involved in regulating the end products of scientific research (de Saille, 2015). An opinion was also issued that the Horizon Swafs/RRI expert advisory group is lacking a clear idea of what RRI ‘is’ (Rip, 2016). A position was also presented that the main obstacle for RRI integration appears to be the policy integration strategy itself: the RRI framework is not clear to those who are the intended users which hinders the effective operationalization of RRI in research practice (Braun, et al, 2019).

Over time, it has been recognized that RRI will inevitably mean different things to different people, and demand different forms of engagement in different countries, cultures and scientific disciplines (Peter, et al, 2018), and the focusing on the term “RRI” creates unnecessary barriers, so, it is better to concentrate on the meaning and principles of RRI (Delaney, et al, 2020).

In this paper, we monitor the results of the implementation of the concept of responsible research and innovation, primarily from the perspective of the world's largest funding programme – the EU Framework Programme RRI related projects (Table 1). We used RRI indicators developed in the MoRRI project (www.morri-project.eu) to monitor the implementation of the four RRI key elements (gender, engagement, open access, governance) in RRI projects themselves.

As we can see in Table 1, the range of issues intended to be addressed in RRI projects is wide: implementing institutional changes in different types of organisations (research funding and performing organisations, higher education institutions, etc.), based on RRI principles; creation of practical tools and best practice examples that directly address societal needs while contributing to environmental and economic sustainability in industry-focused projects; the projects supporting EU regions to develop more open and collaborative approaches to society by taking an RRI approach; plus projects with disciplinary or sectoral approaches (e.g. focused on marine research institutes, the biosciences, energy sector or deindustrializing regions (Delaney, et al, 2020).

Methodology

Data sources

The analysis is primarily based on data on the funded projects related to RRI under the EU Framework Programmes FP7 and Horizon 2020, in total 85 projects with 845 participants (organisations). RRI as a concept in itself does not feature in the proposal template or in the evaluation sub-criteria. If one of the dimensions of RRI (public engagement, gender, ethics, open access, science education) is pertinent, then the topic is flagged for RRI in Horizon Dashboard (Delaney, 2020). One way to monitor the performance of projects is to analyze the publications. As these are projects that require the involvement and synergy of all parties, certain limitations must be taken into account when interpreting the results. From H2020, bibliographic data on project publications will also be publicly available[1], where we see that the number of published publications during Horizon 2020 period is significant (350,000 papers in total, among them 341,000 peer-reviewed papers). On closer inspection, we see that the lion's share of the publications have been completed by the recipients of the ERC grant (198,400 in total, from the 147,600 peer-reviewed). The projects funded by the Science with and for Society (which mainly funded the RRI projects – see Table 1) published a total of 350 publications, of which 341 were peer-reviewed (Horizon Dashboard). For the sake of completeness of the analysis (unified database structure), we used the Clarivate Web of Science database. To perform the search, we used a combination of the WoS fields "funding organisation", "Funding Text ", "Grant number", "Author keyword" and "Keywords Plus". In the interest of data accuracy, a manual check of the data was finally carried out. In total we retrieved 212 papers. The discrepancy of the obtained data with the data in the Dashboard can be explained either by the lack of a correct form of acknowledgments of the author(s) (according to the Horizon 2020 Annotated Model Grant Agreement, Article 38.1.2) or by the fact that the journal title is not covered in the Master Journal List of Clarivate WoS.

[1] In April 2021 the European Commission's open access publishing platform *Open Research Europe (ORE)* was officially launched

Analysis

For data analysis, we used combined data from two datasets. We used the following fields for project data: a) projects: start and end date, funding scheme; b) organisations: name, country, activity type and the role in the project. From publication data we used the following fields: Author Full Names; Author Keywords; Keywords Plus; Funding Organisation; Publication Year; Open Access Designations.

MoRRI indicators

We used selection of RRI indicators proposed by MORRI project (*Monitoring the Evolution and Benefits of Responsible Research and Innovation*) funded by the EU Framework Programme. The project's main objective was to provide scientific evidence, data, analysis and policy intelligence to support directly Directorate General for Research and Innovation (DG-RTD) research funding activities and policy-making activities in relation with Responsible Research and Innovation (RRI). At the end of the project, 36 RRI indicators were proposed for use. In the context of this paper, we take a closer look at the implementation and compliance of the four RRI principles in the projects.

Findings

General findings

A characteristic feature of FPs is their long-term duration, in terms of both signed contracts and the output timeline. Based on the data we can say that in FPs immediate results should not be expected. As in some areas the impact of the project has lasted for decades (Must, 2017).

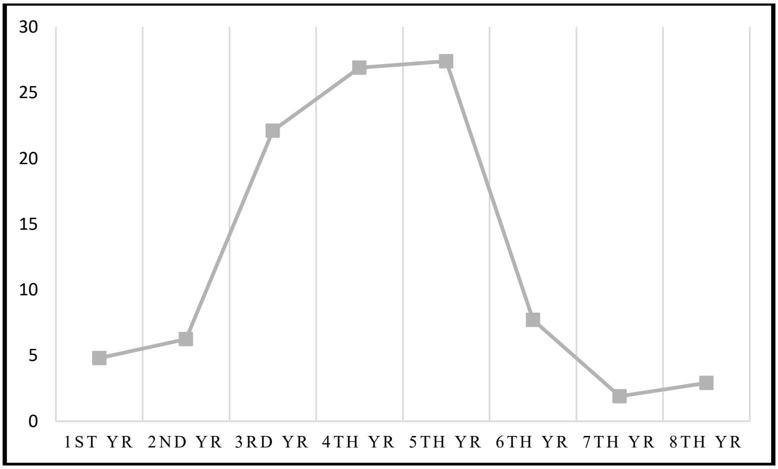

Figure 3. The Frequency of publications of RRI projects during the project time cycle (%) (WoS and Horizon Dashboard as of 01.01.2021)

The continued validity of this statement was also shown by the data of this analysis – the lion's share of project papers have been published in the fourth and fifth year of the project (54.3%) when the majority of projects have already been completed.

Most of the funded projects (63.5%) are funded under the funding scheme *Coordination and support action* (= CSO) which means that it is expected that during the project such activities are conducted as dissemination, awareness-raising and communication, networking, coordination or support services, policy dialogues and mutual learning exercises, also minor studies. In *Research and Innovation actions* (RIA) (34.1% of funded projects) the activities foreseen aim to establish new knowledge and/or to explore the feasibility of a new or improved technology, product, process, service or solution. For this purpose they may include basic and applied research, technology development and integration, testing and validation on a small-scale prototype in a laboratory or simulated environment (Horizon 2020 Online Manual). Against this background, it is somewhat surprising that the data from the present study show that CSA project partners outperformed RIAs in terms of publishing activity.

Public engagement

Traditionally, research and education institutions have been the most active participants in the Framework Programme. From the point of view of RRI aims, the extent to which representatives of business, policy makers or civil society have been involved, is crucial. As we see from Figure 4, representatives of higher or secondary education establishments (HES), research organisations (REC), and other bodies (OTH) constitute the majority of partners in the RRI related projects. At the same time, if we compare these data with overall data, we see some tiny shift to greater involvement of private for-profit entities (PRC) and public bodies (PUB). In terms of EU FP terminology, the organisation type "Other" forms a very heterogeneous community – this includes institutions (foundations) established by the state, political parties, stakeholders, societies. RRI projects have significantly more representatives of these organisations than the average of all projects. As expected, more experienced partners belong to universities, one fifth of HES organisations are involved in more than one RRI projects, in total 23.8% of organisations participate in more than one RRI project. This shows that the core of so-called RRI researchers has developed who involve a wider range of new partners in their projects.

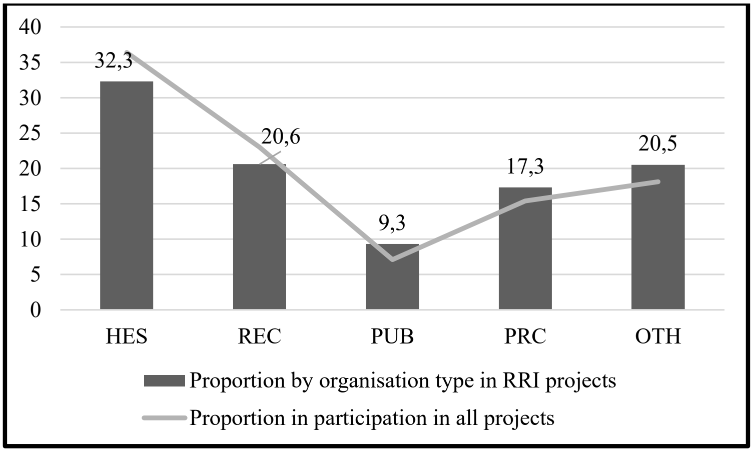

Figure 4. FP project partners by organisation type (Horizon Dashboard as of 01.01.2021)

About ten years of RRI funding allows us to highlight partnerships that have lasted in more than one project: *Applied Research and Communications Fund* (BG) / *Danish Board of Technology Foundation* (DK) have cooperated in five common projects. In four common projects *Fraunhofer-Gesellschaft zur Förderung der angewandten Forschung e.v.* (DE) / *Institute for Advanced Studies* (AT) and *Zentrum für Soziale Innovation GmbH* (AT) / *Universiteit Leiden* (NL). Three projects link five organisations: *Aarhus Universitet* (DK) / *Fraunhofer-Gesellschaft zur Förderung der angewandten Forschung e.v.* (DE) / *Institute for Advanced Studies* (AT) / *Zentrum für Soziale Innovation GmbH* (AT) / *Conoscenza e Innovazione Societa A Responsabilita Limitata Semplificata* (IT). There is no doubt that established partnerships have a positive side but one of the ideas of FP funding is its multiplier effect – the involvement of different new partners makes it possible to consolidate ideas and thus ensure the sustainability of the field. As stated in MoRRI, "There is still a long way to go regarding the 'universe' of researchers in Europe before RRI is more broadly known and accepted." Researchers receiving funding from the EU framework programme are more familiar with the concept of RRI, and they also associate more future benefits than non-funded ones (Mejlgaard, et al, 2018). Operating in a closed circle makes it possible to claim that the feedback from project to policy-making is arguably weak (Nedozhogina and Hõrak, 2019). At the same time we have to take into account that processes (on both sides) take time in RTD. It also means a global introduction to the concept of RRI. As we see from Table 2, the lion's share of project participants and authors to RRI papers come from Europe. However, as we already stated previously, different countries may not call similar activities with the same name, so for example a similar concept of RRI is called "Scientific social responsibility" in India (Braun, et al, 2020), and the concept of RRI is more entrenched in Europe than the rest of the world.

It means that there is a need to adapt existing frameworks so that they can operate within a country's technological, social and political context, while at the same time emphasizing the international environment and the global governance of innovations (Gao, and Zhao, 2019).

Table 2. Participants and authors by geographic area (%)
(WoS and Horizon Dashboard as of 01.01.2021)

Geographic area	*Project Participants*	*Authors*
Africa	0.5	1.1
Asia	1.2	3.8
Australia-Oceania	0.1	2.4
Europe	96.7	87.1
N-America	0.4	3.8
n/a	0	0.5
S-America	1.1	1.3

Gender equality

Gender equality and diversity is not just a matter of social justice, it leads to higher quality science, and is also a component of "smart economics". It is also a well-known fact that gender-mixed teams perform better. In H2020 several indicators are used for the monitoring of gender equality – participation in projects, being project coordinators or members of high level EC advisory groups, etc. On an average, women represent 42% of the participants in projects (including non-researchers) and 28% of projects have women coordinators (Gender equality and diversity, 2019). From this point of view, RRI projects far exceed the results of the FP – half of the project coordinators are women (Figure 5).

The monitoring of research outputs by gender is one indicator which is often used by research funding organisations. The number and proportion of female authors highlights developments in women's representation across fields and sectors over time, on the basis of bibliometric data. The MORRI data show that in 2016 the average proportion of female authors was below 40% (Mejlgaard, et al, 2018). As to papers written by RRI project participants, the gender of authors is almost in balance – 49.5% are female authors, 50.5% are male authors. However, it should be mentioned that women are slightly more productive than men – the average production of women is 1.5 papers, and that of men 1.4. At the same time, the corresponding authors' data are strongly inclined towards male authors (57% vs. 43%) (Figure 5).

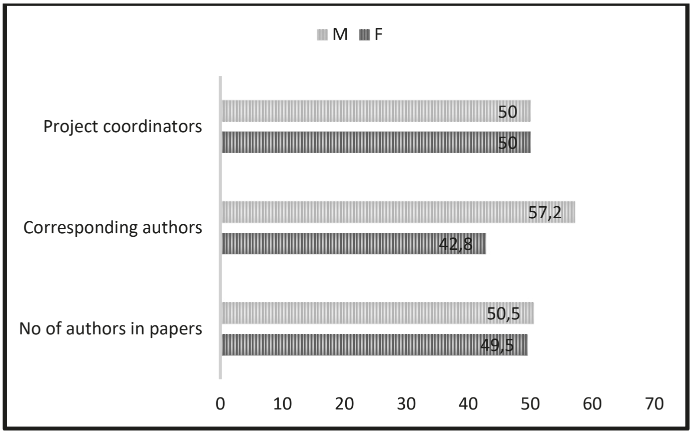

Figure 5. The distribution of RRI papers' authors, corresponding authors and RRI project coordinators by gender (%) (WoS as of 01.01.2021)

When dealing with gender-specific data, a number of factors must be taken into account that may influence results, such as the authors' field of research, working experience, etc.

Open access

Open access is the idea of making research results freely available to anyone who wants to access and re-use them, and thus is one of the most accepted keys of RRI. Originally, open access was separated into 'gold' and 'green' where gold indicates open access journals and green indicates open access through self-archiving. In current survey we use Clarivate WoS data where papers are labelled with three different types of open access (Clarivate):

- Gold: a) DOAJ Gold – Articles published in journals listed in the Directory of Open Access Journals (DOAJ). To be listed in the DOAJ, all articles in these journals must have a license in accordance with the Budapest Open Access Initiative; b) other gold – articles have a Creative Commons (CC) license by Impactstory's Unpaywall Database but are not in journals listed in the DOAJ. Most of these articles are from hybrid journals. Hybrid open access journals are subscription journals that include some open access articles.
- Bronze: the licensing for these articles is either unclear or identified by Impactstory's Unpaywall Database as non-CC license articles. These are free-to-read or Public Access articles located on a publisher's site.

- Green: a) Published – final published versions of articles hosted in an institutional or subject-based repository, b) Accepted – Accepted manuscripts hosted in a repository. Content is peer reviewed and final but may not have undergone the publisher's copyediting or typesetting.

The results of this study show that 68% of RRI articles are OA publications. The most common combination is DOAJ Gold and Green Accepted (33.6% of cases), followed by Green Published and Other Gold (19.6%).

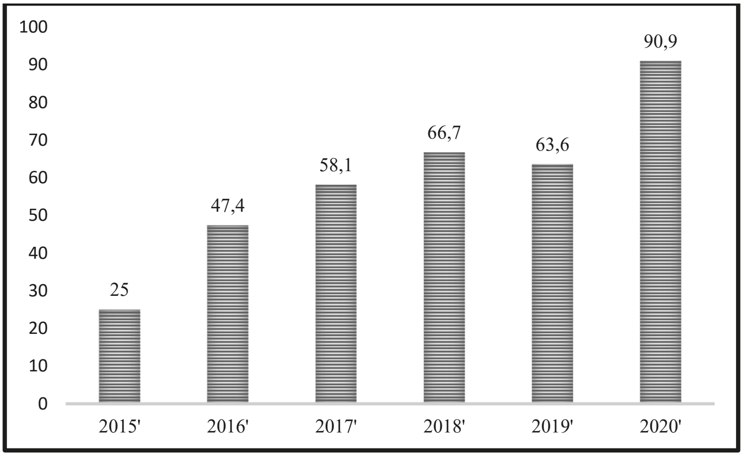

Figure 6. The proportion of OA RRI papers by year (%) (WoS as of 01.01.2021)

As we see from Figure 6, there is a constant growth trend in the distribution of OA publications. It was expected also in MoRRI, when analysing the data for 2012-2015 that a general trend will increase over time. The average annual EU-28 growth rate of the shares for 2012-2015 was 26% (Mejlgaard, et al, 2018).

Governance

The governance dimension fosters institutional transformations, developing conducive framework conditions for RRI, and supporting changing cultures and practices of research and innovation actors. It is defined as a way in which societal and state actors intentionally interact in order to transform ST&I systems, by regulating issues of societal concern, defining processes and direction of how technological artefacts and innovations are produced, and shaping how these are introduced, absorbed, diffused and used within society and economy. In context of RRI, governance mechanisms examine whether research-funding (RFO) and performing organisations (RPO) have established processes for managing the key areas of RRI.
For the present study, we used WoS data of RRI projects to monitor RRI acceptance by funding organisations. In total 294 funding organisations were acknowledged in the papers, from them 86 unique funders. The results showed that more than a half (55%) of the papers were written solely with the support of the EU Framework Programme. In addition to FP support, other EU-based funding sources (COST, ERDF, INTERREG, and Structural Funds) were used. A total of 60% of the articles were published thanks to various EU funding sources.

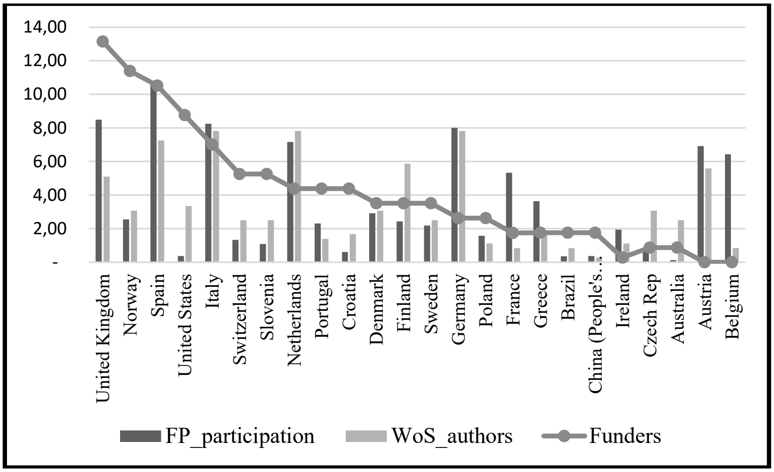

Figure 7. The proportion of FP participation, authors of the papers and acknowledged funders by country (WoS and Horizon Dashboard as of 01.01.2021)

Participants in RRI projects were distributed among 54 countries, of which authors from 38 countries were on the list of authors, and national funding organisations from 22 countries were mentioned in the acknowledgements.

Comparing the proportions of participants in projects, authors of papers and funders, we see certain patterns (Figure 7). The proportion of participation in projects does not necessarily mean a higher proportion of participation among the authors of the papers. This is most proportional for Spain and Germany. However, there are proportionally more papers compared to participating in projects in the Netherlands, and Finland. The list of funding organisations offers interesting results – in addition to the so-called special suspects (UK, NO, ES, US, IT), Slovenia and Croatia are among the top seven funders. At the same time, Austria and Belgium who belong to the top seven project participants, carry out their RRI projects only on the basis of EU Framework Programme funding. Among the list of the five most mentioned funders are the Norwegian Research Council (e.g. Programme on Responsible Innovation and Corporate Social Responsibility), U.S. National Science Foundation, Slovenian Research Agency, National Institute for Health (UK), and Croatian Science Foundation.

Despite the fact that the vast majority of research and innovation (R&I) is funded and produced by industry, companies tend to have no awareness or recognition of this concept (Gurzawska, et al, 2017), and in case of the current survey, only one company was acknowledged among a list of funders.

Discussion

In the present study, we tested what RRI projects look like against the background of MoRRI indicators. Public engagement is the most problematic, as research and education institutions dominate among the partners, and the involvement of other organisations in consortia is quite marginal. At the same time, comparing the data in the general environment, we observe a significantly higher participation of business and government organisations in projects than in the Framework Programme on average.

With regard to gender equality, we can see even more positive trends: the gender of RRI papers' authors is almost in balance – 49.5% are female authors, 50.5% are male authors. When dealing with gender-specific data, a number of factors must be taken into account that may influence results, such as the authors' field of research, working experience, etc.
Open access publication is a growing trend accounting for an average of 68% of all papers. Taking into account that governance mechanisms examine whether research-funding (RFO) have established processes for managing the key areas of RRI, our data show that EU funding plays a key role, and the impact of national funding is low.
The ten years of RRI funding by the European Commission have undoubtedly given a boost to this direction. Horizon Europe calls results will show how sustainable the established RRI partnerships are in the context when the RRI is integrated into the overall context.

Acknowledgments

This project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No 741402.

Diversity and interdisciplinarity - Should variety, balance and disparity be combined as a product or better as a sum? A probability-theoretical approach

Abstract

Diversity is a central concept not only in ecology, but also in the social sciences and in bibliometrics. The discussion about an adequate measure of diversity is strongly driven by the work of Rao (1982) and Stirling (2007). It is to the credit of Leydesdorff (2018) to have proposed a decisive improvement with regard to an inconsistency in the Rao-Sterling-diversity indicator that Rousseau (2018) had pointed out. With recourse to Shannon's probabilistically based entropy concept, in this contribution the three components of diversity "variety", "balance", and "disparity" are to be reconceptualized as entropy masses that add up to an overall diversity indicator div_e. Diversity can thus be interpreted as the degree of uncertainty or unpredictability. For "disparity", for example, the concept of *mutual information* is used. This overall probability-theoretical based concept is applied exemplarily to data on research output types of funded research projects in UK that were the subject of the Metric Tide Report (REF 2014). As expected, research output types depend on the research area, with journal articles having the strongest individual balance among the output types, i.e. being represented in almost all research areas. However, the overall diversity is comparably high (78.8% of the maximum diversity).

Introduction

Diversity is not only a central concept in scientometrics (e.g., interdisciplinarity), but also in ecology (e.g., Jost, 2007) or in the social sciences (e.g., Brusco, Cradit, & Steinley, 2020; Jones & Dovidio, 2018. Therefore, the measurement and operationalization of this concept is of eminent importance, which is also reflected in numerous publications on this concept especially in the field of ecology. A certain break in the development of this concept comes from the work of Rao and Stirling (Rao, 1982; Stirling, 2007), who developed a diversity concept based on the existing literature, which, in brief, consists of three components:

- *Variety*: «Variety is the number of categories into which system elements apportioned. It is the answer to the question: "How many types of things we have? … All else being equal, the greater the variety, the greater the diversity» (Stirling, 2007, p. 709)
- *Balance*: «Balance is a function of the pattern of apportionment of elements across categories… All else being equal the more even is the balance, the greater the diversity.» (Stirling, 2007, p. 709)
- *Disparity*: "Disparity refers to the manner and degree in which the elements may be distinguished… All else being equal, the more disparate are the represented elements, the greater the diversity" (Stirling, 2007, p. 709).

Thus, first Rao (1982) and later Stirling (2007, p. 721) developed a "general diversity heuristic" as a sum indicator of different elements j, i of a system (e.g., different research area in research proposals):

$$D = \sum_{ji(i \neq j)} d_{ij} p_i p_j \ . \tag{1}$$

where p_i and p_j are proportions of elements i and j in the system (as base for balance), and d_{ij} is the is the degree of difference between the elements (disparity). Variety is the number of different elements. This concept had a strong influence not only in ecology (e.g., Rousseau, Van Hecke, Nijssen, & Bogaert, 1999) but also in scientometrics (e.g., Goyanes, Demeter, Grané, Albarrán-Lozano, & Gil de Zúñiga, 2020; Rousseau, 2018; Wang, Thijs, & Glänzel, 2015) The idea of composing an indicator multiplicatively from several individual indicators is captivating and opens up many possibilities for analysis. It is also easy to calculate.

Unfortunately, Rousseau (2018, p. 651) was able to show with a simple data example that a central assumption of the diversity indicator ("monotonicity") formulated by Stirling (2007, p. 711) does not hold. For a given variety and disparity the measure does not increase monotonically with balance. This points to fundamental problems with this concept. It is to the credit of Leydesdorff (2018) and Leydesdorff, Wagner, and Bornmann (2019b) to create an indicator that does not have these problems and continues to multiplicatively link the three individual diversity indicators, which is certainly a viable approach despite criticism and modifications (Leydesdorff, Wagner, & Bornmann, 2019a; Rousseau, 2019).

For i=1 to n_c and j=1 to n_c categories, the diversity is defined as follows (Leydesdorff, 2018, p. 2116):

$$Div_c = (n_c / N) \cdot GINI \cdot \left[\sum_{\substack{i=1 \\ j=1 \\ i \neq j}}^{\substack{i=n_c \\ j=n_c}} \frac{d_{ij}}{(n_c \cdot (n_c - 1))} \right], \tag{2}$$

where n_c is the number of categories, N the total number of categories, GINI is the Gini-coefficient, d_{ij} is the disparity the Euclidean distance in terms of 1-cosine (Ahlgren, Jarneving, & Rousseau, 2003) varying between 0 and 1, which is normalized by the factor (n_c (n_c-1)).

In this paper, a different path shall be taken, namely a path back to the information-theoretical roots of this concept, which is based on probabilistic foundations as already used by Shannon (1948). Although the initial work of Shannon and the entropy concept is mentioned in most publications and is also part of Stirling's concept, the probabilistic foundation and the classical entropy concept seems to have been lost or is currently not sufficiently received. For example, in a paper in Scientometrics, Shaw Jr. (1981) derives his concept of information theory from a thermodynamic representation of entropy, in which probabilities are only implicitly used. But why is probability theory for a consistent diversity concept so important? Four main reasons can be given:

1. *Unclear theoretical basis*: The theoretical basis for combining the different elements of diversity is not immediately apparent. For example, probabilities as p_j or p_i are linked to correlations or similarity measures (d_{ij}, Eq. 1, 2), which is not statistically derived from any probabilistic or statistical framework. Even Rao (1982, p. 7) himself says about the choice of d_{ij}: "The choice of d_{ij} is not a statistical problem and will depend on an individual's assessment of differences between qualitative categories reference to a given problem. However, one can use methods of multidimensional scaling in estimating d_{ij} by using *supplementary information* such as inequality relationships between d_{ij} and d_{rs} for different (i, j) and (r, s)."
2. *Accuracy*: Most diversity indicators are defined numerically, although the relative frequencies or probabilities are statistical quantities and thus have a statistical measurement error. Probabilities based on small sample sizes are far less accurate than probabilities estimated from large samples.

3. *Interpretation of indicators*: Given the large number of diversity indicators, the question remains as to how to interpret the individual indicators and what advantages one indicator has over another indicator.
4. *Statistical analysis*: Diversity indicators often have to be processed statistically, which in turn requires distributional assumptions. Therefore, the question is whether the data should not be formulated in a probabilistic form in order to apply the statistical analysis more or less directly to the raw data.

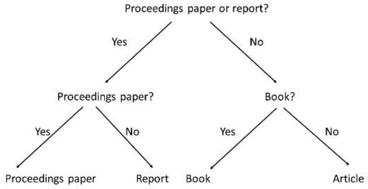
The central idea of the paper is to refer back to Shannon's concept of entropy, which is based on probability theory and forms the basis of today's diversity concepts, to arrive at a modified concept of diversity that firstly avoids previous inconsistencies in the diversity concept, secondly allows a simple form of interpretation in terms of uncertainty and reduction of uncertainty (entropy), and thirdly forms the basis both for new types of diversity indicators and for statistical modelling. In the following, both the modified diversity concept and an indicator will be derived in probabilistic terms, in order to then illustrate the approach with a practical application on research output data from Metrics Tide (https://responsiblemetrics.org/the-metric-tide/). The statistical model implementation must be, unfortunately, omitted here due to space constraints.

Probabilistic framework of information theory and modified diversity indicator div_e

Within information theory, information is defined purely syntactically without reference to semantics based on probability theory. In the following, a simple example will be taken as a starting point: The diversity of research output types of funded projects in the field of Natural Science (e.g., Mutz, Bornmann, & Daniel, 2012, 2014). Let us assume that project reports from 1000 funded projects are available as part of an expost evaluation (synthetic data). The frequencies of N=4 different output types are shown in Table 1, on the one hand before the data analysis without any information (prior or expectations) and on the other hand after the empirical data analysis (posterior).

Table 1. Relative frequencies for different output types (data example) and decision tree

Events	Output type	Code	prior	posterior
1	Books	00	0.25	0.10
2	Articles	10	0.25	0.80
3	Proceedings paper	01	0.25	0.10
4	Reports	11	0.25	0
Entropy			2	0.92



The following metaphor can be used to define information (Amann & Müller-Herold, 2011, p. 1f). If there is in advance no information about an event (here about the research output type), it is still possible to formulate a limited number of binary questions (Table 1, decision tree) to exactly determine which publication output is involved assuming the same probability of each event (Table 1, prior). The self-information is thus $\log_2(N)$, i.e. $\log_2(4) = 2$ bits (see Table 1, code). Another definition of self-information is obtained from probability theory, where the output type is a random variable X with j=1 to N possible events or occurrences (books, articles, ...). Thus, the self-information is $\log_2(1/p_j)$ or $-\log_2(p_j)$ with $p_j = 1/N$ if all events have the same probability (assumption $\log_2(p_j=0) = 0$). The average information over all events is then:

$$H(X) = \sum_{j=1}^{N} -p_j \log_2(p_j) \tag{3}$$

and is called Shannon entropy with the assumptions that $\sum_{j=1}^{N} p_j = 1.0$ and $\log_2(p_j=0) = 0$. It is assumed in a first step that the probability of occurrence of one event does not depend on the probability of occurrence of another event, an assumption which will be given up later. In research projects, the publication of proceedings papers should not depend on whether or not a journal article has also been published.

Shannon Entropy, as a measure of information, ultimately expresses the degree of uncertainty. For example, in a coin toss the uncertainty is highest when the probability of heads or tails is 0.5. A probability of 0.8 for heads, for example, reduces the uncertainty (tampered coin toss). People who bet on "heads" have a greater chance of winning than those who bet on "tails". In the above example, maximum entropy (H(X)=2) is reached when there is equal probability ($p_j = 0.25$) of the events. However, the actual observed frequencies as an estimate of the probabilities are not equal, the resulting entropy and thus uncertainty is reduced by 54% from 2 to 0.92 bits (see Table 1). This approach conforms to Bayes statistics, in which quasi in the context of an empirical learning process the initial expectation or uncertainty about model parameters (priors) is reduced (posterior) in the light of the data (Kruschke, 2011, p. 55). With the entropy concept, a first measure of diversity can be derived, that is "*balance*". For example, the more the observed probabilities resemble an equal probability, the higher is the so-called balance, the higher is the entropy or uncertainty.

Shannon also refers to "*variety*": "With equally likely events there is more choice, or uncertainty, when there are more possible events." (Shannon, 1948, p. 10). Furthermore, variety could also be traced back to an entropy measure. The maximum possible variety would be N, i.e. the maximum possible number of events (here N=4 output types). Finally, the maximum variety can be defined as the maximum entropy of the system as follows:

$$H_{Variety_{\max}} = \sum_{j=1}^{N} 1/N \log_2(1/N) = -\log_2(1/N) \tag{4}$$

In the case of four output types, the maximum variety would be $-\log_2(1/4)$. The observed variety corresponds to the number of events with nonzero probability $p_j > 0$:

$$H_{Variety_{obs}} = \sum_{j=1}^{N} 1/\sum_{j=1}^{N}(p_j > 0)\log_2(1/\sum_{j=1}^{N}(p_j > 0)) = -\log_2(1/\sum_{j=1}^{N}(p_j > 0)) \tag{5}$$

For the above example, the variety$_{obs}$ is $-\log_2(1/3)$. Similarly, Leydesdorff (2018, p. 2115) argues when defining a relative variety $\sum_{j=1}^{N}(p_j > 0)/N$. For an common diversity indicator one could add the two entropy masses balance and diversity, although this sum does not represent a joint-distribution H(A, B) in probabilistic terms, but can still be interpreted in terms of entropy with balance and variety as independent quantities:

$$H_{diversity} = H_{\text{var}iety} + H_{balance} \tag{6}$$

To get to the last component of diversity, "*disparity*", the assumption of independent events has to be abandoned. For example, research outputs in a research project may be published in different output types and this may also create stochastic dependencies. For example, the probability of a research article may depend on whether or not a proceedings paper has been published. In the simplest case, results of a research project can be published in two research outputs with a maximum of two different output types, where it is also possible that none of the output types is published or the same output type can be chosen twice. These two research outputs can be defined as two random variables X and Y.

Table 2 presents a cross-tabulation of cell frequencies and marginal frequencies of the two outputs. It quickly becomes clear that output 2 does not depend on output 1; the ratios of the relative frequencies across the columns remain the same across the rows. Thus p(X|Y) = P(X) or H(X, Y) = H(X) + H(Y), the marginal frequencies are sufficient ("overall balance").

Table 2. Case I: Independence

	Event	Output type	X (Output 2)				Total
			Books	Articles	Proceedings paper	Reports	
Y (Output 1)	1	Books	.01	.08	.01	.00	.10
	2	Articles	.08	.64	.08	.00	.80
	3	Proceedings paper	.01	.08	.01	.00	.10
	4	Reports	.00	.00	.00	.00	.00
	Total		.10	.80	.10	.00	1.00

For Table 2, the situation is different: P(X|Y) ≠ P(X), stochastic dependence is present. For example, articles in both outputs occur more frequently (p=.80) than expected in the case of independence of X and Y (p=.80*.80=.64).

Table 3. Case II: Dependence

	Event	Output type	X (Output 2)				Total
			Books	Articles	Proceedings paper	Reports	
Y (Output 1)	1	Books	.05	.00	.05	.00	.10
	2	Articles	.00	.80	.00	.00	.80
	3	Proceedings paper	.05	.00	.05	.00	.10
	4	Reports	.00	.00	.00	.00	.00
	Total		.10	.80	.10	.00	1.00

In that case, we speak of *mutual information* I(X, Y), i.e. the reduction of the uncertainty of one random variable by considering another random variable. In the case of two random variables, the mutual information is (Eshima, 2020, p. 8f):

$$I(X,Y) = H(X) + H(Y) - H(X,Y) = H(Y) - H(Y \mid X) \qquad (7)$$

$$H(X \mid Y) = H(X) - I(X,Y)$$

The joint entropy of X and Y is then:

$$H(X,Y) = H(X) + H(Y) - I(X,Y) \qquad (8)$$

The mutual information I(X, Y) can be calculated form the data using the following equation:

$$I(X,Y) = \sum_{x\varepsilon X}\sum_{y\varepsilon Y} p(x,y)\log_2\left(\frac{p(x,y)}{p(x)p(y)}\right), \qquad (9)$$

where p(x, y) is the joint probability of X and Y. If the events are independent, then p(x, y) = p(x)p(y) and I(X, Y) =0. *The more the event Y depends on X, the higher the mutual information I(X, Y), the lower the total entropy H(X, Y).* Mutual information represents the stochastic dependence of X and Y and is not a correlation. In Figure 2, the relationships of the different concepts of entropy and mutual information are shown as a Venn diagram.

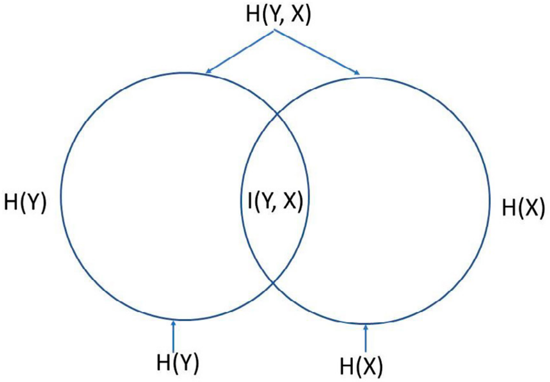


Figure 1. Entropy measures

Finally, mutual information, already mentioned by Shannon (1948, p. 12), defines the third component of diversity, "*disparity*", i.e. the degree of dependence of categories or events. The higher I(X, Y), the lower the disparity. If I(X, Y) is zero, then the disparity is maximal.

In the above example (Table 3), the mutual information is I(X, Y)=.72, the unconditional entropy of X is H(X)=.92, and the conditional entropy is H(X|Y)=.20. This reduces the uncertainty, i.e. overall diversity, by (.92-.20)/.92)=78.3% when taking into account the dependence in the data in the sense of disparity.

In the case of 3 research outputs with a maximum of 3 different output types, for example, the above formula, corresponding to the addition theorem of probabilities, expands as follows:

$$H(Y,X,Z)=H(Y)+H(X)+H(Z)-I(Y,X)-I(Y,Z)-I(X,Z)+I(Y,X,Z)) \qquad (10)$$

Where the last term of Eq. 10 is positive and represents a correction term in a quantity algebraic representation (i.e. subtraction of an intersection).

Unlike Stirling and Leydesdorff (Leydesdorff, 2018; Leydesdorff, Wagner, & Bornmann, 2019; Stirling, 2007), the different components of the *overall diversity indicator div_e* are now additive:

$$div_e = H_{\mathrm{var}iety} + H_{balance} - I_{disparity}\,, \qquad (11)$$

where div_e=4.15 for the above example.

In summary: On the probabilistic basis of Shannon's entropy concept, a modified diversity concept was derived that is consistent, additive in nature and whose components can be empirically derived. The entropy concept gives the diversity concept a clear interpretation: the higher the diversity, the higher the information, the higher the uncertainty, the less structure there is in the data.

Data and methods

To answer the question of how diverse research outputs are across research areas, we drew on data from the Metric Tide Report. Metric Tide analyzed the capabilities and limitations of research metrics and indicators. "It has explored the use of metrics across different disciplines, and assessed their potential contribution to the development of research excellence and impact.

It has analyzed their role in processes of research assessment, including the next cycle of the Research Excellence Framework (REF).

For the analysis, data on submissions for research projects funded since 2006 (Research Excellence Framework 2014) was used. Figure 2 shows an extract of the original cross table indicating how frequently 20 output types occur in 36 units of assessments (scientific disciplines). It would have been desirable for the analysis to have data on the output types for each individual research project. Such raw data were not available. Furthermore, it is not clear whether the frequencies represent the number of research projects in a cell or the sum of research outputs across all research projects in that cell.

To arrive at relative frequencies or probabilities, the absolute frequencies were divided by the total number (N = 190.962). Random variable X is the "output type", and random variable Y is the "research area" (unit of assessment, UOA).

Figure 2. Extract of the table of frequencies for 23 research areas (UOA) × 6 output types (Wilsdon et al., 2015, p. 154)

Results

Different measures can be calculated for the data (Table 4). Thus, a statistically significant χ^2-test value, a Cramer`s V of .24 and a mutual information of 0.40 show that the output type (X) depends on the research area (Y). There are, as expected, significant differences of the research area in the output types of the research output beyond chance. Looking at the ratio of the unconditional entropy of "output type", H(X), and "research area", H(Y), to the total entropy, H(X, Y), it is clear that the differences in frequencies are very much determined by the differences in "research areas" than the differences between "output types". While considering the "research area" reduces about (1.20-0.80)/1.20=33% of the uncertainty in the "output types", conversely only about (4.96-4.56)/4.96=8% of uncertainty in the "research areas" is reduced.. When the balances H(X) or H(Y) are compared with the respective maximum balances, it becomes clear that the balance in the "output types" of H(X) = 1.197 compared to H_{max}(X) of 4.322 is much lower than in the "research areas" (H(Y)=4.961, H_{max}(Y)=5.170). Research output types are essential less balanced than the research areas.

Overall, however, the diversity at 10.88 is very high, which is about 78.8% of the maximum possible diversity of 13.81. The maximal variety in the whole table is fully reached and the overall balance of 6.16 is 64.9% of the maximum possible balance of 9.49.

Table 4. χ^2 and entropy measures

Measure	Label	Value	Maximum
χ^2	χ^2-test value	204,768.3*	
Cramer`s V	Cramer`s V (correlation)	0.24	1.00
I(X, Y)	Mutual information ("disparity")	0.40	0.00
H(X)	Uncond. entropy "output type" ("balance")	1.20	4.32
H(X|Y)	Condit. entropy "output type"	0.80	
H(Y)	Uncond. entropy "research area" ("balance")	4.96	5.17
H(Y|X)	Condit. entropy "research area"	4.56	
H(X, Y)	Total entropy	5.76	9.49
Overall indices			
$H_{variety}$	Variety	4.32	4.32
$H_{balance}$	Balance	6.16	9.49
$H_{disparity}$	Disparity	0.40	0
div_e	Diversity	10.88	13.81

* p<.05 (df=665)

Table 5. Diversity measures for a set of 11 research areas (UOA)

UOA	Name	N	Variety	Balance	Disparity	Diversity
1	Clinical Medicine	4	2.00	0.27	0.02	2.25
2	Public Health, Health Services and Primary Care	4	2.00	0.14	0.01	2.13
3	Allied Health Professions, Dentistry, Nursing and Pharmacy	8	3.00	0.23	0.01	3.22
4	Psychology, Psychiatry and Neuroscience	9	3.17	0.21	0.01	3.37
5	Biological Sciences	7	2.81	0.20	0.01	3.00
6	Agriculture, Veterinary and Food Science	6	2.58	0.12	0.01	2.70
7	Earth Systems and Environmental Sciences	7	2.81	0.15	0.01	2.95
8	Chemistry	5	2.32	0.13	0.01	2.45
9	Physics	8	3.00	0.17	0.01	3.16
10	Mathematical Sciences	9	3.17	0.19	0.01	3.35
11	Computer Science and Informatics	16	4.00	0.23	0.03	4.19

Note. N=number of different output types $\Sigma(p_j>0)$

Finally, diversity measures can be derived for the "research areas", which provide information about the diversity for individual research areas. Diversity indicators for the first 11 research areas are shown in Table 5. “Computer Science and Informatics" has the highest diversity with 4.19 and "Public Health, Health Services and Primary Care" the lowest with 2.13.
"Computer Science and Informatics" has the highest variety of 4.0. "Clinical Medicine" has the highest balance (.27) in this set of selected research areas.
Among the different output types, "Journal articles" clearly shows the highest individual entropy, H(Y), i.e. the highest balance among all other output types across different research area (Table 6).

Table 6. Output types with highest individual balance values

Output type	Balance

Discussion

Diversity is a ubiquitous term used in many disciplines (e.g., ecology, sociology, bibliometrics). A certain break in the discussion on diversity and diversity indicators was brought about by the indicator developed by Rao (1982) and Stirling (2007), which in view of its comparatively simple definition has a very wide circulation. It is to the credit of Rousseau (2019) to point out inconsistencies in this indicator, to which Leydesdorff (2018) has proposed a workable solution. Furthermore, statistical concepts such as probability and correlation / similarity are combined with each other in a way for which there is no statistical basis whatsoever, which was even noted by Rao (1982, p. 7).

Table 7. Data example for the calculation of the diversity indicator *div_e*

	Research Output			
Project-ID	Journal articles	Books	Proceeding papers	Bookchapter
1	1	0	1	0
2	1	1	0	1
3	0	1	0	1
…				

Note. 1 = occurred in the project, 0 = not occurred in the project.

Due to the problems of the Rao and Stirling indicator, the aim of this paper was to go back to Shannon's probabilistic concept of entropy (Shannon, 1948), which implicitly dealt with all three facets of diversity, in order to develop a modified concept of diversity from it, which is additive in its nature and allows for both the calculation of a diversity indicator div_e as well as estimation diversity by a statistical model. The typical data structure is like that in Table 7.
In the sense of Occam's razor principle, the question arises as to why this more complex approach should be given preference in practice over the simple concept of Stirling and Rao. First of all, there is no intention to replace the existing diversity indicators, but to identify opportunities for improvement. The following four reasons could be put forward:

1. *Inconsistencies*: Concepts with obvious inconsistencies are not very convincing and reinforce the negative image of bibliometrics.

2. *Interpretation*: Diversity can be interpreted in terms of entropy as a measure of information. Diversity is at its maximum when events can no longer be predicted, as in a coin toss. The lower the diversity, the more predictable events are, the more structure is in the data.
3. *Open the Pandorra`s box*: The discussions on bibliometric concepts such as field normalization, definition of fields, fractional counting and also diversity seem to be more or less closed with some more or less workable solutions. These considerations might reopen the discussion.
4. *Stochastic nature*: If the occurrence of publications, research output, citations, etc. is assumed to base on a stochastic random process, this must be taken into account within the development of an indicator.
5. *Statistical estimation*: In principle, diversity and its various components can be in principle statistically estimated, which is the subject of future publications (e.g., Bornmann, Mutz, & Daniel, 2013; Bornmann, Stefaner, de Moya Anegón, & Mutz, 2016).

In the end, the present contribution could, actually, only represent an idea of an indicator. There is still a lack of further analysis showing the behavior of the indicator in comparison to other indicators. Furthermore, the calculation of the disparity indicator requires a workable solution on how to deal with the number of components that increases with the number of units (e.g. research output types). For example, with 3 units, there are 4 components of the disparity indicators. Last but not last, efficient statistical models must be developed to estimate diversity as a statistical parameter.

Abstract

Interest in measuring data citation and developing metrics for data is increasing. Despite this interest, basic bibliometric research investigating data sharing, data reuse and data citation practices remains relatively nascent. In this research in progress article, we use the DataCite GraphQL API to gather data for an initial investigation into dataset sharing and reuse as well as consider the current challenges. With over 8 million datasets in DataCite, we look at how datasets are dispersed by publication year, discipline, number of citations, license, institutional affiliation, and language. We find some patterns emerging, such as a recent increase in dataset publishing. However, there are still many limitations to doing this research that are discussed. As well, the future use of DataCite as a resource for doing this research and additional methods of analysis are considered.

Introduction

As data are increasingly becoming recognized scholarly outputs, funders, research managers and publishers are interested in developing data metrics to reflect the usefulness and impact of sharing data (Cousijn et al., 2019). Despite the interest in metrics for data, basic bibliometric research investigating data sharing, data reuse and data citation practices remains an underserved area.

The obstacles for conducting bibliometric research focusing on data are complex, involving decisions made in policies, practices and at the technical level (Borgman, 2016). These factors are compounded by a lack of bibliometric evidence about data sharing and reuse, particularly a lack of standardization in data citation practices. This creates a so-called "vicious circle," where bibliometricians tend not to take data as an object of study, while at the same time such research is required for developing meaningful data metrics and best practices in the field (Morissette, Peters, & Haustein, 2020).

This paper takes the first steps in addressing this vicious circle, presenting a preliminary bibliometric investigation into data sharing and citation practices, using metadata from DataCite (https://datacite.org) as a source. This research in progress article, which is part of a collaborative project involving DataCite and bibliometricians, provides an overview of the current state of the data available from DataCite. While perhaps not as large as other corpuses, DataCite is a relevant resource for bibliometric research as it is: a) not focused on a single discipline, and b) it assigns persistent identifiers (i.e. DOIs) to research data, allowing for a robust tracking of citations. Given documented disciplinary differences in data sharing, reuse and citation practices (Borgman, 2015; Tenopir et al., 2015), and the importance of accounting for disciplinary differences in data metric development (Lowenberg et al., 2019), we pay special attention to the presence (or absence) of information in DataCite about disciplinary domains in our analysis. We conclude our analysis by identifying gaps in the available data from DataCite and highlighting future areas for data-centric bibliometric research.

Background

Data sharing and citation

Data citation, and calls for its standardization, are not new matters of concern (Parsons et al., 2019). Milestones in the development of standards include the Bermuda Principles in 1996, the formation of CrossRef in 1999, and the founding of DataCite in 2009 (Lowenberg et al., 2019). Silvello (2018) extensively analyzes the extant literature on the development of such standards, as well as motivations for data citation current technical systems. The MDC initiative and DataCite have particularly contributed to efforts on the standardization of data citations in recent years (i.e. Fenner et al., 2019), as has the Scholix Framework for Interoperability in Data-Literature Information Exchange (Burton et al., 2017) and recommendations developed within the Research Data Alliance (Rauber et al., 2015). However, these projects focus on data citation infrastructure, not bibliometric research on data citation practices.

At a more granular level, other work analyses the state of data sharing, reuse and citation for individual datasets. Such work highlights the impermanent and untrackable nature of some citations, such as the widespread use of URLs to reference data (Yoon et al., 2019), or the practice of including data references in the body of articles or in acknowledgement sections, rather than in reference lists (Park et al., 2018). A general laissez-faire approach to data citation has been noted in a number of other studies (Fecher et al., 2015), and persists even in cases where recommended citation formats are provided (Belter, 2014).

Disciplinary differences in data sharing and citation remain a recognized yet unsolved problem. Disciplinary norms play an important factor in the willingness to share datasets (Tenopir et al., 2015). Similarly, early work analyzing the Thomson Reuters (now Clarivate) Data Citation Index (DCI) finds that the hard sciences, specifically biomedical fields, account for the majority (80%) of entries (Torres-Salinas et al., 2014). Lowenberg et al. (2019) note that disciplinary differences in the conception of data themselves demand creating discipline-specific usage statistics (i.e., downloads, views). Peters et al. (2016) also caution that statistics derived from data citations must be interpreted in the context of (disciplinary) data sharing practices and norms, finding that 85% of data remain uncited.

DataCite

The case study described in this research in progress article uses DataCite as the source for our bibliometric investigation. DataCite is an international, non-profit organization that has been assigning persistent identifiers, DOIs, for research data and other artefacts since 2009. DataCite is also actively involved in community outreach and provides data management services and support. Institutions become DataCite members to obtain DOIs for their resources. To receive a DOI, members provide DataCite with metadata describing the given data or artefact. This metadata is provided according to a specialized schema consisting of optional, recommended and mandatory fields (see Table 1).

Table 1. Mandatory Fields by DataCite

Field	*Description*
Identifier	The Identifier is a unique string that identifies a resource.
Creator	The main researchers involved in producing the data, or the authors of the publication, in priority order.
Title	A name or title by which a resource is known.
Publisher	The name of the entity that holds, archives, publishes prints, distributes, releases, issues, or produces the resource.
Publication Year	The year when the data was or will be made publicly available.
Resource Type	A description of the resource.

DataCite also collects citation data that can be accessed through the GraphQL API. There are two ways in which DataCite collects this data: DataCite members provide the information or DataCite learns about the citation from other academic resources, i.e. CrossRef (Garza, 2020). Recent studies examine DataCite's coverage and potential role in the development of scholarly metrics. Robinson-Garcia et al. (2017), for example, highlight the lack of a standardized vocabulary amongst metadata field entries as a hindrance to its utility as a metrics source. Another recent report examining the role of DataCite in open science practices supports these findings (Dudeck et al., 2019). Using a sample of datasets from an ocean science repository, the authors further conclude that data reuse within this sample is limited to a small number of organizations or to reuse by the original data creators. The study we present here fits into this literature, taking a high-level approach to provide a current analysis of the state of data within DataCite. We consider features that have not been examined before (e.g., citation data) presenting an initial step to more detailed future analyses.

Methodology

To gather data on datasets, we have used DataCite's GraphQL API to collect the metadata. Data was collected between April 15, 2021. Because DataCite is constantly having new submissions and uploads, it was important to collect data in a short time period. With the GraphQL API queries saved, future research collecting data to investigate any rapid changes to DataCite can be done quickly.

One important limitation to mention is that at the time of data collection, the DataCite GraphQL API only returned a maximum of 10 items per query. This is a design feature of the GraphQL API to help optimize performance. Because of this 10-item limitation, accessing the large amounts of data that is offered by DataCite is a challenge, and required work arounds both in terms of methodology and research questions (e.g., running multiple specified queries). There are ways, however, to customize queries in accordance with the DataCite team which can be explored in future work.

Initial Findings

At the time of data collection, there are 8,643,593 total datasets indexed in DataCite (7,440,415 records in 2017; Robinson-Garcia et al., 2017). The most frequent language of datasets is English, with more than 50% of all datasets in DataCite classified as such. Of the ten most common languages of datasets, all but one (Thai) are European languages. Of all the datasets found in DataCite, the majority have been published in the last 10 years (2011-2020). This accounts for 86% of the total number of datasets. It should be noted that these dates are for when the data was published, and not when the data was collected or used. In Table 2, the number of published datasets in DataCite by decade are listed and the general trend of a recent increase is noticeable. One observation is that there is a steep increase 1931-1940 from the previous and following decade. This is a result of a specific repository (University College Dublin) uploading a batch of data during this time period. This repository had a great deal of data connected to this time period as a result of a specific project covering 1937-1938.

Table 2. DataCite Datasets Published by Decade

Decade	*Number of Dataset*	*Decade*	*Number of Datasets*
2011-2020	7,129,806	1961-1970	8,766
2001-2010	815,399	1951-1960	544
1991-2000	87,782	1941-1950	212
1981-1990	30,249	1931-1940	48,073
1971-1980	10,694	1921-1930	53

There are currently 535,449 datasets in DataCite that have a discipline specified, ca. 6% of all datasets. This is not enough data to do a thorough investigation of discipline behaviors when it comes to data sharing and citation practices. However, based on personal communication with technical experts at DataCite, there will be over four million datasets that will gain discipline classification in 2021. This will allow for a more robust study of this area. Of the datasets that have a discipline identified, the ten disciplines with the most published datasets are listed in Table 3. For each discipline, the number of datasets with a citation are also listed. It should be noted that there are very few datasets in DataCite that currently have citations. In total, 97,734 of the datasets have at least one citation, ca. 1% of all datasets.

Table 3. Ten Most Common Disciplines Listed for DataCite Datasets

Discipline	*Number of Datasets*	*Number of Datasets with ≥1 Citation*
Biological sciences	289,137	286
Earth + related environmental sciences	89,931	414
Health sciences	77,601	29
Chemical sciences	63,285	9
Computer + information sciences	61,483	52
Clinical medicine	58,702	33
Sociology	39,144	166
Mathematics	32,901	12
Physical sciences	17,660	24
Psychology	15,450	25

The size of the dataset is listed for 2,485,517 datasets, or 28% of the total number of datasets. The reporting of the data for this variable is not standardized which makes its analysis challenging. Authors of datasets input information on size free of formatting. For example, some datasets express size by how many bytes a dataset takes up (e.g. 2GB) while others record this in other ways (e.g., number of rows, number of items). With the lack of standardization for size, there is a limited amount of data that can be provided by DataCite and, therefore, the depth of analysis we can conduct.

A mandatory field when inputting a dataset into DataCite is publisher. This variable, like size, does not have standardized data input, which makes evaluation of the metadata challenging and not something that is available via the GraphQL API. However, there are some general observations that can be made based on internal DataCite data. Global Biodiversity Information Facility is currently the most frequently identified publisher (941,335 datasets) and The Cambridge Structural Database is the second most frequent (889,586). There is a discrepancy between our findings and those reported in Robinson-Garcia et al. (2017) that requires further investigation in future work. Again, with the lack of standardization, there is a limitation to the data provided by DataCite and the analysis that we can conduct.

The license that is assigned to a dataset is important because it has a direct effect on the options to reuse a dataset. In Table 4, we have listed the top 10 most common licenses for datasets in DataCite. These licenses have been listed in order of the year in which the license was most used, and the number of datasets for that year and total datasets are listed. Because there has been such a recent uptick in use of DataCite, it is not that surprising that so many of the licenses have been published 2020. It is interesting to note how CC-BY-3.0 was so frequently used in 2006. This license was released in 2007 which would explain why it would have been so heavily adopted by these datasets.

Table 4. DataCite Datasets Published by License

License	*Year of Most Published*	*Number of Datasets for Most Published Year*	*Number of Total Datasets*
CC-BY-4.0	2020	171,807	625,685
CC-BY-NC-4.0	2020	102,918	214,311
CC-BY-NC-SA-4.0	2020	9,487	15,630
CC-BY-SA-4.0	2020	2,776	5,586
CC-BY-NC-3.0	2020	1,314	4,123
CC-BY-NC-ND-4.0	2020	634	2,378
CC-BY-1.0	2020	188	399
MIT	2018	1,036	4,281
CC0-1.0	2016	32,098	140,342
CC-BY-3.0	2006	55,848	283,489

Discussion

The goal of this research in progress article is to give initial insights into dataset reuse, availability, and sharing behaviors. To examine variables including datasets' age, size, license, publisher, language, citations, and discipline, we have used the DataCite GraphQL API. With that we contribute to the bibliometric meta research on datasets, hoping to encourage other bibliometricians to explore this type of scholarly output in more detail.

In bibliometric studies, discipline is an important scholarly variable which we have found to also need more attention in dataset studies. However, with only 6% of datasets in DataCite currently having a discipline classification, there is not enough data to do a robust analysis of datasets by discipline. More (approximately 50% of total) needed discipline classification will be added to DataCite in 2021. Other possibilities for expanding the amount of discipline data that is available will have to be considered, which could include integrating metadata from other sources to infer disciplines. As well, getting publishers and repositories to deliver data on disciplines in the future by asking them to select from controlled vocabulary (such as those provided by Organisation for Economic Co-operation and Development) could be necessary. We believe that this aspect is a rich field for future bibliometric research.

There are other variables, in addition to the ones presented in this research in progress article, that would be useful for this type of analysis. For example, additional variables on dataset reuse (e.g., downloads), the number of authors/contributors or the countries of origin could reveal insights into the nature of dataset sharing. There are challenges to doing this right now, mostly surrounding not having enough data to study it. With the increasing adoption of DataCite as well as DataCite adding more variables to their API we project that this will become an even more important area of research imminently.

Abstract

The classical power law model is widely used in informetrics to describe citations of scientific papers, although it is not addressing variability across individual authors. We report our preliminary results for a novel model based on a certain parametric form of the expected individual citation profile which generalizes the power law frequency formula. The new model interpolates between large citation numbers, where the power law tail is reproduced, and low citation numbers, which are usually truncated when fitting the power law model to the data. In addition, we derive a deterministic limit shape of the citation profile, which can be used to make predictions about various citation function such as the h-index.

Introduction

The classical power-law model was introduced by Lotka (1926) as an empirical match with observed frequencies of citations in scientific publications. In a later development, Price (1965) discovered an important connection with networks, whereby citations were interpreted as nodes' degrees. Examples of fitting the power law to the citation data can be found in Coile (1977), Redner (1998), and Clauset, Shalizi & Newman (2009). In particular, it was found that the power law frequencies do not necessarily fit well in the entire citation spectrum, so that a suitable truncation of lower citation values may be needed.

Importantly, no assumptions are made in the power law model about the frequency distribution of citations for an individual author randomly chosen from the population of authors. This makes it difficult to project the model fitted to a pooled corpus of publications onto individual authors, for example, for the purposes of evaluating their productivity.

The power-law model can be fitted to real-life data using standard statistical methods such as the maximum likelihood or ordinary least squares estimation. As has been documented across many use cases (Clauset, Shalizi & Newman, 2009), the power law usually fits quite well but only in the tail region of the frequency range, which motivates the use of truncated power-law models by excluding the lower values. This may decrease the utility of the model in estimation of various functions of citations, such as the popular h-index, introduced by Hirsch (2005) and defined as the maximum number h of an author's papers, each one cited at least h times.

In an attempt to overcome this shortcoming, we propose a novel model by modifying the power law setting. The new model interpolates between slow (almost flat) decay of the citation frequencies at the bottom of the citation spectrum and then reproducing the power-law behavior at the tail of the frequency distribution. As we will demonstrate below using a small real data set, the model provides a very good fit across the entire citation spectrum. In addition, and in contrast to the scale-free power law, our model possesses a deterministic limit shape of the citation profile, which can be used, for example, to make meaningful estimation of the h-index. In particular, the estimation of the h-index based on the modified model appears to be significantly more accurate as compared to that in the standard power law model.

Power law frequencies

In its classical setting, the power law model states that the relative frequency f_j of exactly j citations accumulated by a randomly sampled paper is proportional to the a-th power of j, with some exponent $a > 1$ (typically lying in the range $2 < a < 3$), that is (to include the case $j = 0$ and to normalize the sum of frequencies to unity),

$$f_j = \frac{c}{(j+1)^a} \qquad (j = 0,1,2,\dots), \tag{1}$$

where the normalizing constant c is given by the reciprocal Riemann zeta function,

$$c^{-1} = \sum_{j\geq 0} \frac{1}{(j+1)^a} = \zeta(a). \tag{2}$$

Here, "randomly sampled" means that a paper is sampled from a *pooled corpus* of papers written by a (large) population of authors. For simplicity, interaction effects due to joint authorship are not taken into account; such effects are complicated but have minor impact.

In terms of analysis of citation data, if there are M_j papers with j citations, out of the total number of papers M, then the power law model predicts that the relative frequencies M_j/M are approximately given by formula (1),

$$f_j \approx \frac{M_j}{M} \qquad (j = 0,1,2,\dots). \tag{3}$$

Note that the total number of papers and the total number of citations in this corpus are given, respectively, by

$$M = \sum_{j\geq 0} M_j\,, \qquad N = \sum_{j\geq 0} j\, M_j. \tag{4}$$

Of course, in any real-life data set the numbers M_j will reduce to zero for j big enough (so that the series in (4) are in fact finite sums), but this is reconciled with the prediction (1) simply by the fact that the theoretical frequencies f_j tend to zero as $j \to \infty$.

As mentioned in the Introduction, the power law model does not address the frequency distribution of citations for an *individual author* randomly chosen from the observed population of authors (say, of size K) and featured by a collection of *citation counts* ν_j, that is, the numbers of papers by this author that have j citations ($j = 0,1,2, \dots$). Moreover, the number of observed authors, K, is often omitted in popular citation data sets (cf. Redner, 1998).

Having in mind statistically homogeneous populations of authors who produce their research outputs according to the same probability distribution, it is natural to assume that these authors are independent from one another due to lack of interaction. Equally reasonable is the assumption of mutual independence of the counts $\nu_j(k)$ for each individual author $k = 1, \dots, K$. In this notation, the pooled numbers M_j are given by

$$M_j = \sum_{k=1}^{K} \nu_j(k) \qquad (j = 0,1,2,\dots). \tag{5}$$

Then, according to the law of large numbers, for $K \gg 1$ we have

$$\frac{M_j}{K} = \frac{\nu_j(1) + \cdots + \nu_j(K)}{K} \approx E(\nu_j), \tag{6}$$

where E stands for expectation (statistical mean) and a random variable ν_j represents the counts $\nu_j(k)$. Recalling (4), the mean number of papers per author is approximated as

$$\frac{M}{K} = \sum_{j\geq 0} \frac{M_j}{K} \approx \sum_{j\geq 0} E(\nu_j) \qquad (j = 0,1,2,\dots). \tag{7}$$

provided that the series on the right is convergent. Thus, combining formulas (3), (6) and (7), we obtain the link between the power-law frequencies f_j and the expected counts $E(\nu_j)$,

$$f_j \approx \frac{M_j/K}{M/K} \approx \frac{E(\nu_j)}{\sum_{j\geq 0} E(\nu_j)} \qquad (j = 0,1,2,\dots). \tag{8}$$

In practice, power law is often fitted in the tail of the frequency distribution, that is, for $j \geq j_*$, with a suitably chosen truncation point j_*. This leads to readjustment of the normalizing constant c_a in the frequency formula (1). Fitting such a model to the data requires optimization over two parameters, a and j_*. Specifically, a natural heuristic tool to fit a truncated power-law model is by looking at the frequency plots (e.g., histograms) with logarithmic scales on both axes, whereby one seeks a straight-line fit, with the slope corresponding to $(-a)$ (cf. Nicholls, 1987). An alternative approach (Clauset, Shalizi & Newman, 2009), which provides the helpful smoothing of the discrete data, is via the complementary cumulative frequencies

$$F_j = \sum_{\ell \geq j} f_\ell \qquad (j \geq j_*). \tag{9}$$

Using again the log-log plots, a good fit corresponds to a straight line, with slope $(1 - a)$.

Generalized power-law model

Setting of the model

The generalized power-law (GPL) model introduced in this section is set out using two hyper-parameters n and m, interpreted as the mean numbers per author of citations and papers, respectively. These parameters can be estimated from the observed pooled corpus by

$$n \approx \frac{N}{K}, \qquad m \approx \frac{M}{K}. \tag{10}$$

There are also two shape parameters, $a > 2$ (akin to the power-law exponent) and $b > 0$. Namely, the citation frequencies are now assumed to be of the form (cf. (1))

$$f_j = \frac{Cm^{ab-1}}{(j + m^b)^a} \qquad (j = 0,1,2,\dots). \tag{11}$$

For small j ($j \ll m^b$) we have $f_j \approx C/m$, while for larger j we get a power-law dependence,

$$f_j \approx \frac{Cm^{ab-1}}{j^a} \qquad (j \gg m^b). \tag{12}$$

This may be viewed as an effective sewing of the formerly truncated lower values with the power-law tail. Recalling the link (8) between the pooled frequencies f_j and the individual expected counts $E(\nu_j)$, we have

$$E(\nu_j) \approx m\, f_j = \frac{C}{(jm^{-b} + 1)^a}\,. \tag{13}$$

Hence, we can calibrate the model using (10) to make it consistent with the hyper-parameters,

$$m \approx \sum_{j \geq 0} E(\nu_j) = C \sum_{j \geq 0} \frac{1}{(jm^{-b} + 1)^a} \approx Cm^b \int_0^\infty \frac{dx}{(x+1)^a} = \frac{Cm^b}{a-1}, \tag{14}$$

and similarly

$$n \approx \sum_{j \geq 0} j\, E(\nu_j) = C \sum_{j \geq 0} \frac{j}{(jm^{-b} + 1)^a} \approx Cm^{2b} \int_0^\infty \frac{x\, dx}{(x+1)^a} = \frac{Cm^{2b}}{(a-1)(a-2)}\,. \tag{15}$$

Considering the ratio n/m (i.e., the mean number of citations per paper), we get

$$\frac{n}{m} \approx \frac{m^b}{a-2}, \qquad C \approx m^{1-b}(a-1). \tag{16}$$

Hence, b is expressed in terms of the hyper-parameters and the parameter a,

$$b \approx \frac{\log n + \log(a-2)}{\log m} - 1\,. \tag{17}$$

The shape parameter a can be fitted to the data using either ordinary least squares or a suitable version of the maximum likelihood estimation (cf. Nicholls, 1987).

Limit shape

It is useful to represent the citation profile of an individual author by ranking their papers according to the citation scores (i.e., accumulated numbers of citations) $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_m$; for example, $\lambda_1 = \max\{\lambda_i\}$ is the score of the most cited paper. The citation profile is succinctly visualized by the *Young diagram* formed by (left- and bottom-aligned) row blocks with $\lambda_1, \lambda_2, \ldots$ unit square cells; its upper boundary is the graph of the step function

$$Y(x) = \sum_{j \geq x} \nu_j \qquad (x \geq 0), \tag{18}$$

where ν_j are the author's citation counts. In particular, $Y(0)$ is their total number of papers.

A useful insight into the structure of the citations data may be available by looking at the shape of suitably rescaled Young diagrams when both n and m are large (Vershik, 1996). Specifically, set

$$A = m^b, \qquad B = n/m^b, \tag{19}$$

and consider the rescaled (expected) shape

$$E\big(\tilde{Y}(x)\big) = \frac{1}{B} E\big(Y(Ax)\big) = \frac{1}{B} \sum_{j \geq Ax} E(\nu_j). \tag{20}$$

Substituting expressions (13) and approximating the sum by an integral like in (14) and (15), it is easy to show that there is a limit shape given by

$$E\big(\tilde{Y}(x)\big) \approx \varphi(x;a) = \frac{a-2}{(x+1)^{a-1}} \qquad (x \geq 0). \tag{21}$$

Data analysis

Goodness-of-fit

In this section, we fit the two models discussed above to real citation data, collected in January 2020 for a small population of 113 authors identified as those who had published at least one paper in the *Electronic Journal of Probability* in the first 10 issues (January–October) of volume 24 in 2019 (https://projecteuclid.org/euclid.ejp/1546571125) and who are also featured on Google Scholar (https://scholar.google.com). The total counts for this data set are $K = 113$ (authors), $N = 245{,}567$ (citations) and $M = 15{,}400$ (papers), including $M_0 = 6{,}472$ papers with zero citations. Noting that the observed frequency $f_0 = M_0/M = 0.42$ is quite high, it was decided to omit the value at $j = 0$ in the GPL model fitting (as seen in Figure 2, this value does appear to be an outlier). According to (10), the hyper-parameters of the GPL are given by $m = (M - M_0)/K = 79.01$ and $n = \ 2{,}173.16$. In turn, the corresponding estimates for the shape parameters are $a = 2.50$ and $b = 0.60$, found numerically using the *optim* command in R.

The power-law model was fitted using a suitable truncation as explained after equation (8); the fitted values, obtained using the *poweRlaw* package in R (https://cran.r-project.org/web/packages/poweRlaw), are $a = 2.32$ and $j_* = 48$. As we will see, the goodness-of-fit of the power-law model is excellent, but a high value of j_* is disappointing. Note that if we opted to ignore truncation and tried to fit a power-law model in the entire range, the fitted value of the exponent would change to $a = 2.42$.

First, let us report the results for the GPL model regarding the match of the theoretical limit shape $y = \varphi(x; a)$ specified in equation (21). In Figure 1, this limit shape is plotted in scaled-back coordinates for a better comparison with the data (represented by an empirical Young diagram as explained above), that is, $y = B\ \varphi(x/A; a)$, with the scaling coefficients given by formula (19) and estimated from the data as $A = 13.75$ and $B = 158.08$.

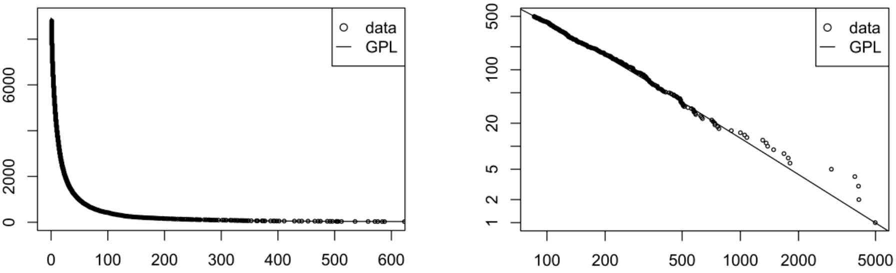

Figure 1. Observed data in the Young diagram representation and the fitted limit shape, with estimated parameters $a = 2.50$ and $b = 0.60$. The left panel illustrates a match for lower values of citations, while the right panel shows the tail comparison in the log-log coordinates.

We see from Figure 1 that the fit of the GPL is remarkably accurate, especially over a large initial part of the citation spectrum. To inspect details of the tail behavior, we use the log-log scale, revealing some minor discrepancies due to few extreme points.

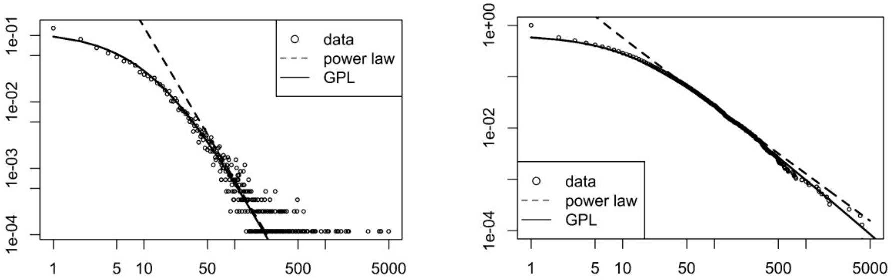

Figure 2. Log-log plots comparing data and the fitted models. The left panel shows frequencies f_j, while the right panel features complementary cumulative frequencies F_j. The left part of the dashed lines indicates an extrapolation of the power law below the truncation point $j_* = 48$. The observed frequency at $j = 0$ (zero citations) is an outlier.

Next, we compare the fit of both models to the data using standard frequency plots (Figure 2). Not surprisingly, the power law works extremely well at the tail but it is useless for smaller values of j. In contrast, the GPL strongly outperforms the power law over the initial range (despite a visible outlier at $j = 0$) but also works equally well at the tail.

Estimation of the h-index

Let us now look at what our models can tell about the h-index. According to Egghe & Rousseau (2006), in the non-truncated power-law model the h-index is estimated by the formula

$$h \approx m^{1/a}, \tag{22}$$

where $m = M/K$ is the mean number of papers per author. In our case, $m = 79.01$; using the non-truncated estimate $a = 2.42$ we get $h = 6.08$, while if we (formally) use the truncated fit $a = 2.31$ then the estimated value of h would slightly change to 6.63.

In the GPL model, the h-index geometrically corresponds to inscribing a biggest square inside the empirical Young diagram of citations. Using the limit shape (21) and scaling back using the coefficients A and B, we find that h is the approximate solution of the equation

$$h\left(\frac{h}{A}+1\right)^{a-1} = B(a-2). \tag{23}$$

Solving this equation numerically yields $h = 20.29$. Comparing with the empirical (mean) value $h = 17.52$, we see that the GPL estimation is superior to that of the power law, which cannot capture the true h-index lying deep below the truncation point $j_* = 48$.

Conclusion

In this paper, we have attempted to connect the pooled frequencies modeled via power law with individual citations per author. We have also introduced the generalized power-law (GPL) model which has been demonstrated to fit to the real data well in the entire range of citations, unlike the power law which frequently needs to get truncated at the beginning. In a real data set that we have studied, the GPL model reveals an inflated frequency of zero citations, which draws attention to a possible lack of impact in scientific output. An additional novel feature of the GPL model is that it possesses a deterministic limit shape which can be useful in estimating informative function of the citation data such as the h-index. Finally, it would be interesting to compare our GPL model with alternative fitting approaches (Sichel, 1985).

Abstract

We address a methodological problem that needs to be solved whenever databases of thematically or regionally circumscribed literature are built from scratch. How does one collect and delineate the scholarly literature produced by a national sub-community in a particular discipline? For our study of communication processes in the German Social Sciences and Humanities (SSH) we need a near-complete collection of the scholarly literature of German national sub-communities in a humanities field, namely art history. In this paper we discuss the definition of a German national sub-community of art history and the first step in the methodology of collecting its literature, namely the creation of a seed dataset.

Introduction

In this paper we report our solutions to a methodological problem that needs to be solved whenever databases of thematically or regionally circumscribed literature are built. How does one collect and delineate the scholarly literature produced by a national sub-community in a particular discipline? The common approach to creating specialized sets of publication metadata utilizes one of the two commercial databases Scopus or Web of Science and creates a subset of their data by thematic or regional delineation, for which sophisticated methods have been developed (Leydesdorff & Cozzens, 1993; Lewison, 1999; Aksnes et al., 2000; Zitt & Bassecoulard, 2006). This approach implicitly or explicitly assumes that the databases index all the relevant literature.

The premise of near-complete coverage has been shown to be wrong for the social sciences and humanities (as well as for many other disciplines, Moed, 2005: 119-136). This is why scholars build dedicated databases for the study of communication processes in these fields (Ardanuy et al., 2009; Colavizza & Romanello, 2017; Hammarfelt, 2012). The methodology of building these databases is rarely discussed. This is unfortunate for two reasons. First, the methodology and particularly the decisions on which publications to include affect the outcomes of studies for which the database is used. Insufficient documentation of methodological decisions thus unnecessarily limits the replicability of findings. Second, building such databases can be very labour intensive, and the exchange of methodologies could increase efficiency.

For our study of communication processes in the German Social Sciences and Humanities (SSH) we need a near-complete collection of the scholarly literature of German national sub-communities in one social science field (international relations) and one humanities field (art history) (Gläser & Oltersdorf, 2019). In this paper we discuss the definition of a German national sub-community of art history and the first step in the methodology of collecting its literature, namely the creation of a seed dataset.

Conceptual background: How to define German art history?

The collection of publication metadata reported in this paper is the prerequisite of an investigation of SSH communication processes with a focus on national communication substructures and the use of languages (Gläser & Oltersdorf, 2019). Collecting publication metadata of all German publications in art history in a specific time period requires a clarification of what we actually mean by “German art history”. The two conceptual problems that must be solved are identifying German *art history* and identifying *German* art history.

We start from the observation that in the sciences, social sciences and humanities knowledge is produced not by disciplines but by smaller research specialties (Chubin, 1976). Research specialties are scientific communities whose collective identity is based on members’ perception of collectively advancing a shared body of knowledge. Members observe this body of knowledge, derive problems and approaches to solving them from it, and offer solutions to these problems to other community members as contributions to the shared knowledge (Gläser, 2006). Membership is a perceived rather than ascribed status.

From this perspective art history as a discipline is a system of overlapping specialties, each of which develops a specific body of knowledge. The specialties share a general object and an historical approach. Members of an art history specialty perceive themselves as such and express this perception by using the community’s knowledge and offering contributions to the community. This means that community members become identifiable by their publications. Overlaps of communities result from researchers using knowledge of more than one community and addressing their contributions to more than one community,

The definition of membership as perceived rather than ascribed and the overlaps of communities create problems for the identification of community members that are relevant to our task. The overlaps do not end with the disciplinary boundaries of art history but extend into overlaps with, among others,

- communities investigating objects closely related to the arts (e.g., architecture),
- communities sharing the historical approach of art history communities (e.g., general history),
- communities utilizing interdisciplinary approaches to the study of art (e.g., area studies), and
- communities investigating contemporary art with non-historical approaches (e.g., art criticism, the sociology of arts).

As for all other communities, membership in an art history community can be partial (when researchers split their activities between several communities) and temporary (when researchers move between communities in the course of their career).

Most scientific communities are international in that they have members working in many countries. Some international scientific communities, particularly in the social sciences and humanities, develop regionally or nationally intensified communication processes in which contributions are primarily addressed to community members from the same region or country. These national sub-communities can develop for several reasons including the existence of a large number of community members in a country, a shared non-English language, or the existence of nationally or regionally specific research objects that are of lower interest to researchers outside the country or region (Gläser, 2006: 184-186).

Operationalization: Methodological decisions

Strategy

From the conceptual considerations follows that we are looking for a collection of publications that draw on the same knowledge (have references in common) and represent the formal communication process of the German sub-community (cite each other). Thus, the ultimate decision about the delineation of German art history as a nationally intensified discourse will be based on citation relations and shared references. The strategy of producing such a dataset is in accordance with the common approach in bibliometrics in that we create a seed dataset that is subsequently enhanced by adding publications to which it has citation relations and reduced by excluding publications without such relations. However, it differs in its first step due to the problems of creating the seed data set. In this section, we first discuss possible sources of publication metadata from which a seed data set could be created. We then describe the strategy for creating the seed data set and the methodological decisions made.

The most important consideration for creating the seed data set is that its composition must not introduce bias in the publication collection. To reduce the danger of bias, the seed data set needs to be large enough to cover the variation of publications, in particular with publication types and languages used.

Sources for the seed data set: Dead ends

Metadata of publications in German art history can be collected from a variety of sources, each of which has its specific limitations.

Curated collections that include references have insufficient coverage

The two main databases that index publications, Web of Science (WoS) and Scopus, have the main advantage that they include the references of indexed publications and links between publications that are indexed in the database and appear in reference lists. There is widespread consensus that they are not suitable for analyzing SSH communication processes due to their insufficient coverage of the SSH literature and their bias against particular publication types and publication languages (Engels et al., 2018; Hicks, 2004; Kulczycki et al., 2020). We included publications indexed in these databases but could not use them as exclusive source of a seed data set due to the limitations of their coverage of the literature.

Collections of links to internet sites do not provide publication metadata

The most prominent collection of links to internet sites that host publications, Google Scholar (GS), indexes web documents and links them with web documents that cite them or are referenced by them. GS differs from WoS and Scopus in its collection strategy, which is inclusive and automated. The Google crawlers are indexing any academic document that can be found on the web. The coverage of literature by GS thus depends on the internet publication strategies of authors and publishers. As a consequence, older publications are poorly covered as neither the publications nor the citations are (yet) online. Detailed information about the coverage of GS is not available. GS does not include publication metadata but points to internet sites that do. Publications are not thematically indexed.

For these reasons, GS can be used to extend the seed data set via citation relations but not to build it. Another source that links items and references is the member driven platform CrossRef. The coverage is determined by the metadata provided by the CrossRef community, and is therefore uneven and ill understood. Citation based analysis in CrossRef is limited to 59% of the items, for which free and open reference information are provided by publishers and cooperating institutions (Martín-Martín et al., 2021). Therefore, CrossRef can be seen as a broker of metadata between organizations (Hendricks et al., 2020).

No national publication data collections exist in Germany

Confronted by the limitations of existing databases, some countries have chosen to develop national research information systems, with complete bibliographic coverage of the scholarly output at research institutions e.g., Belgium (*VABB-SHW Database*) or Croatia (*CROSBI*) (Sīle et al., 2018). No such national-level research information system exists in Germany. There is not even a register of institutional bibliographies, as not all higher education institutes provide a publicly available bibliography of their researchers' output.[1]

Specialized international collections insufficiently cover the German literature

Répertoire international de la littérature de l'art (RILA) and *Bibliography of the History of Art* (BHA) are specialized art historical bibliographies. They include articles from over 1,200 journals, and cover material published between 1975 and 2007. The *International Bibliography of Art* (IBA) is the successor to BHA. Its description of coverage is only vague. Its website claims that it retains the editorial policies of BHA without providing further explanation.[2] Rinehart (1990) described the content and policy of BHA as follows: "The overall framework remains postclassical Western art. […] Practical considerations have naturally played a part, and the general feeling has been that what is done should be done well and comprehensively before undertaking more. […] The policy of BHA is to reflect, not to define, the changing boundaries of the discipline." (Rinehart, 1990: 134)

IBA includes several types of publications but is limited to 500 international journals, many of which are covered only partially. About 60% of the entries are from non-English language publications. Despite its apparent comprehensiveness IBA's coverage of German art history is very patchy. An author search for five randomly selected German art historians showed no results or returned only small proportion of their research output.

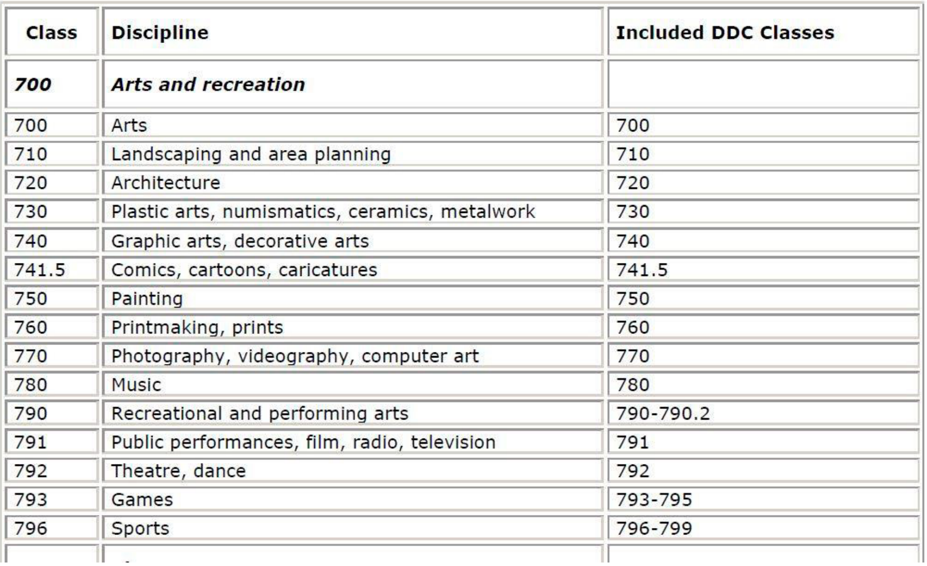
<u>German library collections are decentralized and difficult to collate</u>

The organization of library collections through classifications, subject headings or thesauri is context-dependent and subject to permanent revisions (Chen, 2013; Hjørland, 2013; Nohr, 1996). Creators of a classification impose a particular view of the knowledge on the users by organizing the research field. Any field of knowledge may, in fact, be classified from different epistemological perspectives which, in turn, may produce quite different classifications and publication collections (Hjørland, 1998). This is not problematic as long as publication metadata are collected by one library consistently using one system.[3] Unfortunately, the German library infrastructure is fragmented, with several libraries forming a distributed national library. Scientific libraries are organized into six library networks that rely on different classification schemas for indexing, without an integrating layer in form of a union catalogue of all six networks (Seefeldt, 2017). There are several research libraries that are specialized in art history, and belong to different networks.

A comparison of *Dewey Dezimalklassifikation* (DDC), *Basisklassifkation* (BK) and *Regensburger* Verbundklassifikation (RVK) reveals the complexity of that delineation problem. All three classifications are used for indexing in the German library system, and all three classifications consider art history differently. We illustrate the problem by comparing the classifications of art history and architecture because the distinction of art history from architecture is one of the main delineation issues. RVK includes a main class *art history* and assigns the subclass architecture to it. BK also includes a class *art history* as part of main *class Kunstwissenschaft (*art studies*)*, but subsumes architecture as part of the main class *Bauwesen* (civil engineering). DDC, in contrast, does not contain a main class with the name art history at all. Instead, it uses a class *Arts and recreation* (Figure 1). This is not only a question of labelling. Rather, the creators of DDC did not intend a classification of the discipline of art history, but actually wanted to classify *the arts*. This inevitably leads to a completely different classification, in which there is no place for a class *art history*.

This fragmented structure with different classification schemas for indexing, unlike meta data standards, divergent depth of indexing, and the lack of a union catalogue hinder retrieval and download of meta data for delineation.

Each of the sources we reviewed represents only a subset of existing publications. That leads to the assumption that completeness in coverage can only be considered regarding predefined indicators. As all databases deal with a certain degree of publication loss we decided to turn the focus from the question of coverage to the question of how to best identify the community.



Class	Discipline	Included DDC Classes
700	***Arts and recreation***	
700	Arts	700
710	Landscaping and area planning	710
720	Architecture	720
730	Plastic arts, numismatics, ceramics, metalwork	730
740	Graphic arts, decorative arts	740
741.5	Comics, cartoons, caricatures	741.5
750	Painting	750
760	Printmaking, prints	760
770	Photography, videography, computer art	770
780	Music	780
790	Recreational and performing arts	790-790.2
791	Public performances, film, radio, television	791
792	Theatre, dance	792
793	Games	793-795
796	Sports	796-799

Figure 1: DDC Subject categories class 700

Constructing a seed data set: methodological decisions

In the light of the problems with sources of publication metadata, we decided to start from the self-identification of researchers as art historians and to extract publication metadata from their publication lists, and reference information from additional sources or full texts of publications (Oltersdorf et al., 2020). This approach required two methodological decisions. First, researchers in art history must be distinguished from those in adjacent disciplines. Secondly, researchers belonging to German art history must be distinguished from those belonging to other national art history communities.

Who is an *art historian*?

Self-descriptions of art history are not free of contradictions and regional variation, and disciplinary boundaries have been moved in several directions by the art history community itself. We decided to accept a broad definition of art history that we found in the review literature (Belting, 2008). This definition is organized along three indicators: time, object of investigation and territory. In terms of time, art history is limited to the Christian-influenced eras starting in the 4th century to the present. With regard to the present, art history must be distinguished from art criticism as there are fundamental differences in the methods applied (Michalski, 2015). Regarding the territory, art history is conceived as a discipline that deals with research objects generated and shaped by the European conception of art. This includes the art of North and South America as well as the Christian cultures of the Near East and the Caucasus. Research objects of art history include architecture as well as sculpture, painting, graphic arts, craftwork, up to photography and new media.

We operationalized this delineation by identifying organizational structures of universities that label themselves as being art historical according to that definition. We then identified all affiliated researchers and parsed the publication lists from the universities' websites. It is quite clear that the organizational structures do not always coincide with the cognitive classification of publications (Bourke & Butler 1998). It is also undeniable that the completeness of the literature lists presented at the universities' websites varies. Despite these limitations, the publications thus identified are very likely to include the majority of publications for the time frame considered. Since they also include all publication types that are common in art history, they form a suitable seed data set that can be completed in subsequent steps.

Which publications belong to *German* art history?

The decision to parse literature lists from researchers affiliated to a German university with a department or institution that corresponds to the definition of art history also implies a decision of who belongs to German art history. From the definition of a national sub-community, several indicators for membership in the German art history sub-community could be derived. A first publication-based indicator to distinguish *German* art history from other countries could be the language. However, German is used as a publication language by a variety of researchers. In addition to researchers from Austria or Switzerland, other researchers also publish in German because art history as a field is multilingual. By the same token, using the publication language as an indicator would exclude the large number of publications written in languages other than German, which is not acceptable in a multilingual discipline as German art history (Gläser & Oltersdorf, 2019).

An author-based approach to delineating German art history could further consider indicators like membership in a national professional association or institutional affiliation. Membership of a particular professional association, is a fuzzy indicator in so far as membership of such an association is not coextensive with community membership. Depending on the respective society's rules, students, retired researchers who are no longer active or researchers from adjacent fields can become members. It is also unlikely that all active researchers are members of the professional association.

Considering this theoretical implications and limitations for operationalization, we decided to accept only the institutional affiliation to a research unit that self-describes as conducting research in art history as an indicator of community membership. Therefore, we included all researchers affiliated to the selected university institutes regardless of their biographical background. We used this information to build the seed data.

This selection does not consider some specifics of German art history. First, three non-university research institutions abroad (listed in Table 1), and the *Zentralinstitut für Kunstgeschichte*, a non-university research institution in Munich, are part of the German art history network but are not included in our search strategy for the seed data set.

Table 1: Non-university research institutions abroad

Institute	*Location*	*Funded by*
Kunsthistorisches Institut in Florenz	Florence (Italy)	Max-Planck-Society
German Center for Art History	Paris (France)	Max Weber Foundation
Bibliotheca Hertziana – Max Planck Institute for Art History	Rome (Italy)	Max-Planck-Society

This observation reveals two delineation problems. First, it turns out that the German art history subcommunity may extend beyond German borders. Secondly, art historians also work in organisations other than universities. As for the first problem, it is quite likely that art historians who work outside Germany are members of a German art history subcommunity. However, even for those working in foreign subsidiaries of German non-university research associations, community membership would first have to be established. After all, it is participation in a specific discourse that makes a researcher a member of the German art history subcommunity. Since there is no clear causal link between German funding for a research institute and the employed researchers' membership in a German national research subcommunity, we excluded publications of these researchers from our seed dataset.

The decision is less easy for non-university organisations in Germany because important research is contributed by art historians working in museums and art galleries (Dilly, 2008). The German *Institute for Museum Research* identified 718 art museums in 2018 (Institut für

Museumsforschung, 2019). They exhibit artefacts from art and architecture, arts and crafts, ceramics, church treasures and ecclesiastical art, film to photography. Information about art historians affiliated with museums is not publicly available. These community members can only be identified through their publications. However, most of these publications are edited volumes published by the institution, which also features as editor. Therefore, identifying the edited volumes does not help. Since publication metadata for book chapters are rarely available, author information could only be obtained from (printed) full texts. We therefore decided not to include these publications in the seed data set.

Discussion

By presenting our considerations on the task of identification and definition of a regional research community we highlighted the complex interplay between conceptualization, operationalization, and practical opportunities. The decisions made for the construction of the seed data set for our database are specific to the German context. For example, we had to respond to severe shortcomings of the German library infrastructure. Approaches that utilize library collections might be more successful in countries with a more centralized or more standardized library system. While some of our decisions may have been made differently, it is difficult to see how a seed dataset that covers most German art history publications in a specified time frame could be made.

Conclusions

The need to manually build a database of publication metadata highlights how many decisions that have consequences for research are left to commercial database providers whenever their data are used. Three points are of particular importance. First, even for fields that are well covered by the databases coverage is not complete. Bibliometrics should establish a standard for discussing coverage when it is likely to affect results, similar to the discussion of non-responses to surveys.

Secondly, our discussion of who should count as a German art historian highlights possible consequences of delineations based on author addresses. In many cases, delineation by address is the correct approach. For example, if effects of institutions are investigated, researchers working in a country are the population affected by its science policy institutions (with the interesting exception of research organisations abroad). However, if national sub-communities or discourses are to be investigated, attention should be paid to the specific consequences of different decisions on whom to include.

Thirdly, the internet offers the opportunity to link existing metadata collections rather than creating data collections from scratch. The number of tools providing this service is increasing. On the one hand, these services are important because they save resources by facilitating access to data. On the other hand, using these tools is not without danger because the data quality depends on third parties – the many providers of metadata - and is therefore more difficult to manage. In addition, curation in the sense of delineation is often fraught with problems as the selection criteria of the data providers vary substantially or are not known at all.

As a general conclusion, we would like to raise the question whether we know enough about the way in which the data in commercial databases are curated. Bibliometricians have pointed out for a long time bibliometrics' unusual situation as a research community not in control of its data. At the same time, we base our reputation as researchers on the analysis of these data. Until attempts to create community-controlled alternative data sources, we should be wary.

A Typology of Research Discovery Tools: Bibliometric Redundancy vs. Bibliometric Variety

Andreas Pacher[1]

[1] *andreas.pacher@tuwien.ac.at*

and Vienna School of International Studies, Favoritenstraße 15, A-1040 Vienna (Austria)

Abstract

Bibliometric links between scientific publications may exhibit redundancy (i.e. expectable co-occurrences between publications) or variety (i.e. unique and original reference patterns). The roots of aggregate redundant or variety-prone citation interlinkages may lie in the way how researchers find relevant publications. But how can we make sense of the potential landscape of all such research discovery tools? This paper conceptualizes a typology based on the common variable of redundancy/variety. On the redundancy-reproducing end of the spectrum are machines that draw from co-citations or keyword queries (such as academic search engines and paper recommender systems), while the variety-end harbours services that enable categorial browsing or that suggest publications randomly (such as journals' tables of contents or random paper bots on Twitter). Currently, redundancy-reproducing research discovery tools proliferate. In contrast, there is little awareness about variety-generating ones. But if the scientific system demands a balance between both redundancy and variety to bring forth innovations, then the designs and discussions of future research discovery tools should better appreciate aspects of variety.

Introduction

Imagine a scientific system in which every research finding must be cited once, and only once. Such a condition would ensure maximum *variety* of reference patterns within the system. One may also imagine the opposite, namely a structure under which only a single publication must be cited in every work, while all other research papers remain uncited. This pattern would amount to a repetitive reproduction of bibliometric *redundancy*.

Neither scenario is wished for; both push the scientific system into entropy. The first scenario (of maximum variety) does so by constantly bringing forth surprising citations without a predictable structure conducive to an accumulative knowledge growth. The second one (of maximum redundancy) engenders entropy due to a permanent repetition of the same. A well-functioning scientific system, in contrast, would combine both variety and redundancy (cf. the right illustration in Figure 1): A new publication conveys familiarity by referencing already-known works, but it simultaneously energizes the system with new information requiring new citations – e.g. through an innovative perspective, an unusual theory, an original question, or novel data.

Balance between
variety & redundancy

Figure 2. Three variants of how 100 citations may be distributed among 100 (in the center: 99) scientific publications. – Left: Variety (each paper accrues 1 citation). – Center: Redundancy (each paper is uncited, with the exception of a single publication which accrues 100 citations). – Right: Some papers are cited more than others in a seemingly random distribution.

The same observation applies to research discovery tools, i.e. to machines that draw from a set of scientific publications so as to recommend a selection of them to users. Research discovery would be inadequate if it recommended publications merely once and then never again (maximum variety), or if it always recommended the very same paper (maximum redundancy). Like scientific reference patterns, the landscape of research discovery tools should instead find a balance between variety and redundancy.

While neither the maximum-variety nor the maximum-redundancy-scheme seems realistic, the current structure of scientific publications does approximate the latter version. The standard assumption departs from a Pareto distribution whereby 80 % of all citations go to just 20 % of all research outputs (Nisonger, 2008). Thus, the modal publication remains little-cited, while a few 'highly cited' papers accrue most attention. This redundancy-prone pattern finds its reflexion in the designs and discussions of many research discovery tools. Rather than enabling variety, they reproduce bibliometric redundancy through query-based and citation-based algorithms. On a closer look, even the literature on 'serendipity', i.e. on the accidental discovery of useful publications for research purposes, falls in this vein; its paradoxical aim of transforming the 'irrelevant' and 'useless' into the 'relevant' and 'useful' leaves variety in a blind spot. However, the scientific system requires a quick tempo of internal variety to bring forth innovations; it is through non-redundant combinations of research findings that original discoveries and conceptual leaps take place (Acemoglu et al., 2016). The focus on redundancy should thus be accompanied by a clearer incorporation of bibliometric variety into the current discussions and designs of research discovery.

This paper addresses this blind spot by conceptualizing a typology of possible research discovery tools based not on the useful/useless-distinction, but on the conceptual dimensions of bibliometric redundancy/variety. In brief, it proposes a schematic typology ranging from devices that draw from co-citations and semantic queries (which are both at the 'redundancy'-spectrum) to machines that recommend publications based on certain categories and randomness (which are located at the 'variety'-end). On the one side are therefore platforms that detect bibliographic couplings, academic search engines and paper recommenders that systemically reproduce bibliometric redundancy. On the other side are category-based browsing-featured tools (e.g. institutional repositories, a set of journal table of contents, or a list of latest or trending papers) and instruments based on sheer randomness (such as random paper bots). The closer a tool reaches the variety-end of the spectrum, the more its recommendations are unbiased from publication dates, measurements of impact, research fields, or extant citational links and academic or semantic networks.

This paper elucidates the common variable behind all research discovery tools and suggests a more conscious combination of both redundancy- and variety-based platforms in order to address the scientific system's structural demand for plurality. It also departs from earlier attempts to categorize research discovery services by providing a universal variable common to all such platforms. Previous attempts, in contrast, confined themselves to a narrower focus, such as to query-based variants (e.g. whether a tool enables Boolean search terms or not; cf. Kim & Rebholz-Schuhmann, 2008), on personalized and non-personalized services (Kotkov et al., 2016), or on paradoxical distinctions such as 'useless' versus 'useful' publications (e.g. Ge et al., 2010).

The following section illuminates the theoretical concepts of informational redundancy and variety. The paper then briefly reviews the current state of research discovery tools and the literature on serendipity, finding that they all tend to reproduce scientific redundancy. To address this one-sidedness, a conceptual typology of research discovery tools based on the distinction of redundancy and variety follows that review. A final section discusses the advantages and limitations of this typology and concludes with suggestions regarding the discoveries further research on research discovery may await.

Variety and Redundancy

Every information provides a surprise: For it momentarily appears and disappears, resolves uncertainty, and renders any given context slightly different than before (Bateson, 1999; Luhmann, 1992, p. 391). However, the surprisefulness inherent to an information can vary by degrees. For instance, there is less surprise in cases of informational *redundancy*, that is, when the knowledge of one information allows inferences about other (yet unknown) information (Shannon, 1951). The revelation of the other (redundant) datum would then seem expected, predicted and superfluous. A non-redundant system, on the other hand, harbours *variety*, or a rich plurality of distinct events so that an observer's knowledge of one information does not disclose another one (Luhmann, 1992, p. 438). At their extreme, redundancy reproduces self-circularity in a permanent repetition of the same, while variety increases a system's openness towards more and more stimuli.

Applying this distinction of redundancy and variety to the issue of interest here, namely to a bibliometric 'information encountering' regarding scholarly publications (Erdelez, 1999), redundancy would be akin to co-citation patterns: With bibliometric redundancy, a given scientific reference increases the probability of the presence of another specifiable reference. For instance, say that *AAA* is often co-cited alongside *BBB* as both study similar aspects of *X*. Now, if a paper on *X* cites *AAA*, it will most likely cite *BBB*, too. Or, if a research discovery tool recommends *AAA* based on a specific user-input, it will not be a large surprise if it also recommends *BBB* based on the same user-input. Only specific works profit from this redundancy, while all others remain in an uncited and thus invisibilized spot. Another paper on *X*, namely *CCC*, may have 0 citations so far despite its topical relevance to both *AAA* and *BBB*. *AAA* and *BBB* may nevertheless accrue dozens of co-occurring citations while *CCC* is left with none. In total, there may be 100 papers on that topic of *X*, but only the most probable two of them were realized: the "maximum information content" of the system remains in a non-realized state (Leydesdorff et al., 2018, p. 1182). It is thus that bibliometric redundancy gets reproduced.

Redundancy and variety may serve as two opposing sides of a distinction, but they are not antipoles: The scientific system can increase both its redundancy and its variety simultaneously. A paper can cite both *AAA* and *BBB* on the one hand and *CCC* on the other hand. What the system requires is a mixture of both, conveying familiarity so as to enable the temperate growth of a given knowledge-field, but, at the same, rendering the familiar more interesting (Davis, 1971) by injecting a surprising novelty into it, a new perspective, a new theory, a new datum, with new scholarly references.

Note that the distinction variety/redundancy does not refer merely to the relation between two publications, but rather to an aggregate pattern that grows over time from the viewpoint of a specific topic *X* (see Table 1 for an illustration). Thus, if a new paper on the topic of *X* cites *AAA* and *BBB*, it reproduces redundancy (because these references were structurally predictable given that these two are the most cited papers on the topic *X*), but if it cites *CCC* or *DDD*, it generates variety (for these two references are relatively surprising within the topic of *X* as they are little-cited within that field). The concepts of variety and redundancy are thus not properties of publication-dyads, but rather of a whole network of multiple publications.

Neither redundancy nor variety bear an inherent value of 'good' or 'bad' (Luhmann, 1992, p. 436). Redundancy is not *per se* to be condemned, but rather exercises vital functions in communicative settings. If there was no redundancy, i.e. if every paper was cited or recommended only once, one would require greater labour in searching for a specific reference or publication, rendering an informational loss more probable. Redundancy thus saves time and serves as an insurance against research waste. Great variety, on the other hand, is not *per se* to long for, but it rather generates an unpredictable system whose capacity may not suffice to carry the immense plurality of unique information within it. As publications would quickly fall into oblivion, bibliometric variety would also risk a high amount of wasted research. Both one-sided redundancy and one-sided variety ultimately render the system entropic: Maximum redundancy would mean entropy due to an almost complete loss of any energizing surprises; maximum variety would mean entropy due to an almost complete loss of predictable structures.

Table 1. Three examples of how a citation can generate bibliometric redundancy or variety.

Cited paper	*Property before it is cited*	*When a new paper on topic X cites it, this leads to…*
Paper I	Already well-cited in the field of *X*	Redundancy (because it reproduces extant citation pattern)
Paper II	A little-cited paper	Variety (because it opens up a novel reference)
Paper III	Well-cited on the topic of *Y*, but has never been cited on the topic of *X*	Variety (because it bridges two topics in an original way)

These abstract-theoretical propositions find empirical illustrations in various scientometric studies. For example, redundant references serve as orientations for scholars to determine whether a given paper matches their fields and interests (Riviera, 2013); they enable an iterative assessment and re-assessment of studies; by allowing citation-couplings, they ensure that efforts of a study conducted at one moment in time may bear fruit over decades (van Raan, 2004); and, quantified into citation counts and similar measures, they aid in the numerical and comparative observation of career trajectories among researchers, concepts, and publication outlets (Garfield, 1972; Leydesdorff, 1998; Min et al., 2018).

The tendency to reproduce redundancy can, however, engender detrimental effects. A bibliometrically redundant system lacks the influx of new information necessary to energize scientific innovations; it instead tends to reproduce the same contents over and over. Such predictable patterns then become “not … very useful, or very interesting” (Maloney & Conrad, 2016, p. 9), reducing “exposure to less popular (and perhaps more interesting) information” (Maloney & Conrad, 2016, p. 4). What is more, outdated works may grow in citation counts while new publications are overlooked (Merton, 1968), leading to a perceived injustice against scholarly newcomers. The number of uncited or low-cited works may then be perceived as problematically reflecting wasted research efforts and public funds (van Leeuwen & Moed, 2005). And as soon as redundant citation patterns can be measured on a large scale, they are subject to ‘cheating’ behaviors on the levels of researchers, institutions and journals – with the symptomatic accidents of high self-citation rates, a culture of ‘publish or perish’, predatory journals, irreproducible research, and an inflation in publication and citation counts.

Bibliometric variety in citation patterns may serve as a remedy against these perils of systemic redundancy. Original citation patterns, for instance, offer a robust indicator for innovative research; for it is the “cross-pollination” of ideas across disciplines (Erdelez, 1999, p. 4) that pushes the evolution of knowledge further (Bornmann et al., 2019; Wang et al., 2017). Through surprising references, variety “stimulates creativity by illustrating new connections, connections that were not […] anticipated” by the structure of citational co-occurrences (Race, 2011, p. 140). It extends a given research field's capacity for processing information and thus corrects the narrowness of its former bibliometric structure (Luhmann, 1992, p. 450). In addition, it helps integrating societally marginalized researchers into the scientific system.

However, variety alone would likewise exhibit perilous effects. With variety modelled to the extreme, researchers would lose important markers for orientation within hitherto familiar research fields, which discourages a cumulative knowledge growth illustrated in the self-reproducing interconnectivity of citation patterns (Riviera, 2013). If translated into a growing number of references per publication, variety may lead to 'superficial' citations (van Wesel et al., 2014) and, ultimately, to an inflation of indicators that are supposed to measure scientific impact, resulting in the necessity for ever-more complicated algorithms to measure how influential a scientific publication was (Mingers & Leydesdorff, 2015). As such measurements deeply affect researchers', funders' and students' behaviour – such as through world university rankings (Dearden et al., 2019) – artificially skewed data due to an overgrown bibliometric variety could multiply decision errors across various sectors of life.

A balance of both redundancy and variety is thus functionally important in ensuring the autopoiesis of the scientific system. But do research discovery tools and the discussions thereof meet the systemic demand for balancing both aspects? The next section argues that there may be an overemphasis on redundancy what to the detriment of the equally vital aspect of variety.

Research Discovery and Serendipity: An Overemphasis on Redundancy

Research discovery tools require a pre-selected input to narrow down the range of recommendable publications. Such a pre-selection is necessary to avoid total randomness; for instance, a research discovery tool should not recommend a nocturnal poem from Ancient Japan to a user interested in discussions of how contemporary Western politicians co-manage global crises in the Middle East. At the minimum, the genre of recommended documents should be confined to scientific publications. A mere genre-level pre-selection, however, is still too broad to be useful. The user interested in the political dimension of Middle East conflicts in the beginning of the 21st century should, for instance, not be recommended papers on gene editing or on chemical engineering simply because they are scientific publications. The pre-selection could rather be narrowed down to a specific research domain (e.g. political science), or even narrower, to detailed keywords (e.g. 'Political Conflicts', 'Middle East', 'Sovereignty'). Whatever the degree of narrowness, the pre-selection ensures that the recommended paper does not deviate too much from the user's needs.

For a discovery tool to be useful to researchers, the input-output-scheme should not be overly trivial (von Foerster, 1960). The literature on informational relevance and serendipity stresses how algorithms should go beyond a narrow semantic distance between the user-input and the output in the form of a recommend publication (Race, 2011). However, instead of using the concepts of redundancy and variety, they depart from the distinction of irrelevant/relevant, accidental/planned or useless/useful. They principally ask how irrelevant 'accidents' can be made relevant and 'purposeful' so as to render the 'useless' 'useful' (Race & Makri, 2016), to 'expect the unexpected' (Maloney & Conrad, 2016, p. 1), or to 'search for the unsearchable' (Campos & Figueiredo, 2001, p. 159). In the end, reflections on serendipity paradoxically equal *x* to its contrasting *y* (Spencer Brown, 1969), finding that the distinct are identical to themselves as they propose the 'useless' to be undistinguishable from the 'useful' (McCay-Peet & Toms, 2015, p. 1464).

A consequence of the paradox is that while the literature on serendipity aims at producing 'novel' and 'surprising' paper recommendations, i.e. at enhancing bibliometric variety, they ultimately offer technical suggestions that remain in a redundancy-reproducing realm. Recent surveys of serendipity in research recommender systems, for instance, explicitly leave 'non-personalized' approaches in the blind environment while confining their reviews to ‘personalized algorithms’ (Kotkov et al., 2016, p. 180). These, however, are *per definitione* oriented towards a target user’s revealed preferences (cf. Abbas & Niu, 2019; Bai et al., 2019). It is the researcher’s pre-existing catalogue of scientific publications (or their semantic proxies) that serves as the departure point for all these allegedly serendipitous recommender tools. Whatever the path they take in order to reach the output of a paper recommendation, all the tools orientate themselves towards the input of their user’s past behaviour, citational links, and existing networks – even if they use algorithms harnessing machine learning (Rakhshani et al., 2020), topological structures of academic communities or heterogeneous information networks (Boussaadi et al., 2020; Ma & Wang, 2019), a re-ordered ranking of ‘similarity scores’ (Afridi et al., 2020, p. 226) or complex co-citation analyses (Sakib et al., 2020). Thus, be they content-based or utilize collaborative filtering, be they graph-oriented or use hybrid methods – all these services first necessitate a user-input and then design an algorithmically distanced, but nevertheless unescapably proximate association to that user’s research interests. If the paper recommendation is a function of the user-input, then the tools cannot avoid the output’s proximity to the user. As every output is ultimately based on existing bibliographic or semantic co-occurrences (though with some algorithmic distancing), from a systemic viewpoint, all these so-called serendipitous research discovery tools are tendentially repetitive in terms of fostering a systems-wide bibliometric redundancy – despite their pledge to enhance variety.

The distinction between the useless and the useful seems too paradoxical to be useful in itself; for whatever the algorithmic design of a retrieval system, it will always and unavoidably exhibit a bias emphasising selected weighting functions based on an input. The best tool is then not a non-biased, but merely a ‘least biased’ model (Wilkie & Azzopardi, 2014). Instead of using the elusive concepts of the serendipity-literature (McBirnie, 2008), as in useful/useless papers or accidental/intentional discovery, this paper prefers to build a conceptual approach based on the distinction of redundancy/variety to differentiate research discovery tools.

Both the dominant landscape of research discovery tools and the related literature on serendipity focus on the reproduction of *redundancy* while leaving out, or only retaining a paradoxical vision towards, *variety*. But how would variety-centered research discovery tools look like? A conceptual typology based on the dimensions of redundancy and variety may aid in clarifying how the variable common behind all research discovery services can be operationalized at both ends

A Typology

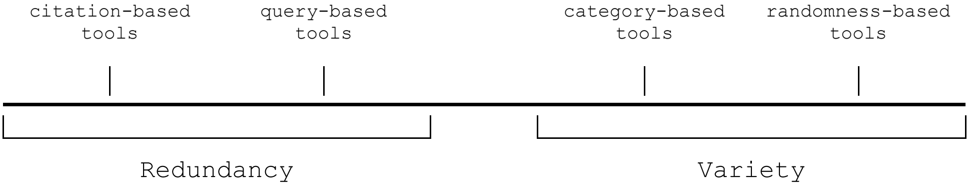

Figure 2. A typology of research discovery tools ranging from those that reproduce bibliometric redundancy (comprising citation-based and query-based tools) to those that generate bibliometric variety (comprising category-based and randomness-based tools).

The present section suggests that all research discovery tools can be located within a dimension ranging from (bibliometric) redundancy to (bibliometric) variety. At the redundancy end of the spectrum are tools that at least indirectly reproduce extant reference patterns between scientific publications. They may be citation-based (citational proximity) or query-based (semantic proximity). Other tools are located at the variety end of the spectrum. These variety-generating ones may be category-based (e.g. finding publications in a common journal or by a common researcher or in a common scientific domain) or randomness-based. Figure 2 illustrates the typology.

Redundancy-Generating Tools

First, citation-based research discovery tools are most prone to generating bibliometric redundancy for it is their very function to reproduce extant reference patterns. They indulge in "the gravity of highly cited papers" (Maloney & Conrad, 2016, p. 4). The user-input comes in form of a token for a scientific publication (or a set of multiple publications), such as by having the user insert a publication's title or DOI. The tool then looks for the citations to or from that publication; it may also detect second-order references, i.e. references to publications that cite or are cited by those publications which are citationally interlinked to the user input. Examples for citation-based tools are *CitationGecko*, *ConnectedPapers* or *CoCites*. Many query-based search engines likewise contain functions to reproduce reference patterns, such as, most prominently, *Google Scholar*'s feature to list citations to a certain publication.

A second type of research discovery tools at the redundancy-end of the spectrum are query-based ones. Many of these are search engines that require keywords to search for papers containing similar strings. *Google Scholar* is primarily built around this function. With varying functionalities (e.g. advanced search functionalities, Boolean operators, semantic web-searches), other prominent databases likewise work in this fashion: *Microsoft Academic*, *Dimensions*, *Web of Science*, *Scopus*, *Semantic Scholar, LENS* etc. mainly revolve around a search bar into which users type in their queries. Some recommender systems may likewise draw from semantic distance-formulae to narrow down their paper recommendations to users. In addition, tag-based platforms that enable users to attribute categorical labels to scientific publications in a manner of a 'collaborative filtering' operate on the same principle. Such tools (like *CiteULike*) aggregate semantic commonalities across research outputs (Heck et al., 2011). Whatever the precise approach, query-based tools are similar to citation-based platforms in that they are prone to reproduce bibliometric redundancy; semantic similarities thus serve as a proxy for extant inter-citation linkages.

User profile-based recommender systems likewise fall within this redundancy-end of the spectrum; they may either follow the logic of co-citations or of semantic proximities. Their main difference is that their user-input does not come in form of an actively inserted information of publications, but rather in the form of algorithmically generated user profiles. For instance, *Mendeley Suggest* or *ResarchGate*'s recommender system look at the papers stored by a user to recommend proximate publications. As it is their very task to generate user-near suggestions, they cannot but reproduce bibliometric redundancy.

Variety-Generating Tools

We have seen how citational proximity and semantic similarity reproduce citational redundancy across the scientific system. On the other side are tools that enhance variety. But how do these variety-generating research discovery tools operate?

First, the discovery tool may be based on the selection of certain categories. Such category-based platforms often facilitate a 'creative browsing' through publication lists (Bawden et al., 2011). There is a multitude of such instruments, but they are seldom analyzed as full-fledged research discovery tools, even though they serve the same function of conveying links to scientific publications to interested users. Even a *curriculum vitae* (CV) of an individual scholar can be subsumed under this category: It enables a profile-based discovery of research. Institutional repositories operate on the same basis; they allow for an institution-based research discovery. A more common way to explore publications uses a journal-based approach, where one browses through a specific outlet's table of contents, either in print or digitally (an experience that can be enhanced through RSS feeds or e-mail alerts). Some systems aggregate tables of contents from a greater set of journals, such as *Current Contents* and *JournalToCs*. If that set of journals is defined by a specific research domain, we have discipline-based platforms such as those narrowed down to Criminology (e.g. *Criminology Papers*) or Philosophy (e.g. *Philosophy Paperboy*) – these tools then regularly send out titles of the latest papers published in a specific research domain to their users.

Most of these category-based platforms simply look at the *latest* papers based on their publication dates. Others may incorporate additional indicators, such as whether the publications of a specific research domain published in a certain date range (e.g. past 30 days) are 'trending'. For instance, the *Observatory of International Research* (*OOIR*) not only lists the latest papers from political science and related domains, but also ranks them according to their *Altmetric Attention Scores* based on social media mentions and news attention.

Thus, discovery tools of this sort list the latest or trending papers according to a pre-selected category, whereby that chosen unit may be defined by a certain scholar, by a shared research institution, by a common journal or a set of journals, or by a research domain. The more general the categorial unit, the less redundant the research discovery tool: The knowledge of the category does not reveal knowledge of specific publications anymore, as opposed to co-citation patterns. Most importantly, the listed outputs of these category-based research discovery tools are detached from extant reference networks. Such tools do not directly reproduce bibliometric redundancy, but enhance variety instead.

However, even category-based platforms are not completely free from biases that may be conducive to an indirect redundancy. They at least implicitly demand a more or less specific category (e.g. an individual scholar, a set of journals, or a certain scientific discipline) to which the user may already have developed systemic affinity. In addition, browsing-featured tools usually list the *latest* papers – but if bibliometric patterns bear a biased citation life cycle towards newer publications to the detriment of older ones (Cano & Lind, 2005), then even these platforms reproduce this tendency and thereby serve to nourish at least a small degree of systemic redundancy. Tools that list *trending* papers are perhaps likewise stained by a structural bias whereby papers in highly-cited 'top journals' will more likely be 'trending' in social media and news platforms (cf. Ferreira Araujo, 2020). Thus, even category-based platforms may indirectly contribute to citational redundancy.

In contrast, an even more variety-enhancing research discovery platform would list new *and* old papers, trending *and* non-trending papers, discipline-specific *and* discipline-deviating papers with equal probability. Such truly variety-enhancing tools would be one based on a large sample of scientific publications and on a high degree of randomness (Maloney & Conrad, 2016, p. 4); they may not even exist yet. A fictitious example would be a huge corpus of the scientific literature in all research domains covering various centuries that would regularly (e.g. hourly) spit out a random publication of this corpus through, say, a Twitter bot. It may 'recommend' a philosophical paper on epistemology from a German journal of the 1820s, and at the next instance one medical publication from a low-ranked journal from the 2000s, then a highly-cited sociological work from the 1970s. The pattern of outputs should be unpredictable, with every new recommendation equally improbable as other ones, gushing out a truly 'blind variation' (Campbell, 1960) that would constantly nourish the evolution of science. Only such a tool would ensure a high degree of liberty from extant biases, thus serving as a research discovery platform that is veritably variety-enhancing for the whole system of science. And it would then be up to the system's evolution – or, as earlier centuries would say, up to individual geniuses and their sagacity – to fetch these random surprises and to de-randomize them by transforming them into scientific knowledge (Luhmann, 1992, pp. 466–467).

Discussion

This paper proposed a conceptual typology of all possible research discovery tools based on the dimensions of bibliometric redundancy (the reproduction of extant citational links between scientific publications) and variety (the generation of novel ties between research outputs). The exemplary tools harboured by this typology comprise a highly heterogeneous landscape, including a journal's table of contents, a researcher's CV, scholarly databases, academic search engines, institutional repositories, or Twitter bots that regularly recommend random scientific works to its users.

This typology demands universality, in that it makes visible a common variable to be imputed behind *all* research discovery tools. It thus departs from previous attempts to categorize scientific discovery services in a narrower manner, e.g. by typifying merely query-based approaches (e.g. whether they allow 'boolean queries' or not; cf. Kim & Rebholz-Schuhmann, 2008, p. 454). Furthermore, this paper indicates how the extant and oft-used research discovery tools are designed such that they suppress the element of systemic surprise. The discussions and designs of research discovery instead tend to reproduce citational redundancy. The ideal and extreme type of a variety-enhancing tool does not even seem to exist yet: There is not yet the fictitious bot that spits out random scientific publications from a huge corpus from centuries of publications of which each work has an equal probability to be listed, regardless of the publication's age, discipline, authors, citational impact, or publication outlet. This absence may be telling of how much meta-scientific reflections and implementations have so far focused on redundancy while leaving the issue of variety in a blind spot.

In effect, if researchers only used *Google Scholar* and *Mendeley Suggest* to discover relevant publications, they would mainly reproduce bibliometric redundancy; this "too precise" discovery "can end up reinforcing habits rather than exposing students and researchers to new information, sharply limiting the researcher's view of the world" of scientific papers (Maloney & Conrad, 2016, p. 9). They would only discover publications whose contents do not deviate too much from a semantic or co-citational closeness to the pre-specified user-input (e.g. a typed-in query of keywords, or a list of publications one has already read). To use the example from above, if the users have already read or are interested in the topic of *AAA*, then they would be recommended *BBB* because of their dense co-occurrences – that is perfectly well-expected, but not innovative. Finding only papers of topical proximity, such tools would minimize the element of surprise and thereby inhibit innovative cross-pollinations from distant fields. The scientific system would only contain a slow tempo of variety, with only rare energization through new information and original reference patterns.

Systemic bibliometric citation patterns begin with the way researchers find publications to skim, read, interpret, evaluate and cite (cf. Crestani et al., 1998). The algorithms of research discovery tools and information retrieval systems thus trickle down to aggregated reference patterns within the scientific system. Their design may thereby generate greater or lesser system-wide entropy. It is for this reason that more awareness of the shared variable on the basis of which a landscape of various such tools can be mapped, and greater efforts at balancing the opposing sides of the dimensions at the level of research discovery would be wished for. Variety-enhancing tools can be utilized even with a "vague, fuzzy, or even unspoken information need, when users do not quite know what they're looking for" (Maloney & Conrad, 2016, p. 2). Without this appreciation, researchers will "discount serendipity because it is not viewed as a formal search strategy" (Race, 2011, p. 140). Extant platforms (for instance, *Altmetric*) could be harnessed more consciously for variety-enhancing purposes (Holbrook, 2019, p. 6); this typology just serves as a first step in conceptually illuminating such potentials.

The distinction of redundancy/variety also shows that there is no obvious "paradox of control" (McBirnie, 2008, p. 611) behind serendipity; it is not inherently rare and does not need "both luck and skill" and is not "both unpredictable and yet can be cultivated" (Copeland, 2019, p.

2386). It is, instead, an empirically observable, systemic distribution of references to scientific publications that have some of its roots in the machines that recommend them to researchers.

Despite all practical implications from this paper, there is, of course, "no single web service that satisfies all demands" (Kim & Rebholz-Schuhmann, 2008, p. 452). Science needs both redundancy (for orientating oneself through familiar structures) and variety (for generating novel and innovative knowledge). Indeed, research discovery platforms often do contain multiple services built within them, some of them redundancy-reproducing, others of them variety-enhancing: A journal's website may show both the latest papers (variety-enhancing) and its most-cited ones (redundancy-enhancing). To make it more complicated, and to repeat a statement from above, redundancy and variety are not contrasts; both can be heightened at the same time. *Google Metrics* (which is built within *Google Scholar*) may serve as an example: It enables a category-based browsing tool (i.e. variety-enhancing function) whereby each publication list is ordered by a journal-level h-index, and thus by citational impact (i.e. redundancy-enhancing function).

Innovation does not always originate from specific approaches to research discovery, but also through external triggers. Any cue in life can offer potential ideas – be it a look outside the window, be it a Twitter acquaintance, be it a lab meeting over a coffee. However, as they all remain outside a conceptualization of science as an autopoietic system that reproduces itself through instances of verity-claiming publications (Luhmann, 1992), they are environmental 'irritations' that do not reflect the aggregate structure of research links *within* the system itself, but only the venues through which the science takes inspiration from *outside*. Otherwise the whole world could be deemed a 'research discovery tool', which might be too much of a semantic overstretch.

How to proceed further in the research of research discovery tools? For scientific explorations of research discovery tools, one may generate a clearer empirical mapping of extant discovery services based on the dimensions proposed here. One may also devise experiments of exposing researchers only to specific research discovery tools for a limited period of time, and see how it affects their citation patterns. As regards technical implementations, one may generate a truly variety-enhancing tool as that fictitious random paper bot outlined above, and see how it affects its users' serendipitous experiences and their drive for innovation. Whatever the next directions for scientific research and technical implementations of research discovery tools – there is much variety to discover.

Abstract

Cancer is now one of the leading components of the global burden of disease. Causes of cancer that are amenable to intervention are multiple: tobacco control closely followed by obesity treatment, including promotion of a healthy diet and physical exercise, remain the global priorities. We interrogated the Web of Science (WoS) from 2001 to 2020 to determine the numbers of papers describing research into 14 different possible risk factors causing cancer. These ranged in relative importance from tobacco to the consumption of excessively hot drinks (linked to oesophageal cancer), pollution (linked to lung cancer particularly) and also non-interventional genetic risks; how they had varied in time, and between different continental regions. Because many of these factors are subject to human behavioural choices, we also investigated how such research was being presented to the European public through newspaper reportage. About half of the factors that influence cancer incidence can be attributed to particular causes. They are led by tobacco use, but this is slowly declining in most high-income settings. Research outputs on some of these different factors in the continental regions correlated positively with their influence on the cancer burden. However, the selection of European newspaper stories was biased towards those risk factors that could be considered as being under the control of their readers. The multifactorial causes of cancers vary by country, but within-country differences are also observed in the research output. Reports of research in the mass media may have a role in the control of cancer.

Introduction

As public health improves worldwide, life expectancy increases, and there is demographic ageing. This means that cancer, and other non-communicable diseases (NCDs), have become ever larger contributors to the global disease burden, see Figure 1.

As with other NCDs, prevention is cheaper and more effective than cure, so there is an increasing effort world-wide to understand context-specific causes of cancer and to intervene (Ginsberg *et al.*, 2009; Zimmermann *et al.*, 2017; Hurry *et al.,* 2020). Many of these cancer risk factors are in theory under our control, such as our behaviour, our diet, and some aspects of our environment, but others are not, such as our genetics. In this study, we sought to determine which of these causative factors were being researched, and by which countries. We also sought to compare the global research agenda with the distribution of the different factors, see Table 1, and with how such research is being presented to the European public through the mass media. This is because a large part of the causal risks of cancer is contributed by activities that we choose to undertake such as whether we smoke, what and how much we eat, and where we live and work.

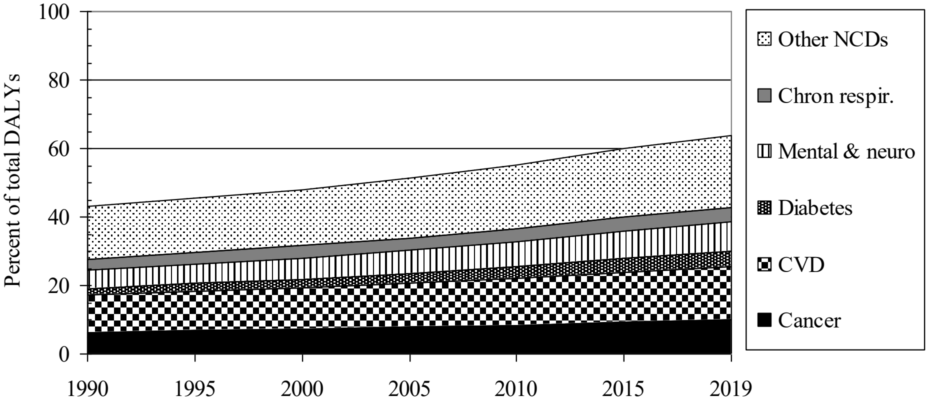

Figure 1. Contributors of different non-communicable diseases (NCDs; World Health Organization group 2) to the total global disease burden, measured in Disability-Adjusted Life Years (DALYs), 1995-2019. ***CVD = cardiovascular diseases. Data from the Institute for Health Metrics and Evaluation (IHME), University of Washington, Seattle.***

Table 1. Main causes of cancer risk, 1990-2019. Data from the Institute for Health Metrics and Evaluation (IHME), University of Washington, Seattle.

Cause		*1990*	*2000*	*2010*	*2019*	*Trend*
All		39.8	40.6	41.5	41.8	+
Behavioural		35.2	35.5	35.4	34.9	
of which:	Tobacco	24.5	24.5	24.3	23.6	–
	Dietary	5.69	5.63	5.67	5.55	
	Alcohol	4.83	4.98	5.07	5.17	+
	Sex, low act., drugs	4.75	4.78	4.70	4.68	
	High BMI	2.72	3.28	3.86	4.45	+
Air pollution		3.49	3.49	3.71	3.56	
Occupational		2.75	2.68	2.85	2.77	

Some of these causative factors are also constrained by government regulation. This is seen most obviously in the way that the tobacco industry has been circumscribed over recent decades, with restrictions on where people may smoke, the price of cigarettes, and controls on packaging (Flor *et al.*, 2021). One consequence is that smoking has, almost uniquely, decreased as a cause of cancer over the last three decades in many (but not all) settings, when others have increased, notably high Body Mass Index (BMI), that is obesity, and low physical activity.

Although there is an abundance of research on the epidemiology of cancer, there are remarkably few bibliometrics papers that have examined the outputs quantitatively, as opposed to systematic reviews and meta-analyses. The only one that we could find in relation to the topic was published 14 years ago (Ugolini *et al.*, 2007), and was reviewed later that year (Boffetta, 2007). There the matter rested until November of last year (Lin *et al*, 2020) when a team from Xiamen University examined Chinese publications, but only ones in the Surveillance, Epidemiology, and End Results (SEER) database, so their coverage was inevitably very incomplete.

In this study, we examined the world output of papers on cancer research that involved epidemiology as applied to cancer risk factors, and classified them by 14 subject areas, some of them corresponding to the modifiable cancer risk factors listed in Table 1. Most of the papers concerned an increase in the risks, but some described means of lowering it, such as taking more exercise or eating a good diet (*e.g.,* one rich in fruit and vegetables). These papers were classified by year, and by the continents of their authors.

We also analysed the research papers behind stories in 31 European newspapers reporting the epidemiology of cancer risk factors. These were all classified by inspection of the reported story. We classified the stories by the countries of the citing newspapers rather than those of their researchers.

Methodology

The papers about the risks of cancer were taken from the Web of Science (WoS, © Clarivate Analytics) from the 20 years, 2001-20. They were limited to articles and reviews, but with no language restriction. First, we selected all papers on cancer research by means of a complex filter based on 323 title words and 185 specialist cancer journals, which had been developed for other projects (see Begum *et al.*, 2018). It had a precision, p, of 0.95 and a recall, r, of 0.98, so it over-estimated the numbers of cancer papers by 3%. We then applied an epidemiology filter, consisting of 25 title words, such as:

*associat**, *cohort-study, determinant, exposure, incidence, predict**, *risk*

and a set of 35 epidemiology journals. They were selected from the list of all the journals used for cancer research where the papers had the selected title words, and whose names contained the strings *EPIDEM* or *PREVENTION* or *RISK*. This second filter was calibrated with reference to the outputs of researchers in epidemiology departments (Lewison, 1999), and had a precision of 0.78 and a recall of 0.89, so it over-estimated the numbers of epidemiology papers by 12%. The application of this second filter identified a true total of 126,594 papers, or 6.4% of the total in cancer research. The actual number of epidemiology papers identified in the WoS was 144,597, and these formed the database and were the ones whose characteristics were determined.

In order to select the main causes, we used the "compare" tab tool on the IHME website to identify the ones that were responsible for many cancer DALYs (Disability-Adjusted Life Years) or could be clearly defined by means of title words in their papers. [The settings were as follows: Display = Risk; Location = Global; Year = 2010; Age = All ages; Sex = Both; Level = 2.] We then inspected a large number of the cancer epidemiology papers and made a provisional list of the distinctive title words of the papers that could be used to identify those on each selected cause. This process was iterative, as the lists of title words were inevitably initially incomplete and was repeated until we created a comprehensive list of the title words to be used, some of which are reported in Table 4, below. We proceeded to download the long list of journals that had been used to publish the epidemiology papers. Journals whose names indicated that they were in one of the 14 selected subject areas (see Table 2) were then listed and used to select a second set of papers. We examined those papers that were so identified, but which were *not* identified by the provisional list of title words. This suggested both title words that could be added to the provisional list, and also that some of these specialist journals were not appropriate because many of the papers that they generated were not relevant. [They were often about the increased risks of *other* diseases because the patients already had cancer. However, we retained papers where the risk of cancer was increased because the patients were suffering from other diseases.]

Table 2. List of the 14 causes used for classification of the cancer epidemiology papers.

Code	*Subject area*	*Code*	*Subject area*
ALCO	Alcohol use	INFE	Infections
DENT	Dental health and	LIFE	Lifestyle choices
DIET	Food and drink consumed	OBES	Obesity and its *sequelae*
DRUG	Medication use	POLL	Pollution, and occupation
ECON	Socio-economic factors	RADI	Radiation, incl, medical use
GENE	Genetics	TOBA	Tobacco, incl. passive
HEAT	Hot drinks	UVRA	Ultraviolet radiation, tanning

The list of title words was then finalised for each subject area, complemented by the specialist journals, and applied to the epidemiology file in order to generate sets of papers, both in the world and in eight continental regions, see Table 3. [The geographical analysis presented here was by continent rather than by individual country in order to reduce the amount of data and make the results more easily understandable.]

Table 3. List of eight continental regions with their definitions

Region	*Short form*	*Definition*
Africa		
Asia		Including Taiwan and Turkey but excluding China
China		
Eastern Europe	E Eur	Including Russia and Ukraine
Latin America and the Caribbean	LatAmC	Including Mexico
North America	N Amer	Bermuda, Canada, USA, but excluding Mexico
Oceania		Australia, New Zealand and Pacific Islands
Western Europe	W Eur	The 15 European Union Member States in 2000, plus Iceland Norway, Switzerland and small nations

Table 4 lists the title words for five of the selected subject areas. They were designed to be used with the WoS software, and the hyphen indicates that the words must be next to each other in the titles. The WoS automatically includes plurals as well as singular forms, *e.g.*, *vitamins* as well as *vitamin* but wild cards (*) are needed to cover different forms such as *infected, infection, infects*. Some papers would have been classed in more than one of the 14 causes, and others not in any of them.

A description of the methodology used to record and analyse the newspaper stories about cancer research was given earlier (Pallari & Lewison, 2019). The study period was shorter, from 2002 to 2013, and stories were collected from selected newspapers in 20 European Union Member States (MS), 13 in "Western" Europe (the MS as of 1995, less Greece and Luxembourg), and seven in "Eastern" Europe who joined in the 21st century. Most of these stories were from the UK, Belgium, and Ireland, so they were not representative of the totality of European newspapers. The spreadsheet of stories contained their details, and also the bibliographic data of the research papers that they cited, taken from the WoS. These data were used to identify the cancer epidemiology papers, which were relatively numerous (991 out of a total of 3873 cited by the cancer research stories, or 26%). Their titles were individually inspected and the papers were marked with the tetragraph codes listed in Table 2.

Table 4. List of five of the 14 subject areas (causes) chosen for analysis of the cancer epidemiology papers, with the title words used to identify them.

Diet	*Genetics*	*Infection*	*Lifestyle*	*Obesity*
carbohydrate	allele	AIDS	exercise	bariatric surgery
consume	BRCA	e-coli	fitness	BMI
consumption	chromosom*	Escherichia	interval-training	body-fat*

	triple-negative		walking	
	variant		weight-training	

Results

Figure 1 shows the world outputs of cancer research papers from 2001 to 2020 (left scale), and the percentage that is represented by epidemiology (right scale). The former has increased by a factor of nearly four. This is partly real, but is also caused by the greatly increased journal coverage of cancer research in the WoS, from 2468 in 2001 to 6653 in 2020. Epidemiology as a percentage of cancer research increased slowly from 7.4% to 8.9% in 2014, and then dropped in 2015 as a result of the addition to the WoS of the Emerging Sciences Citation Index, and then continued to decrease to 6.9% in 2020. Of the countries with at least 1000 cancer research papers, the five Scandinavian ones (Iceland (29%), Finland (17%), Denmark and Norway (16%) and Sweden (15%)) published relatively the most on epidemiology. Those relatively the least active were Egypt (5.8%) and Switzerland and Turkey (6.2%).

Figure 2 shows the numbers of papers in each of the 14 subject areas, plotted on a logarithmic scale. There is a difference of almost three orders of magnitude between the largest (genetics) and the smallest (hot drinks). The latter seems to be locally or regionally important (mainly for oesophageal cancer) but does not feature among the main causes in Table 1. Table 5 shows the percentages of epidemiology papers in each of the 14 subject areas for the eight continental regions.

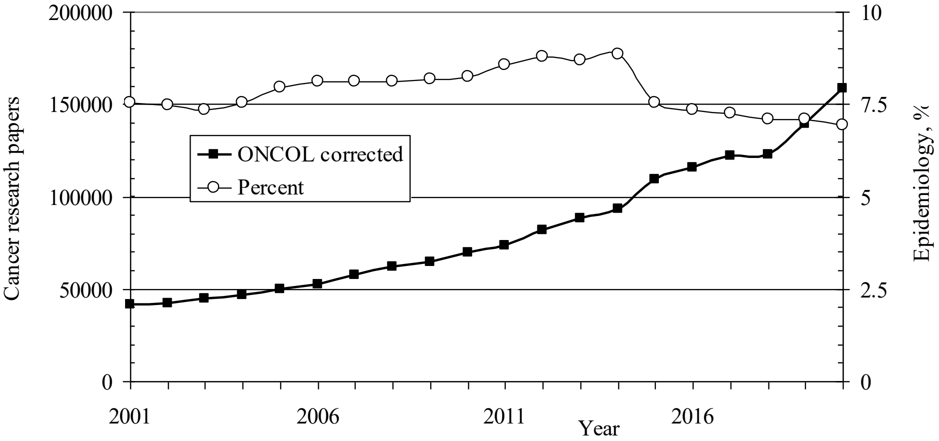

Figure 2. Outputs of cancer research papers (ONCOL, left axis) and percentage of epidemiology papers (right axis) in 2001-20.

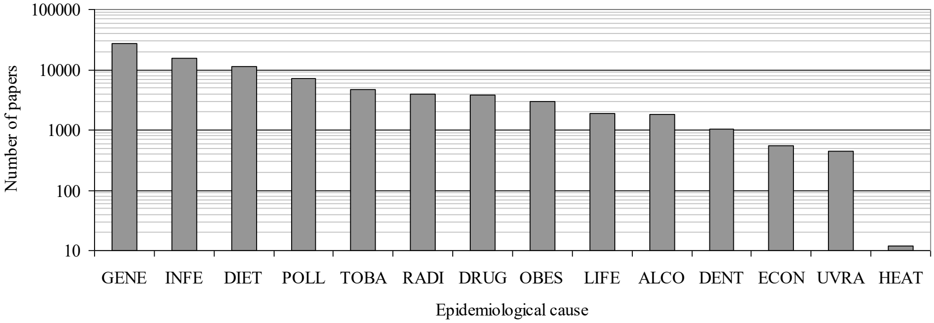

Figure 3. Outputs of cancer epidemiology papers on 14 causes, 2001-20; ***For tetragraphs, see Table 2***

The analysis of the 991 newspaper stories that we processed is shown in Figure 4, with solid columns for the seven Eastern European countries, and diagonal striped columns for the 13 Western European countries. Their output was dominated by three countries: the UK (285 stories), Belgium (118) and Ireland (111).

Comparison with Figure 3 shows that the newspapers concentrated much more on diet, lifestyle, pharmaceutical drugs, and tobacco than the researchers did. This is not surprising because these are subjects in which the readers can make choices. There are stories about genetics, which may be thought to generate the residual risks of cancer not specified in Table 1, but even in Western Europe they only account for just over 8% of the total, less than the 17% of research (Table 5). In Eastern Europe the disparity is greater: between 5.3% of newspaper stories and 28% of research outputs. Figure 5 shows a direct comparison of the results for both Eastern and Western Europe's news stories, and their research outputs.

Table 5. Percentages of all cancer epidemiology papers in eight continental regions that are in the 14 listed subject areas (see Table 2 for codes). Highest values in bold, second highest values are underscored.

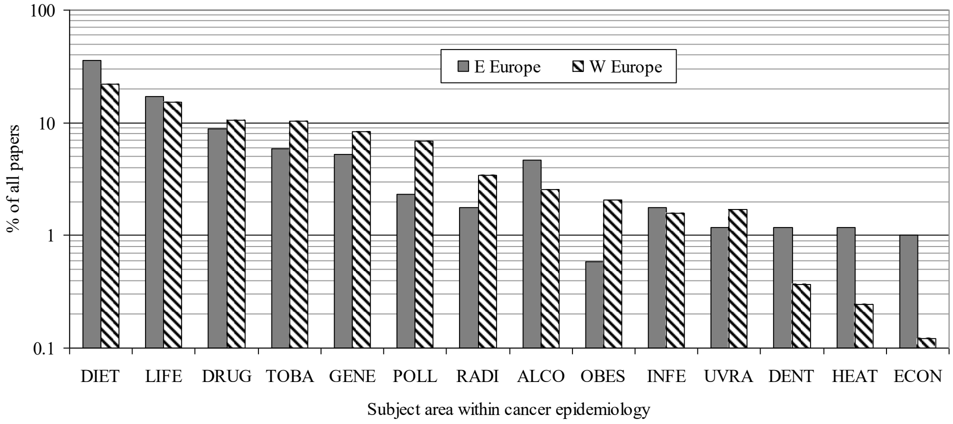

Figure 4. Chart of the percentage contributions to cancer epidemiology of 14 subject groups of European newspaper stories, 2002-13, integer counts. ***For tetragraphs, see Table 2.***

The IHME data on the causes of cancer in different continents are available, and some results for 2010 are shown in Table 6 (GBD Compare | IHME Viz Hub (healthdata.org)). These data show that there are some big differences between continents on which causes are the most important with regard to the development (or the reduction) of cancer.

Table 6. Percentage contributions to the causes of cancer for eight world regions in 2010, according to the IHME. ***Tetragraph codes are in Table 2. Regions are specified in Table 3.***

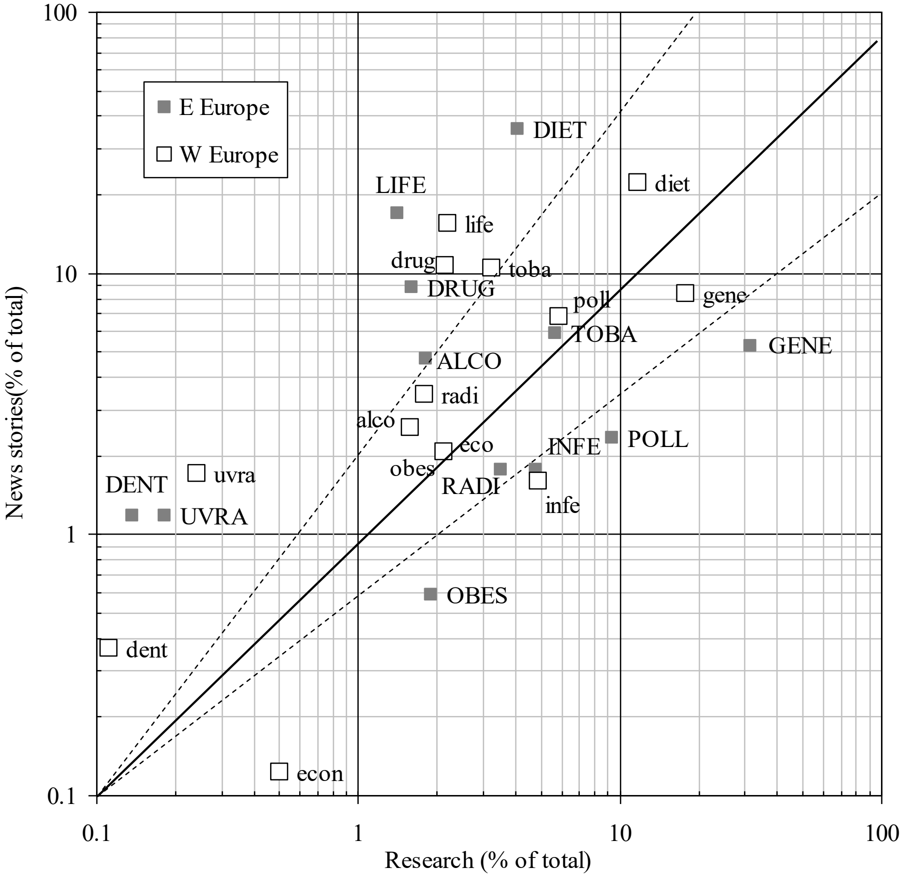

Figure 5. Comparison of newspaper coverage of the different subject areas of cancer epidemiology for Eastern Europe (solid squares, upper case labels) and for Western Europe (open squares, lower case labels), 2002-13, with their research outputs, 2001-20. Log-log scales. Solid diagonal line: equivalent percentages; dashed lines: news coverage five times or one fifth percentages of research. ***For tetragraph codes, see Table 2.***

The individual causes (from tobacco use to occupational causes = OCCU) add to more than the total, probably because of double counting with some causes combining to increase the risk of cancer. Tobacco as a cause of cancer varies greatly, from 31% in North America to only 10% in Africa. Alcohol has the biggest effects in Oceania and Europe, but much less in Africa, many of whose countries are Muslim-majority where alcohol is not freely available. However, Africa suffers more from lifestyle choices, principally unsafe sex. Obesity has the largest effect in North America, and the least in Asia (but not in China). China suffers mainly from its diet, and from pollution. So, these data tend to confirm some subjective views of the world.

It is possible to make a comparison of these causes in the eight continental regions with research data (taken from Table 4) for four of the subject areas listed in Table 1, tobacco, alcohol, diet and obesity. This is intended to show whether the researchers are focusing their attention on the areas deemed to be of importance to the control of cancer in the eight continents. The correlation is positive for all four; it is highest for obesity and lowest for diet, probably because dietary data are not so readily available as data for the other three.

Discussion

In this work, we report (what we think is for the first time) a comparison between the causes of cancer, the amount of research on each of the main risk factors, and the extent of their news coverage in Europe. News coverage is important because several of the causes of cancer are to some extent under readers' control, and therefore may be influenced by the stories that they read. It was clear from these data that the journalists had selected cancer research stories, not as an unbiased sample but rather ones that they thought would interest their readers. Thus, of the 74 stories about genetics, the largest number (27, or 36%) were about breast cancer, which is always a popular subject (Lewison *et al.*, 2008).

The 14 cancer risk factors are somewhat different from each other. Genetics (GENE) is the dominant subject area in most of them, but infection (INFE) is top in both Africa and Latin America because of the papilloma virus and its effect on cervical cancer, which is less well screened and treated there compared with Western Europe and North America (Vaccarella *et al.*, 2017). Pollution (POLL) is evidently a subject for a lot of research in Eastern Europe, as is smoking (TOBA). There is relatively little research on this in China; this may reflect the policy of the Chinese government, which derives very substantial tax revenues from cigarettes (Li & Lewison, 2020). The interest of the countries of Eastern Europe in radiation (RADI) is probably attributable to the long-term health effects from the Chernobyl nuclear accident in April 1986 (Ivanov *et al.*, 2012. Rivkind *et al.,* 2020). It is also notable that obesity (OBES) is of particular interest in Oceania (mainly Australia) and the rich countries of North America and Western Europe. Australia is also the most concerned with research on ultraviolet radiation (UVRA) because of its high incidence of solar-induced skin cancer (McLoone *et al.*, 2014; McMeniman *et al.*, 2020). We added the subject areas of dental issues and hot drinks because of the belief that dental health has wider effects on bodily health and the risk of various manifestations of cancer (Chen *et al.*, 2020; Kawasaki *et al.*, 2020; Wu *et al.*, 2021), and the problems, particularly in China, with oesophageal cancer which can result from the drinking of very hot tea (Yu *et al.*, 2018; Yu et al., Li & Lewison, 2020).

The impact of such modifiable risk factors and the disease burden of cancer, however, may not be entirely understood at the population level until there is a clear communication and awareness strategy from the government. Such a distinction between policy and action was made in a recent study that showed that government strategic plans focused on the treatment of diabetes rather than its prevention in Cyprus, Iceland, Luxembourg, Malta and Montenegro (Cuschieri *et al.* 2021). Furthermore, the importance of translating burden of disease studies for use in policy-making was recently raised with efforts concentrated in producing a knowledge translation framework (Pallari *et al*, 2020). To support these efforts the European

COST Action burden of disease network was set up. It is intended to integrate technical initiatives in the development and use of these metrics into findings relevant to stakeholders. It will also strengthen the capacity for cross-country collaboration, as reported by Devleesschauwer (2020). To this end, and to effect such a change in health communication and policy-making, data visualisation tools may enhance the engagement of decision-makers and relevant stakeholders, as a disconnect between research and public health has been reported (Lundkvist *et al.,* 2021).

Strengths and limitations

The study involved the analysis of voluminous research outputs at the global level, the comparative assessment using burden of disease data from IHME and examination of news-media reports. We were fortunate to have developed such a database of newspaper stories from so many different countries, albeit confined to Europe. Additionally, we have drawn comparisons between the countries concerned from the research outputs and newspapers with data on the causes of cancers as part of an effort in linking these data and identifying gaps in public health communication and informing policy-makers on how to reduce the burden caused by cancer in these countries.

The study has several limitations. Because of time, the file of 144,597 cancer epidemiology papers was a "virtual" one, and the analysis was based only on the WoS software. The details of the papers were not actually downloaded to file, which would have allowed us to examine the fractional counts of countries, which provide a fairer assessment of their individual contributions to the research. It would also have allowed us to link the various causes, *e.g.*, diet, alcohol use, to the different manifestations of cancer that are particularly affected, which might help researchers to focus their work better. We have done this only for two examples, but there must be many others besides the link between smoking and lung cancer, which is one of the best-established. The allocation of papers to causes that we performed has similarities with the topic modelling process in which documents are classified in multiple subject areas based on text mining using natural language processing techniques, although in this paper we manually examined samples of the papers and used our judgement to classify them through a complex iterative process.

Implications for further research

There is some evidence that cancer researchers in different continental regions are studying the subjects that are the most important for their influence on the risks. This is only an association, and it would be necessary to carry out a survey of some of the leading researchers to establish whether they are aware of the relative importance of the different causes, and whether this knowledge had influenced their choice of research topics. It would also be useful to ask funders of such research whether they try to support the research that was most likely to reduce the cancer burden in their countries, or whether their allocation of funds was based only on their perceptions of the potential quality of the work. Additionally, mapping out the factors based on a country analysis may provide useful results that are of value to local policy-makers.

Conclusions

Epidemiological research into the causes and prevention of cancer only represents a small percentage of the total, despite this being more cost-effective than treatment once the disease is established in a patient. However, it appears to be targeted at the most important causes in different continents. Although the prevention of cancer depends heavily on governmental public health campaigns (notably to control smoking), the lifestyle choices of members of the public also make a difference. These can be influenced by information about new research findings that are reported in the news-media. Within Europe, it seems that these are chosen to reflect the topics that are likely to have the most interest for their readers, which is helpful.

Acknowledgment

We are grateful to the many research assistants and volunteers who worked to analyse the European newspaper stories at King's College London. This project was led and managed by EP, now at University College London, and was supported by the European Commission's Seventh Framework Programme (grant no. EC/FP7/602536).

Abstract

Drug repurposing may be a pivotal means of fulfilling urgent needs for treatment of the novel coronavirus disease 2019 (COVID-19), but current studies on drug repurposing for COVID-19 seem to show a lack of consensus in their drug candidate focus. Using bibliometric methods in a non-expert perspective, in a review of 34 published articles on the COVID-19 and drug-repurposing, we investigated obvious and less obvious points of consensus on drug candidates. To establish these two types of consensus, we first implemented document clustering. Within a set of five clustered papers, we established an obvious consensus, relying solely on the occurrence of entities by using term frequency and inverse document frequency and a comparison of mentioned drugs, finding that remdesivir and chloroquine were discussed with a certain degree of agreement. For the less obvious consensus, we created a drug entity co-occurrence network to establish low-high centrality combinations to probe the crucial drugs found in article clustering that are not plainly apparent through the mere counting of the occurrence of drug entities occurrences. Lopinavir emerged as having possibly potent effects in spite of underuse, while the mainstream of studies focus more on drugs such as chloroquine that enjoy explicit consent. Using an entitymetrics perspective, we expect that our research will support investigations of drug repurposing, expediting the process of establishing treatment for COVID-19.

Introduction

In the context of the current novel coronavirus disease 2019 (COVID-19) pandemic and the pressing need for adequate treatment of it, it can be instructive to revisit the history of treatment discoveries during past pandemics. Ebola virus disease (EVD) is a complex infectious disease with a much higher mortality rate than COVID-19, killing an overall average of 50% and up to 90% of those infected (World Health Organization 2020). The first outbreak of EVD was in Sudan and

Congo in 1976, in a village near the Ebola River, and dozens of intermittent outbreaks followed throughout sub-Saharan Africa over the last 40 years. Between 2017 and 2018, the severe outbreaks of the disease in Congo led World Health Organization to declare EVD a world health emergency (Feldmann and Geisbert 2011). The first EVD vaccine, Ervebo, was only approved in the United States in December 2019 (FDA 2019), more than 40 years after the first outbreak, and still no antiviral drug has been approved by the FDA to treat it. More than 140 drugs have been repurposed for EVD, and there are reports of in vitro potency and in vivo effectiveness in animal models and clinical trials with EVD patients (Bai and Hsu 2019). Remdesivir, originally developed for treating hepatitis C, has been tested on EVD, but it failed in a recent clinical trial (Mulangu et al. 2019). However, remdesivir has been proven to effectively shorten recovery times for COVID-19 patients (Beigel et al. 2020). Recently, the FDA authorized the emergency use of remdesivir to treat severe COVID-19 (Dolin and Hirsch 2020). Unlike in earlier pandemics, an unprecedented worldwide scientific workforce has been brought together from universities, research labs, pharmaceutical companies, and organizations, exhibiting a laser focus on finding novel treatment for COVID-19 through drugs or vaccines.

Drug repurposing seeks new uses of existing drugs and is known to effectively shorten treatment development times (Pushpakom et al. 2019). Due to the urgent need to find a cure, drug repurposing has become a mainstream goal for COVID-19 research. It is thus crucial for us to understand the current status of research in this area as relates to COVID-19 and in particular to establish whether scientists have reached any consensus on a list of candidate drugs with potential for COVID-19.

iWe retrieved 34 papers on COVID-19 literature from Kaggle, which is the world's largest data science community, with the criterion that each used scientific method to propose a list of drug-repurposing candidates for COVID-19. By analyzing the resulting list of recommended candidate drugs for COVID-19 using bibliometric methods, we demonstrated a lack of consensus among drug repurposing literatures. Specifically, we observed two types of consensus: obvious and indistinct consensus.

Our research constitutes an early and objective investigation of scientific consensus without direct input from active researchers, relying solely on methods of data science for ease and speed of research. In short, this study outlined the key scientific outputs of drug repurposing for COVID-19 through the use of entitymetrics (Ding et al. 2013) that studies how drug and disease entities affect knowledge transfer and impact different fields or subjects.

Related Work

Drug Repurposing

Drug repositioning, also called drug repurposing or drug reprofiling, is a common term in the drug discovery context where new therapeutic opportunities for existing drugs are sought (Doan et al. 2011). This method is attracting more attention at present due to the advent of COVID-19, but it has been in widespread use since the beginning of the twenty-first century. In 2006, a study of drug repositioning was conducted that used a computational approach (Li et al. 2006), and 3 years later, in silico compound profiling was used to broaden the knowledge map of drug repurposing (Dubus et al. 2009). After the onset of the global pandemic in 2020, the drug-repositioning literature grew rapidly. The main reason for this is that since SARS-CoV-2, which causes COVID-19, is a type of a coronavirus, researchers expected that drug repurposing was a plausible method for finding treatment (Altay et al. 2020).

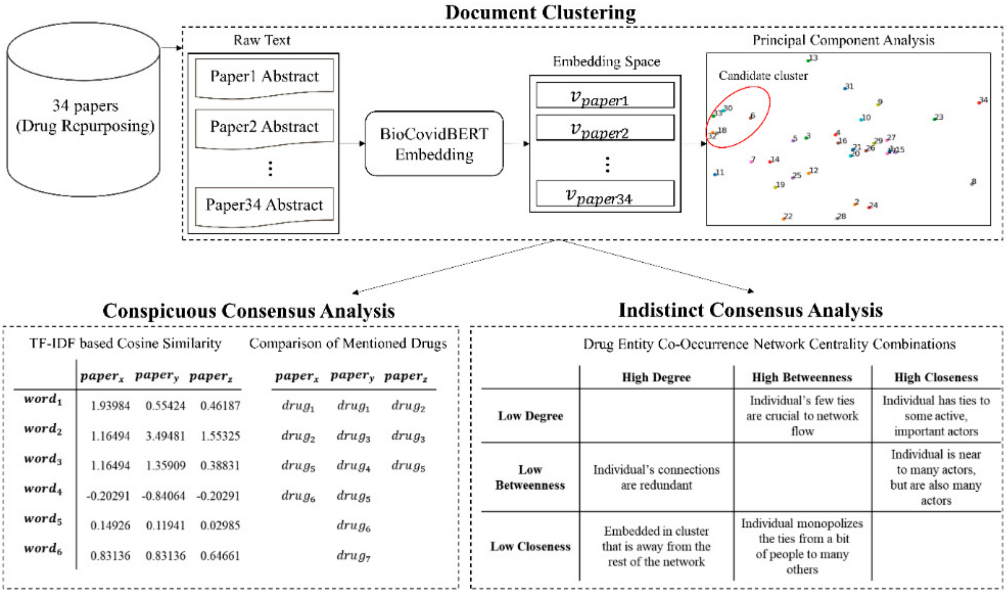
Consensus Check

There has been little treatment of the scientific consensus on COVID-19 treatment or any other subject because pursuing such research is time consuming and requires a certain level of domain knowledge. The most best-known research on scientific consensus, that of Cook et al. (2013), investigated the consensus on anthropogenic global warming . Its goal was to identify the evolution of this consensus, and it indicated that an increasing number of publications accepted the consensus. As a part of the citizen science project, volunteers with domain knowledge manually rated each publication's level of endorsement, adopting a criterion set by the authors. Nearly 25,000 abstracts were rated in this experiment. However, because all of the ratings were assigned manually, the work was time consuming, and the different volunteers had different backgrounds and perspectives, which likely affected their ratings. This lack could lead to doubt regarding the results and may damage the reliability of the conclusions. Therefore, we suggest a streamlined method of observing consensus without resorting to potentially biased opinions from experts.

Proposed Approach

We selected papers from PubMed that proposed a drug candidate for repurposing using the following search query:

drug candidate or repurpos* or reposition* or re-purpos* or re-position**



TF-IDF based Cosine Similarity

	$paper_x$	$paper_y$	$paper_z$
$word_1$	1.93984	0.55424	0.46187

Drug Entity Co-Occurrence Network Centrality Combinations

	High Degree	High Betweenness	High Closeness
Low Degree		Individual's few ties are crucial to network flow	Individual has ties to some active, important actors
Low Betweenness	Individual's connections are redundant		Individual is near to many actors, but are also many actors
Low Closeness	Embedded in cluster that is away from the rest of the network	Individual monopolizes the ties from a bit of people to many others	

Figure 1. Overview of the adopted approach

56 publications were found, among which we removed those that did not propose any repurposed drugs in their results parts. As a result, 34 papers were left. Our study had two main steps: document clustering and consensus analysis. Document clustering is the process of finding the set

of candidate publications for review. Using the candidate documents established in the first stage, we conducted two analytical stages to check the consensus exhibited among them. Conspicuous consensus analysis involves methods that rely solely on term frequency and inverse document frequency (TF-IDF) and a comparison of the mention of certain items. It checks obvious consensus among candidate documents. Indistinct consensus analysis, by contrast, targets implicit agreement among documents, using a method that assesses the occurrence of entities and different types of network centrality. Figure 1 illustrates the overall analytical process.

Document Clustering

First, we presumed that the abstract of an article is the summary of the entire document, and all essential information is always included in it. We extracted the abstracts of 34 papers and then plotted them in vector space.

The word-embedding model used in this experiment was BioCovidBERT developed by Tonneau (2020), a fine-tuned version of BioBERT, created by Lee et al. (2020). BioCovidBERT was trained on a preprocessed COVID-19 dataset accessible in the COVID-19 Open Research Dataset Challenge (Kaggle 2020). It was created with the help of several leading research groups in response to the COVID-19 pandemic, and over 181,000 coronavirus-related publications are included in the data of the COVID-19 Open Research Dataset Challenge. We assumed that BioCovidBERT, on this rich resource, could effectively represent each document as a vector while preserving their semantics, especially for words related to COVID-19. After document embedding, each paper was represented as a 1,024-dimensional vector. To check the similarity of the documents, we used Kernel Principal Component Analysis (KernelPCA), which can effectively reduce the dimensions of non-linear high-dimensional data. With KernelPCA, we visualized each document vector in a 2- and 3-dimensional space, and K-means clustering was used to elaborate groups of vectors. Among the derived clusters, we selected the one with the shortest intra-class distance and the longest inter-class distance, meaning that its components are self-similar, and the differences between points from other clusters are relatively high. The components of the selected cluster are determined as candidate documents and considered for further analysis in the next phase.

Conspicuous Consensus Analysis

With the candidate documents, two experiments were conducted for further investigation. To begin with, we used the TF-IDF for each candidate document. The following equation is the formula for TF-IDF, where N refers to the number of documents in the corpus:

$$TFIDF_{word,doc} = tf_{word,doc} * \log\left(\frac{N}{df_{word}}\right)$$

TF-IDF is a scalar value and is used to determine how important a word is in a document. TF gives the number of appearances of the target word in each document, and IDF represents whether it is used commonly or rarely for each document. For example, the word “the” appears commonly in most document, so df_{the} is relatively high, but inverse document frequency is low. Therefore, a high TF-IDF value indicates that the target word is rarely used in other documents but frequently appears in the target document.

For a more complete analysis, we extracted lists of all drugs mentioned in each paper and checked whether there were intersections between the drugs. This was done using PubTator Entity Tagger (U.S. National Library of Medicine and National Center for Biotechnology Information 2020) and with the help of the COVID-19 Drug and Gene Set Library developed by the Mount Sinai Health System (Icahn School of Medicine at Mount Sinai 2020), and we double-checked whether the extracted entities are included in the drug set. A total of 147 drugs were mentioned in 34 papers.

Indistinct Consensus Analysis

We formed drug entity co-occurrence networks for the clustered papers by setting the nodes as entity instances and the edges as the number of co-occurrences between the entity instances, making an entity co-occurrence network. In this network, we calculated the degree, betweenness, and closeness centrality values for each node (i.e., entity instance). After the logarithmic values for degree and closeness centrality values and the square roots of the betweenness centrality values were calculated, we cut the values into terciles, labeled as low, medium, and high. Using the values in the low tercile for one centrality and those in the high tercile for another, we created a low–high centrality combination for each entity. This combination indicates hidden gems within the entity network that cannot be observed from a direct observation of the centrality combinations.

In Table 1, we list the features of each centrality combination for the low–high centrality combinations (Zhang and Luo 2017). The instances in each entity co-occurrence network in the low–high centrality combination table could affect the network in a non-obvious but pivotal way. However, it should be noted that not all instances that occur in the low–high centrality combination table have low-profile importance, and that those that do appear in one of the following four low–high centrality combination groups: (a) low degree–high betweenness, (b) low degree–high closeness, (c) low closeness–high degree, and (d) low closeness–high betweenness.

Table 1. Low–high centrality combination features

	High Degree	*High Betweenness*	*High Closeness*
Low Degree	-	An individual's few ties are crucial for network flow.	An individual has ties to some important actors
Low Betweenness	An individual's connections are redundant and communication bypasses him/her	-	The network may hold many paths where an individual is near many actors, but so are many others.
Low Closeness	An individual is embedded in a cluster that is away from the rest of the network.	An individual can monopolize the ties of a few people to many others.	-

Results

Document Clustering

Figure 2 on the next page represents document embedding in a 2-dimensional space. At first glance, it is not easy to observe the existence of meaningful clusters or find a consensus among the 34 drug repurposing papers. To develop our investigation, we used the K-means clustering algorithm, an unsupervised machine learning approach that is widely used for cluster detection. Our goal was to check potential clusters within this 2-dimensional space, where horizontal and vertical axes represent the principal components. In other words, we assumed that if there are to be similar points among some of the papers, they would form a cluster in vector space, in which the components may share elements. Before applying the K-means method, it was necessary to develop a process to derive the optimal number of clusters. Using the elbow method and silhouette scoring, we discovered that three is an optimal number for our clusters. The results of our clustering are given in Figure 3-a, where the six dots on the left side of the 2-D plane form a relatively meaningful cluster, as the inter-class distance is longer there than in the other clusters, and intra-class distance is shorter. Therefore, we anticipated that documents corresponding to the points on the left side of the 2-D plane (6, 7, 11, 18, 30, 32, and 33) have the highest probability of addressing issues common to all 34 papers. We also checked KernelPCA in 3-dimensional space to improve the validity of the candidate documents (Figure 3-b). We found that documents 7 and 11 had low similarity in 3-dimensional space, although they seemed were located close together in 2-dimensional space. Using these means, five documents (6, 18, 30, 32, and 33) were shortlisted for possible consensus publications.

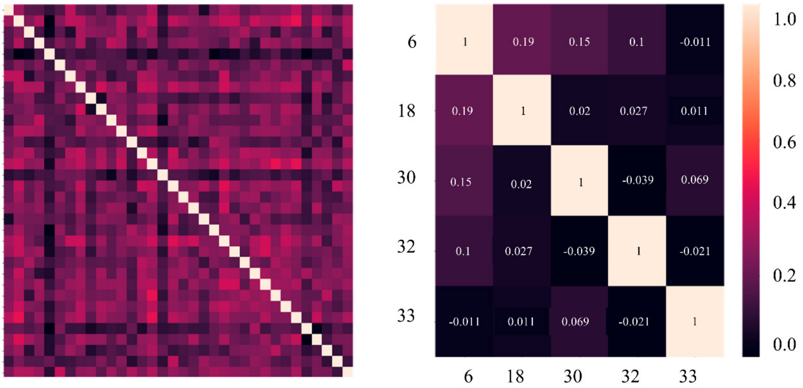
Lopinavir	0.53063	0.00000	1.06126	1.59188	3.18377

After removing stop words, we identified the 1,374 most frequently used words from 34 papers to generate a TF-IDF matrix. Table 2 presents part of this matrix for the five candidate documents, and certain several characteristics of each paper can be observed. In Paper 6 (Da Silva 2020), entitled "Convalescent plasma: A possible treatment of COVID-19 in India," convalescent plasma, which can be collected from an infected individual, is proposed as a treatment to COVID-19. The TF-IDF for plasma in Paper 6 is high, but it is not mentioned in other four documents. In Paper 18 (Devaux et al. 2020), it is reported that chloroquine interferes with ACE2, a protein on the surface of the cell that is known to be a pathway for coronavirus penetration. The TF-IDF values for chloroquine and ACE2 are relatively higher than its TF-IDF values from other documents. Thus, our TF-IDF matrix reflects each document's main ideas quite well. Following this assumption, we calculated the cosine similarity for each TF-IDF vector from each publication (Fig. 4).



(a) Cosine similarity of TF-IDF vectors from all 34 papers

(b) Cosine similarity of TF-IDF vectors from 5 candidate papers

Figure 4. Heatmap of cosine similarity based on the TF-IDF vectors

The average cosine similarity of TF-IDF vectors was 0.1556 when calculated with all 34 papers, whereas the similarity values for the five candidate papers were lower, with an average of 0.1133. The fact that all five candidate documents, which formed the most meaningful cluster in the clustering section, showed a lower level for TF-IDF vector similarity implies two things.

A first is that there is information loss when the dimensions of document embeddings are reduced. On this view, some common issues may appear to be shared in a 2- or 3-dimensional space, but there is no consensus in reality. A second is that, if there was no information loss, the cross sections among these publications may be too trivial. To be specific, the words that contribute to the clustering may not be about the 1,374 core words we used to generate TF-IDF vectors. If some critical information were shared, shared vocabulary used to present that discovery would result in a high similarity in TF-IDF vectors. Overall, only eight drugs were mentioned more than twice: lopinavir, hydroxychloroquine, Arbidol, chloroquine, ritonavir, remdesivir, favipiravir, and ribavirin. Remdesivir and chloroquine were each mentioned in four of the five candidate documents, followed by lopinavir, ribavirin, and ritonavir, which appeared three times each. Thus, remdesivir and chloroquine appear to enjoy a certain consensus, but there is still no broad agreement, as these documents discuss too wide of a range of drugs. Figure 5, presenting the network visualization of Table 3, which reports the list of drugs mentioned in the five publications, buttresses our point. The self-loops in Figure 5 highlight drugs that appear only in a single document. For example, potassium, amiodarone, and azithromycin are only mentioned in 33. The multiple self-loops observed in Figure 5 and the multitude of edges labeled remdesivir or chloroquine reinforces our claim that no strong consensus exists, except for these two drugs.

Table 3. Mentioned drugs list in five candidate papers

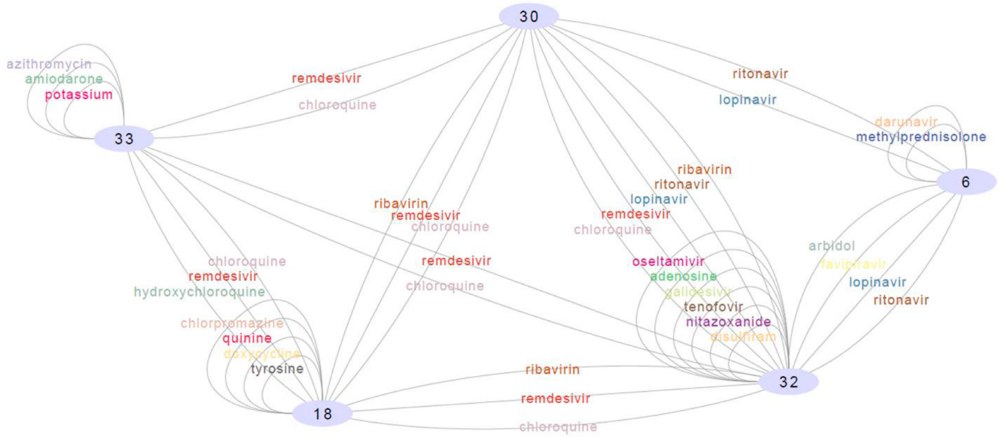

Figure 5. Multigraph network illustration of the mentioned drugs in the five candidate papers

Indistinct Consensus Analysis

In the drug entity co-occurrence network for the five clustered papers, chloroquine and teicoplanin were found to have high degree centrality scores, but they also had low betweenness and closeness centrality scores, which meant that their connections were redundant: important communication simply bypassed them, and they were embedded in a cluster that was distant from the rest of the network (Table 4). Lopinavir had few ties that were pivotal to network flow but had ties to other important drug instances in the network. This implies that lopinavir may be a hidden gem for the cluster formation of drug repositioning research in a high entropy situation.

Table 4. Drug entity co-occurrence network in low–high centrality combination for the five clustered papers

Drug	*High Degree*	*High Betweenness Centrality*	*High Closeness Centrality*
Low Degree	-	Lopinavir	Lopinavir
Low Betweenness	Chloroquine, Teicoplanin	-	-
Low Closeness	Chloroquine, Teicoplanin	-	-

Discussion

The data used to find conspicuous and indistinct consensus in treatments for COVID-19 were abstracts of COVID-19 drug repositioning papers published before April 15, 2020. To determine whether our predicted focusable drug was actually a target of COVID-19 drug repositioning research, we examined research trends before and after April 15, 2020, for the three drug instances found in low–high centrality combinations in the drug entity co-occurrence network. We investigated the number of research papers on each drug before and after April 15, 2020, on PubMed and calculated the rate of increase in the research by dividing the number of papers published after April 15, by the number of papers published before that date.

In Table 5, it is shown that all three drugs increased in the number of studies targeting them, but the higher research increase rate for chloroquine and teicoplanin should be noted. Although these two were not in the main part of the co-occurrence network, and important communication bypassed them, the number of studies conducted on these two were higher than those on lopinavir, which has few ties but ones that are crucial the network flow. The difference in research increase rate between lopinavir and chloroquine may not be significantly different, but a comparison of the absolute number of studies conducted shows that chloroquine was researched approximately 4.517 times more often than lopinavir, which indicates a notably low research focus on the latter. Thus, since the inconspicuous consensus analysis did not receive sufficient attention, probing this drug may help develop innovatory drug repositioning results.

Table 5. Lopinavir, chloroquine, and teicoplanin research trends before and after April 15, 2020

	Lopinavir	*Chloroquine*	*Teicoplanin*
Before April 15, 2020	11	47	1
After April 15, 2020	60	271	7
Research Increase Rate (# of Papers After April 15, 2020/# of Papers Before April 15, 2020)	5.455	5.766	7.0

Conclusion

In this research, we examined the consensus among publications on COVID-19 drug repurposing using two data science approaches. First, we derived several conspicuous features using document clustering, a TF-IDF matrix, and co-occurrence of drug entities. Among five papers that formed a cluster, we found that the cosine similarity for each publication's TF-IDF was low, and that only eight drugs were mentioned more than twice in this group. Remdesivir and chloroquine appeared in four out of the five clustered papers, which implied the conclusion that these drugs are the subjects of a certain agreement. Second, using co-occurrence network analysis, we conducted an additional experiment to determine an indistinct consensus. Lopinavir was the only drug to show high betweenness centrality, high closeness centrality, and low degree, which implies that it may have potential for repurposing. However, the rate of increase in research on chloroquine is still higher than that of lopinavir, which indicates that most publications are still concentrating on chloroquine.

In future work, we hope to extend our search for drug repurposing publications on the rapidly growing area of COVID-19. Applying these methods, we can continue to monitor what overlaps will emerge from the proposed repurposed drug candidates for COVID-19 from novel studies. These overlaps may eventually lead to a research consensus on an established list of repurposed drug candidates for COVID-19.

Abstract

Science, technology, engineering and math (STEM) fields are crucial for innovation capacity and life long learning in a rapidly changing world. But the gender gaps are so pronounced globally in STEM education and thereby in the workforce as well. Does this also reflect on the awards and recognitions bestowed on female scientists. This work attempts to examine the status of women laureates in terms of selected prestigious awards including Nobel prize, Fields medal, Abel prize and Turing award through scientometric analysis.

Introduction

Women are underrepresented in the fields of Science, Technology, Engineering and Mathematics (STEM), globally. In the last 50 years or so, the trend is improving but nevertheless the increase is not so sharp as to compensate for the challenges women face. In almost all parts of the world, a crude representation of the ratio of male to female population stands equal. The gap begins as early as in high school enrolments, though not sizable, but then widens in university degrees enrolment (particularly in STEM), and then on to pursuing postgraduate & research doctoral degrees. This, in turn, creates an imbalance in the national economy with regard to expenditures on women's education, and also leads to less representation of women in the general science-oriented workforce. Needless to say, there are far fewer women tackling global issues like climate change, renewable energy and so forth. In spite of barriers and the glass ceiling, some women do make it to the top in science fields. This necessitates to study the women's presence in the realm of prestigious academic awards.

There are a number of ways to assess the role of women in STEM and thereby examine the impact of their representation in the national economy (Beede et al. (2011)). This work tries to explore scientometric parameters of elite women achievers in terms of indicators like recipients of selected prestigious & coveted awards which include Nobel Prize (in Physics, Chemistry, Medicine or Physiology), Fields Medal & Abel Prize (both for Mathematics) and the Turing Award (Computer Science).

In the last 100+ years, only 28 women have received Nobel (119 years old), Fields Medal (84 years old), Abel Prize (17 years old) and Turing Award (53 years old) totally. Though it is known that women's representation is in these scientific awards, it is appalling to note that it is so low. It amounts to 3.5% of recipients' in Mathematics, 2% in Physics, 5% in Chemistry and 9% in Medicine or Physiology. If one looks into the geographical distribution, these women achievers in Mathematics are from Iran and US. Four female Physicists are from Canada, Poland each and two are from US whereas seven women from US, UK, France, Poland and Israel have received awards in the field of Chemistry. Twelve Laureates in the field of Physiology or Medicine field are from different countries viz., Australia, China, France, Germany, Italy, Norway and US amongst which 50% are from US. These statistics clearly indicate that the majority of the achievers are from US & EU either as a country of origin or adopted as emigrant citizens (nobelprize.org, abelprize.no, mathunion.org, amtur-

ing.acm.org).
There seems to be various factors that contribute to limited number of women achievers in STEM fields which include fewer women pursuing doctoral degrees in STEM, continuance of women doctoral degree holders as academicians / researchers, fewer publishing research works, receiving grants or establishing laboratories for a sustainable research environment, etc. All this together with breaks at these stages for family and elder care restrict a woman's opportunities to become achievers and this ultimately becomes a vicious circle.

As far as the authors know, particular characteristics of women in Nobel awardee lists have not been critically analyzed. Hence, this work focuses on a Scientometric analysis (through Web of Science / Scopus) of the scientific output of these women Nobel Laureates: Number of articles published, impact factors, and number of citations. The outcome of this analysis thus may help in revisiting the pathways & or policies related to women's empowerment in STEM with particular emphasis on cross-disciplinary activities, collaboration networks, and support toward exceptional creativity in scientific research.

Methodology

The research design was to collect the data of all elite awardees which included Nobel Laureates (Chemistry, Medicine & Physics), Abel Prize winners, Field Medalists, and Turing Awardees. Data regarding name, gender, year of award, date of birth and relevant information are taken from their respective websites (nobelprize.org, abelprize.no, mathunion.org, amturing.acm.org) and compiled for this study. For scientometric study, the data are drawn from the Scopus covering the years 2000-2018 in order to have reasonable sample distribution of both gender. To check the prevalence of gender disparity with regard to age and the scientific accomplishments, a non-parametric statistical analysis using t-test was done.

Gender asymmetry in prestigious awards

The growing importance of the issue of gender imbalance in STEM has led to discussion on number of defining factors operating over a period of time like leaky pipeline, crystal glass ceiling, scissors effect, impossible pursuit and overtaking model (Naldi et al (2004)). In STEM fields, making a critical breakthrough is always intriguing as it is an interplay of numerous factors including the foundational knowledge, consistent training, access to resources, cultural background, science of work (nature, theory, experimental), age, educational graph to list a few. In spite of major changes in higher education and in scientific career pursuits, gender imbalances still persists today especially in STEM fields.

Lack of use of women's skills and knowledge weigh heavily in STEM fields as shown in Fig. 1. The data has been presented here into two blocks (from the inception of the awards to 1970 as pre-1970 & 1971-2020 as post-1970) just for brevity and ease of interpretation. If we look at the data of gender distribution of the coveted awards, it clearly indicates an asymmetrical pattern across all fields as shown in Table 1.

Age

From around the time of Einstein, deliberations about age and productivity of scientists have taken place. It was during the early 20th century, when the majority of awardees were young , the average age was less than 50 across all fields. With time it has been constantly growing and interestingly in 2019, Physicist John B Goodenough received his Nobel Prize at the age of 97 contrary to the popular belief & saying by Einstein & Dirac that by age 30, a Physicist was effectively dead. Thus scientists receiving at the age above 50 has been on increase. The age at which scientists do their most significant work is also an important parameter when considering age and productivity.

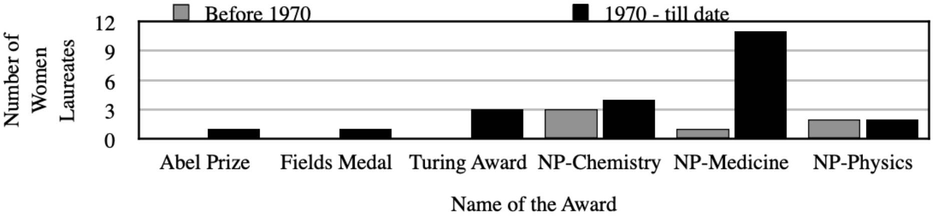

Figure 1. Women Laureates: Pre & Post 1970 status.

Table 1. Gender distribution across all fields

Award	*Field*	*Period*	*Total*	Ratio F/M
Abel Prize	Mathematics	2003-2020	22	5:95
Fields Medal	Mathematics	1936-2019	60	2:98
Turing Award	Computer Science	1966-2019	72	4:96
Nobel Prize	Chemistry	1901-2020	186	4:96
Nobel Prize	Medicine/Physiology	1901-2020	222	6:94
Nobel Prize	Physics	1901-2020	216	2:98

With the available data so far, the average age of women winning these awards are in 50-59 yrs band which appears to be similar to that of male awardees. Interestingly the age band has been increasing of late which is a welcome sign and might be attributed to return after break in career, increasing publications, availability & success of research grants, to name few factors.

It is also interesting to note that the age - productivity relationship is found to be field dependent and also the age at which award winning work was carried out (Table 2). It is only logical to infer that with time the odds (in terms of resources, time available, experiments) for researchers decrease and fall off precipitously after age 50 particularly in the fields of chemistry and physics which require more experimentation (Fones & Weinberg, 2011). In order to know, if there exists any difference in the ages at which these awards were received by men and women, the statistical t-test is done (Table 2). As seen in the table, the computed t-value is compared with the critical t-value at a confidence level of 95%. It is found that the computed value is less than the critical value, the result suggesting that there is no significant difference between the age of men and women at the time of winning the award.

Demographical Distribution

Out of 28 award recipients, if one looks at their locations at the time of receiving their awards, 14 of them are attached to USA based universities, whereas 5 from France (this includes Marie Curie receiving it in Physics & Chemistry), 2 from Israel, rest 1 from UK, Italy, Germany, Norway, China, Canada & Iran each. So, USA has more women laureates but which is quite similar to that of male recipients as well.

Field of Study

Even in 2020, the gender asymmetry is very much visible overall and across almost all fields. When we examine the data as pre & post 1970, there is no major sign of growth in terms of women awardees (Fig. 1). Before 1970, women never received Fields Medal and Turing award whereas the distribution of male:female of Nobel Prizes in Chemistry, Medicine and Physics, till date since inception, stands at 96:4, 95:5 and 98:2. It is relevant to note that Marie Curie is the only woman to receive two Nobel Prizes that too in different fields, so far. In the last 50 yrs (1970-2020), there is only a very marginal increase in the above fields (Chemistry, Medicine and Physics) and stands at 95:5, 91:9 & 98:2 as of now. The first woman to break the glass ceiling in Mathematics happened only recently i.e. at 2014 & 2019 viz., Maryam Mirzakhani being the first woman to receive Fields Medal in 2014 and Karen Uhlenbeck is the first woman to receive Abel Prize in 2019. So, the gender disparity is very much prevalent across all STEM fields. If one compares the data of gender gap in STEM vs NON-STEM (including Nobel Prize in Literature, Peace and Economic Sciences) fields, in STEM there is roughly only 1 woman for every 30 men whereas in NON-STEM the ratio seems to be encouraging at 1:10.

Award	*Field*	*Age Range*	*Female (avg)*	*Male (avg)*	t_{calc}	$t_{critical}$
Abel Prize	Mathematics	63-90	77	77	0.71	2.069
Fields Medal	Mathematics	31-40	37	36	0.92	2.160
Turing Award	Computer Science	50-79	65	57	0.99	2.035
Nobel Prize	Chemistry	43-98	51	56	0.35	2.007
Nobel Prize	Medicine/Physiology	46-85	63	58	0.28	2.007
Nobel Prize	Physics	36-96	54	59	0.02	2.004

Table 2. Comparison of average age of winners and statistical analysis data

Fractional Distribution

While much has been made of the Nobel's large gender imbalance, an analysis based on fractional counting reveals an even wider gap. An assessment of gender imbalance based on full counting, which doesn't account for prize share, reveals that women have received 20 (3.24%) of the 624 Nobel medals awarded since 1901. But an analysis based on fractional counting, considering prize share, finds that only 2.74% of the 334 sciences prizes have gone to women (natureindex.com). Out of 28 women who have received prizes across Chemistry, Medicine and Physics fields, 21% of them received full share, 32% of them received half, 18% received one-third share and 29% received quarter share of the prize value.

Scientometric Analysis

The data for scientometric analysis are drawn from the Scopus database for the period 2000 - 2018. The collected data includes number of citations of the individual authors, number of documents authored by the awardees and h-index of these awardees. While looking at these data, it is not surprising to see the asymmetric pattern given the low number of women awardees (Fig. 2) (Pavanasam & Basu, 2019).

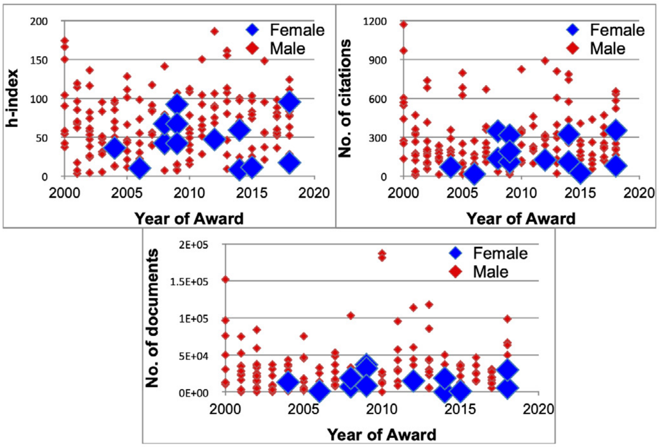
For a better understanding, *t*-test was carried out for all 3 parameters viz., total citations of the awardees, total documents created by the authors and h-index (Table 4). It is found that for all

3 data, the calculated *t*-value is lesser than the corresponding critical *t*-value suggesting there is not enough evidence for a significant difference between scientific achievement of men and women laureates scientific achievements. This leads to an observation that the quality of research work by women is equivalent to that of men, but women's participation and visibility in these fields are much less prominent.

There are number of papers that focus on the gender gap in publication productivity which state that there is a progress with regard to publication but women are still far from reaching parity across fields globally. Also, there are fields like mathematics, physics, computer science which might take longer time (maybe beyond this century) compared to other fields to reach equilibrium in terms of publications[Aguinis et al, 2018]. So far we have not reached a specific pattern of this asymmetry on the publication productivity in terms of fields, period, or geographical location. So it will be interesting to systematically analyze and arrive at the directions to be taken forward.

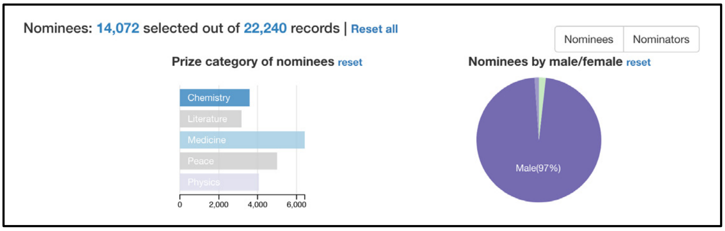
Table 3: T-test: Scientometric data

Scientometric Data	t_{calc}	$t_{critical}$
h-index	0.04	1.96
Number of citations by authors	0.01	1.96
Number of total documents by awardees	0.01	1.96



Nominations vs Laureates

Currently, data regarding nominations of candidates is available for the period 1901 - 1963 for Physics and Chemistry whereas for Medicine or Physiology, data is available until 1953. This is in compliance to the statutes of the Nobel Foundation i.e. only material older than 50 years can go public. From this data, it is clear that in all 3 fields, women were nominated at only 2% overall [Fig. 3]. This includes multiple nominators nominating one candidate. Considering the data for actual number of women nominated and winning the Nobel Prize, it is very encouraging i.e. 6 awards received out of 24 women nominated for the above said period. So, this leads to one important observation that the glass ceiling prevails at the initial of the process i.e. nomination itself. Hence, this has to be addressed appropriately by the awarding bodies without delay to improve the gender diversity in these awards.



Nominees: 14,072 selected out of 22,240 records | Reset all

Figure 3 Gender distribution of nominees in the fields of Chemistry, Physics & Medicine

Conclusion

The concern over very low representation of women in awards like the Nobel prize and Abel Prizes, Fields Medal and Turing awards, particularly in STEM fields, is often addressed of late. Few known and simple facts are educational empowerment, women's workforce, space for professional enhancement and the visibility of successful researchers. If we look at women receiving these awards considering the age, demographical location, scientometric analysis and quality of work it appears that there is no substantial difference with regard to their male counterpart. On the other hand, while looking at nominations, we find that women's representation is very low. In spite of governments and associated organizations working on schemes and frameworks to give due weight to women so that their knowledge, and their research output are suitably utilized, it appears there is still a huge scope to study important factors for narrowing the gap in such elite recognitions.

Research performance and scholarly communication profile of competitive research funding: the case of Academy of Finland

Janne Pölönen[1] and Otto Auranen[2]

[1] *janne.polonen@tsv.fi*
Federation of Finnish Learned Societies, Snellmaninkatu 13, 00170 Helsinki (Finland)

[2] *otto.auranen@aka.fi*
Academy of Finland, Hakaniemenranta 6, 00531 Helsinki (Finland)

Abstract

The Academy of Finland (AKA), Finland's major public research funding agency, uses a Web of Science (WoS) based bibliometric indicator to assess the performance of research it has funded. In this paper, we use an alternative methodology to compare 1) the research performance and 2) scholarly communication profile of AKA funded research to the 13 Finnish universities' entire output across the major fields of science using the national data of 142,742 publications (years 2015-2018) registered in the VIRTA Publication Information Service. Research performance is analyzed using the Finnish Publication Forum (JUFO) rating of publication channels. Our results show that AKA-funded research is published on higher JUFO level journals and book publishers than Finnish universities' entire output, and that AKA-funded research is more focused than the universities on using peer-reviewed publications, articles published in journals, English language, and open access publishing. JUFO levels and WoS-based indicator produce consonant results in regard to the performance of AKA-funded research across all fields. The national publication data also provides added value by enabling assessment of the broader publication profile of AKA-funded research, including science communication, bibliodiversity, multilingualism, collaboration and open access.

Introduction

Like many research funders, the Academy of Finland (AKA) as a major Finnish public research funding agency is interested in the effects of its funding. As a partial measure for its goal of promoting high quality, renewal and impact of research, AKA uses a bibliometric indicator to compare the citation impact of AKA-funded publications to the citation impact of the entire Finland. Indicator has been in use since 2016 and the main elements of method have been described by Auranen & Leino (2019). The indicator is called the Top10 index, which describes the unit of analysis' relative share of the 10% most cited publications in the world, world average being 1 (Academy of Finland, 2020a). Web of Science (WoS) is used as a data source for calculating the Top10 index. Publications from two AKA's funding instruments are included in the calculation of the indicator: Academy Projects and Academy Research Fellows, which represent bottom-up funding instruments in AKA's funding portfolio (Academy of Finland, 2020b), and of Fellows: Academy of Finland, 2020c). Results show that AKA-funded publications have a higher Top10 index than publications from Finland on average (1.29 vs 1.09 in 2020). However, Top10 index for Academy Research Fellows is usually higher than for Academy Projects (1.38 vs 1.26 in 2020).

Web of Science allows international bench-marking, however the disadvantage is the narrow focus on peer-reviewed international journal articles. Comparisons with the comprehensive institutional CRIS data, which in some countries - including Finland - has been integrated at the national level, have shown that WoS and Scopus coverage is seriously lacking in the social sciences and the humanities (SSH) (van Leeuwen et al., 2016; Aksnes & Sivertsen, 2019; Sivertsen, 2019; Pölönen et al., 2020b). This is because in the SSH fields, local publication languages and books play an important role in the scholarly communication (Kulczycki et al., 2020; Kulczycki et al., 2018; Engels et al. 2018). Due to lack of WoS coverage, AKA's bibliometric indicator misses a large share of scientific publishing particularly in the SSH, as 41 % of the peer-reviewed articles reported from the social sciences and 79 % from the humanities are not included in the indicator (Auranen & Leino 2019). In addition, especially in the SSH but also in other fields, dissemination of research knowledge within and beyond academia involves a broad range of publications that are not peer-reviewed (Hicks, 2004). Also these types of publications, which are highly relevant for the societal impact of research, are excluded from the WoS-based analyses but they are covered in the CRIS data. In Finland, peer-reviewed and not-peer-reviewed publications are comprehensively covered in the national VIRTA publication information service, which integrates the publication metadata from the local CRIS of 13 Finnish universities (Pölönen, 2018).

One challenge in using the national publication data for assessing research performance, as opposed to WoS or Scopus, is the lack of citation data. In several countries, performance-based research funding systems (PRFS) use a comprehensive list of peer-reviewed publication channels as a quality-index (Hicks, 2012; Sivertsen, 2016; Pölönen et al, 2020a). In Finland, Publication Forum classification (in short, JUFO) has been developed since 2010 to support the Ministry of Education and Culture's PRFS for allocating part of core-funding annually to universities. The main rationale is to reward universities not only based on quantity but also quality of output, namely publishing in channels that are valued by the scientific community, are demanding in terms of peer reviews, and reach the widest critical expert audience. Several Finnish universities have also used local CRIS data and JUFO levels, in addition to bibliometric citation analyses based on WoS or Scopus data, to inform expert-panels conducting institutional research assessments (Wang et al., 2014; Pölönen et al, 2021). So far, the national VIRTA data or JUFO classifications have not been used to assess the performance or broader scholarly communication practices of the AKA funded research.

In JUFO classification (Publication Forum, 2021), domestic and foreign peer-reviewed publication channels (journals and book publishers) are classified to four level categories (1=basic, 2=leading, 3=top, 0=other) by Finnish experts in the field (Auranen & Pölönen, 2012; Pölönen et al., 2018). The evaluation of channels is entrusted to 250 experts in 23 field-specific panels, who represent the Finnish research community. The experts' main tasks are 1) to identify reliable peer-reviewed channels, and 2) indicate the leading channels of their field in terms of average quality, impact and prestige. JUFO evaluation is informed but not constrained by citation-based journal metrics, such as the Journal Impact Factor (JIF) or Source Normalized Impact per Paper (SNIP). In the SSH fields, also national language journals and publishers without impact factors are included among the leading channels (Pölönen et al., 2021).

Research questions, data and methods

According to the international initiatives for responsible metrics, evaluation should take into consideration the disciplinary diversity and plurality of research outputs (https://sfdora.org; Hicks et al., 2015; Wilsdon et al., 2015). Also the Responsible Research and Innovation (RRI) and Open Science (OS) policies have called for a broader-based evaluation of research taking into account societal interaction and impact. In this study, we compare the research performance and scholarly communication profiles of the Finnish universities and the AKA-funded research based on comprehensive national publication data and the JUFO classification. We pose the following two research questions:

1. How does AKA-funded research at Finnish universities perform in publishing compared with entire research activity at Finnish universities? We use the share of peer-reviewed outputs published in journals, conferences and book publishers in JUFO levels 2 ("leading") and 3 ("top") as the indicator of publication performance. We also compare the results based on JUFO levels with those based on the WoS-based Top10 index.
2. What is the scholarly communication profile of AKA-funded research at Finnish universities in comparison with the entire publication output of Finnish universities?

We compare the scholarly communication profiles according to the following indicators derived from VIRTA data across the main fields of science:

1. Science communication: share of not-peer-reviewed publications aimed at academic, professional and general audiences.
2. Bibliodiversity: share of peer-reviewed book publications (chapters, monographs and edited volumes), conference articles and conference articles.
3. Multilingualism: share of peer-reviewed publications in languages other than English (Finnish, Swedish and other languages).
4. Open access: share of peer-reviewed open access publications, including gold, hybrid and green OA.
5. Research collaboration: share of peer-reviewed publications with co-authors, with co-authors from more than one Finnish university, and international co-authors.

To investigate these research questions, we created a dataset based on three sources:

1. VIRTA publication data, consisting of 158,029 publications (publication year 2015-18) the 13 Finnish universities have validated and reported annually to the Ministry of Education and Culture. The Ministry used this data to allocate 13% of core funding annually to universities in the performance-based research funding system . Publications with authors affiliated with more than one Finnish university figure in the data as duplicates.
2. AKA publication data, consisting of 7,971 publications (publication year 2015-18), which the PIs of the Academy Projects and Academy Research Fellows from the call years 2011-2013 have reported as outputs. Publication reported by more than one project or fellow figure in the data as duplicates. Since 2017, AKA-funded research outputs have been reported using VIRTA as one of the information sources.
3. JUFO publication channel classification, consisting of 31,597 journals and series, conferences and book publishers evaluated and rated according to quality, impact and prestige by national expert-panels. Information about the channel identified by unique JUFOID and the JUFO level is included in the VIRTA data for all peer-reviewed publications.

We matched AKA and VIRTA publications, and indicated in the VIRTA data which publications by the Finnish universities have been produced with funding for AKA Projects and Fellows (Table 1). We also deduplicated the VIRTA data to arrive at full-counts at national level. Our final dataset consists of 142,742 Finnish universities' publications, of which 6,143 (4%) are an AKA-funded subset. Dataset comprises only publications where at least one of the authors is affiliated at a university. It should be noted that while the Academy of Finland grants funding to researchers with various affiliations, appr. 80% of the funding is granted to researchers at universities (see Academy of Finland, 2020d).

The identification of peer-review status, target audience, publication type, language, open access status, number of authors and international co-authorship of publications in VIRTA is based on researchers' self-reports and/or validation by the data-collection personnel at the universities. Over two-thirds (69%) of all Finnish Universities' publications reported in VIRTA are peer-reviewed scientific publications, including articles in journals, conferences and books, as well as monographs and edited volumes (Table 1). Almost one-third of the outputs are not peer-reviewed publications for the academic, professional and general audiences. Of 6,143 publications reported as outputs of AKA-funded research, the vast majority (89%) are peer-reviewed.

Table 1. Finnish universities' publications and Academy of Finland (AKA) funded publications 2015-2018 by scholarly status

SCHOLARLY STATUS	ALL PUBLICATIONS		AKA-FUNDED	
	Number	Share	Number	Share
Scientific peer-reviewed	98472	69.0 %	5478	89.2 %
Not peer-reviewed	44270	31.0 %	665	10.8 %
All	142742	100 %	6143	100 %

Of the AKA-funded publications, 4,359 are reported as Projects' outputs and 1,896 as Fellows' outputs (Table 2). This includes 112 publications that have been reported as outputs of both AKA-funded Projects and Fellows. All publication outputs are assigned to OECD FOS main fields based on the field-classification in the VIRTA data based on researchers' self-reports. The share of Natural sciences and Engineering publications is larger, and that of SSH publications smaller, in the AKA-funded output compared to the universities' entire output.

Table 2. Finnish universities' publications and Academy of Finland (AKA) funded Projects' and Fellows' publications 2015-2018 by main field of science

MAIN FIELD	ALL PUBLICATIONS		AKA-FUNDED		AKA PROJECTS		AKA FELLOWS	
	Number	Share	Number	Share	Number	Share	Number	Share
1 Natural sciences	34565	24 %	2449	40 %	1684	39 %	809	43 %
2 Engineering	15464	11 %	784	13 %	429	10 %	370	20 %
3 Medicine	27387	19 %	1144	19 %	942	22 %	217	11 %

6 Humanities	24990	18 %	626	10 %	478	11 %	170	9 %
All fields	142742	100 %	6143	100 %	4359	100 %	1896	100 %

Results

Publication performance of AKA-funded research compared to Finnish universities' entire peer-reviewed publication output in 2015-2018

In this part, we limit our analysis to 98,472 peer-reviewed publications, of which 5,478 (5.6%) are AKA-funded research outputs, including 3,892 (4%) outputs related to AKA Projects and 1,681 (1.7%) to AKA Fellows. Overall, both the universities' peer-reviewed output and the AKA-funded research is published in channels in all JUFO level categories from 0 to 3 (Table 3). The AKA-funded research is, however, more strongly concentrated to channels the national expert-panels have rated as JUFO level 2 "leading" and 3 "top" channels. The share of JUFO level 2 and 3 publications is 45% for the AKA-funded research, compared to 32 % for the Finnish universities in general (Figure 1). Also, a larger share of publications by AKA-funded Fellows (48 %) is on JUFO levels 2 and 3 than publications by AKA-funded Projects (43 %). Our analysis also shows that AKA-funded research outperformed Finnish universities in all fields, and in case of each university's peer-reviewed output (Figure 2). These results are consonant with the WoS-based bibliometric analysis, as the AKA-funded research has a higher Top10 index than the Finnish research in general, and also the research by AKA Fellows has a higher Top10 index than AKA projects.

Table 3. Research performance: share of peer-reviewed publications of Finnish universities and Academy of Finland (AKA) funded research according to JUFO level of the publication channel

JUFO-LEVEL	ALL PUBLICATIONS		AKA-FUNDED		AKA PROJECTS		AKA FELLOWS	
	Number	Share	Number	Share	Number	Share	Number	Share
3	9372	9.5 %	739	13.5 %	502	12.9 %	250	14.9 %
2	22425	22.8 %	1699	31.0 %	1170	30.1 %	564	33.5 %
1	57194	58.1 %	2766	50.5 %	2038	52.4 %	770	45.8 %
0	9481	9.6 %	274	5.0 %	182	4.7 %	98	5.8 %
All JUFO levels	98473	100 %	5478	100 %	3893	100 %	1681	100 %

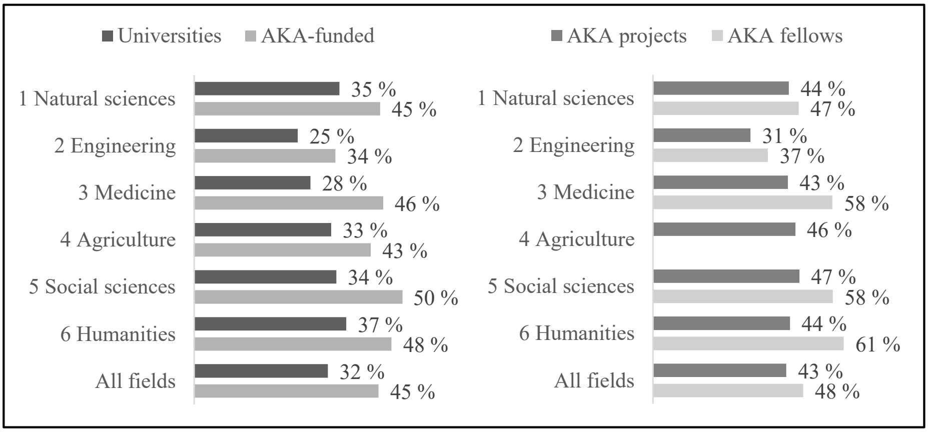

Figure 1. Share of JUFO-level 2 and 3 channels of all peer-reviewed publications of Finnish universities and AKA-funded projects and fellows by the main field of science.

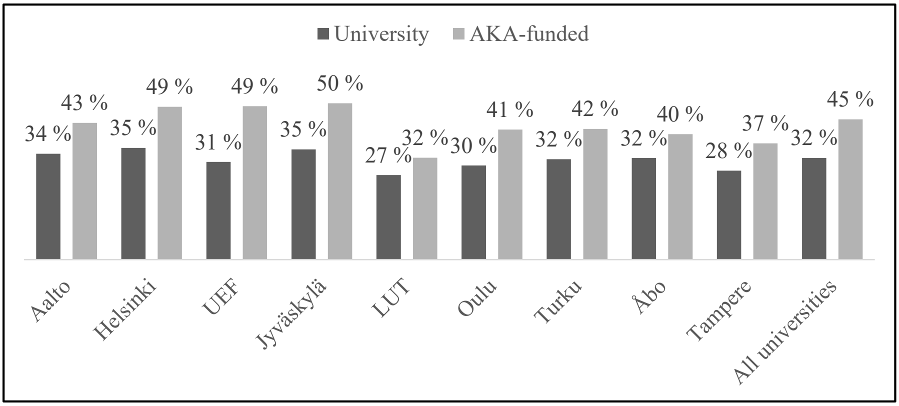

Figure 2. Share of JUFO-level 2 and 3 channels of all peer-reviewed publications of 9 Finnish universities and AKA-funded projects and fellows (Lapland, Hanken, UNIArts and Vaasa are excluded because the number of AKA-funded outputs is less than 50).

Publication profiles of AKA-funded research compared to Finnish universities' entire publication output in 2015-2018

1. Science communication. According to our analysis, both Finnish universities and AKA-funded research (Fellows and Projects) use a broad range of publications, mostly peer-reviewed publications but also non-scholarly publications aimed at academic, professional and general audiences (Table 4). The AKA-funded research is, however, much more focused on peer-reviewed scholarly communication within academia. The share of not-peer-reviewed publications of the total output is 11% for the AKA-funded research compared to 31% in the case of Finnish universities. The share of not-peer-reviewed publications is much larger in the SSH fields in case of both AKA-funded research and Finnish universities' output (Figure 3).

2. Bibliodiversity. Both Finnish universities and AKA-funded research use peer-reviewed journal, conference and book publications for scholarly communication (Table 4). Nevertheless, the AKA-funded research is more focused on using peer-reviewed journal articles. The share of articles in conferences and books, as well as monographs, of the total peer-reviewed output is 22% for the AKA-funded research compared to 29% in the case of Finnish universities. Both AKA-funded research and Finnish universities' output shows traditional disciplinary differences in use of different publication types, especially in engineering (conferences) and the SSH (book publications). Interestingly, in the case of humanities the share of journal articles is slightly smaller for AKA-funded research than Finnish universities in general (Figure 3).

3. Multilingualism. Both Finnish universities and AKA-funded research use multiple languages in peer-reviewed scholarly communication, including English, Finnish and Swedish (Finland's two national languages), as well as other languages (Table 4). The AKA-funded research is, however, much more focused on English language publications. The share of peer-reviewed publications in languages other than English is 4,5 % for the AKA-funded research compared to 11 % in the case of Finnish universities' entire peer-reviewed output. Despite the strong focus on English language publishing, the share of publications in languages other than English is much larger in the SSH fields in case of both AKA-funded and Finnish universities' output (Figure 3).

4. Open Access. Both Finnish universities and AKA-funded research use different routes, including gold, hybrid and green OA, to enable open access to peer-reviewed publication outputs (Table 4). Overall, the share of Open Access publications is larger in case of the AKA-funded research. While the share of outputs in gold OA channels is almost the same, AKA-funded research has a larger share of hybrid and green (self-archived) OA outputs. Overall, the share of Open Access peer-reviewed output is 53% for the AKA-funded research compared to 48% in the case of Finnish universities. There are some differences between fields in the overall Open Access share, however the Open Access advantage of AKA-funded research is stronger in medicine, agriculture and social sciences, and non-existent or modest in case of natural sciences, engineering and humanities (Figure 3).

5. Collaboration. According to our analysis, both Finnish universities and AKA-funded research produce the vast majority of peer-reviewed publications in collaboration between two or more authors, who are often affiliated with other Finnish or foreign universities (Table 4). The AKA-funded research is, however, more focused on research collaboration. The share of co-authored publications of the total peer-reviewed output is 91 % for the AKA-funded research compared to 82 % in the case of Finnish universities. Also the share outputs produced in Finnish inter-university collaboration and international collaboration is larger for the AKA-funded research (23% and 50%, respectively) compared to Finnish universities in general (12% and

46%, respectively). Single-authorship is most common in the SSH fields, so the increased collaboration related to AKA-funded research is visible especially in these fields (Figure 3). Perhaps surprisingly, the share of internationally co-authored publications is smaller for AKA-funded research in all fields except medicine.

Table 4. Scholarly communication profiles of Finnish universities and the AKA-funded research

SCHOLARLY COMMUNICATION PROFILE	**ALL PUBLICATIONS**		**AKA-FUNDED**	
	Number	**Share**	**Number**	**Share**
1. Science communication				
● Peer-reviewed	98472	69.0 %	5478	89.2 %

● - International co-authors	45186	45.9 %	2729	49.8 %
● All	98472	100 %	5478	100 %

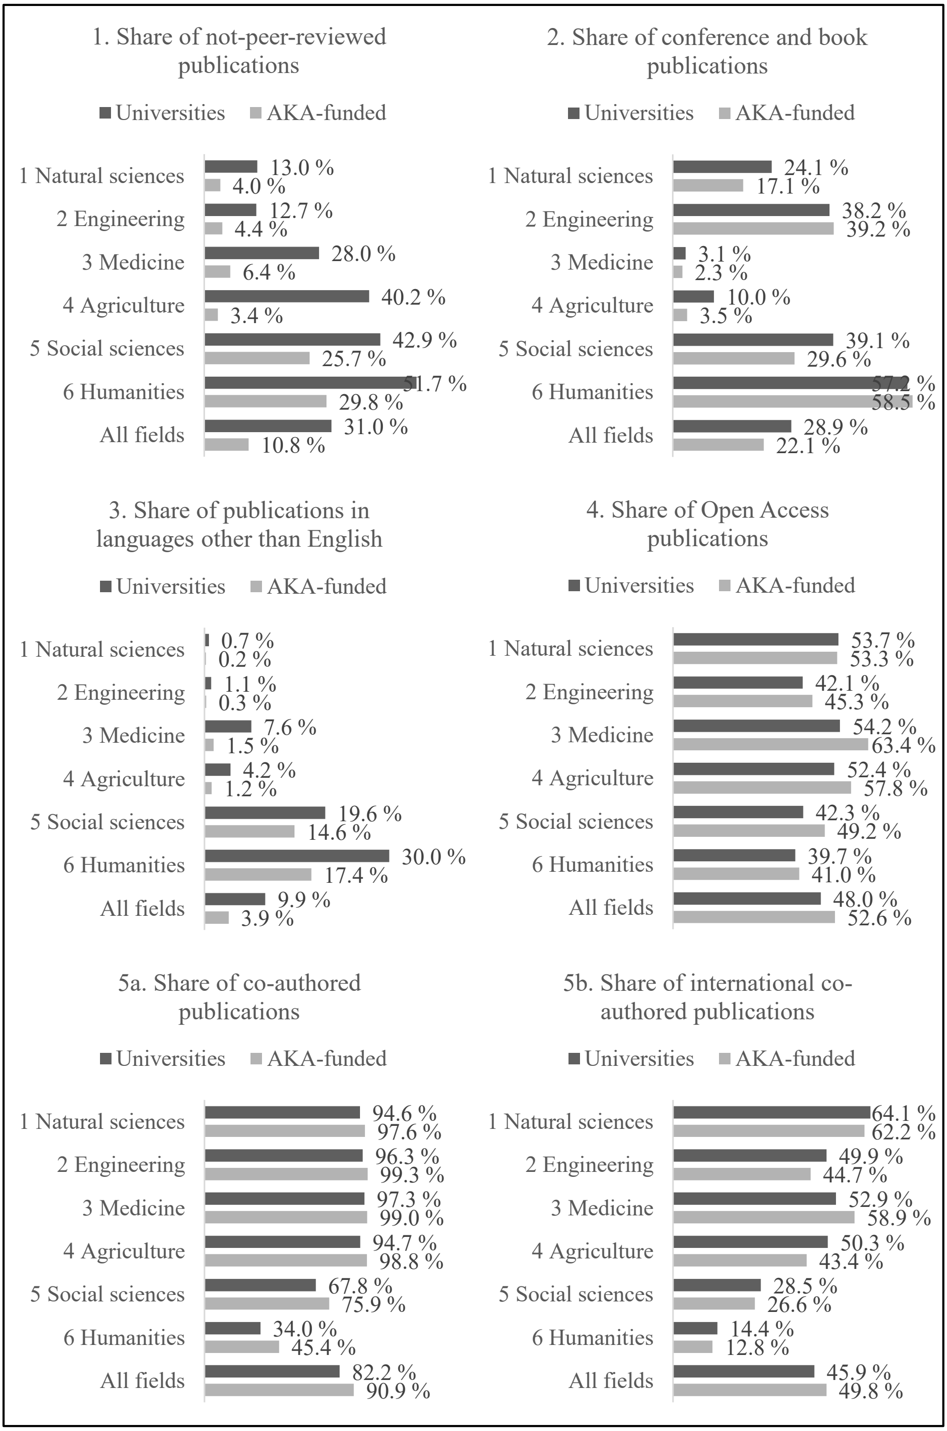

Figure 3. Scholarly communication profiles of Finnish universities and AKA-funded Projects and Fellows by main fields of science.

Discussion and conclusions

In this study we first compared the research performance of AKA-funded research and research conducted in the Finnish universities in general. Instead of bibliometric citation analysis based on WoS data, we measured research performance by using comprehensive national publication data including all publication types and languages, and the Finnish national expert-based JUFO classification of journals and book publishers as a quality-index. Indicator based on JUFO levels and the WoS based Top10 index produced consonant results, as the AKA-funded research outperforms the baseline (Finland or Finnish universities) both in the citation impact as well as in the share of peer-reviewed outputs published in journals, conferences and book publishers the JUFO expert-panels have nominated as "leading" publication channels (levels 2 and 3) (Figure 4). Similarly, AKA Fellows outperformed AKA Projects based on both indicators. The same was observed in the case of individual universities as well. JUFO-based indicator has the advantage of taking into account the disciplinary diversity and plurality of research outputs.

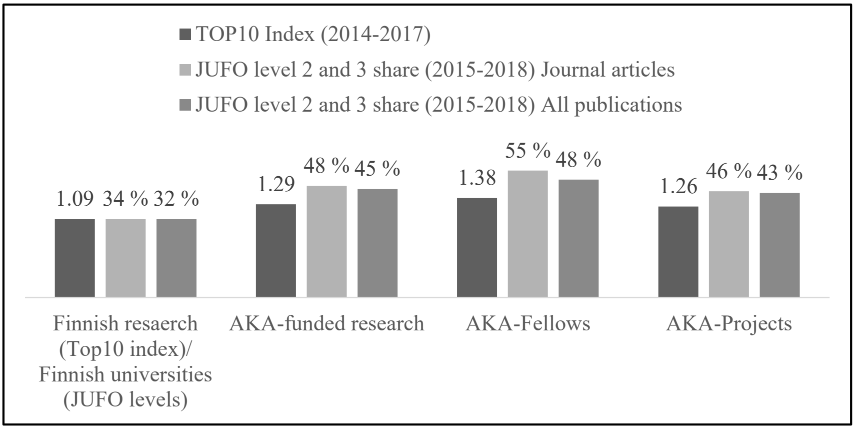

Figure 4. Comparison of Top10-index and share of JUFO levels 2 and 3 outputs as research performance indicators for Finnish research/Finnish universities, AKA-funded research, AKA-funded Fellows, and AKA-funded Projects. Both indicators have been calculated including all peer-reviewed publication types: journal, conference and book articles, as well as monographs.

The national publication data also provides added value by enabling assessment of the scholarly communication profile. We looked at publication profiles in the second part of this study, and discovered that both the Finnish universities and AKA-funded research take care of the responsibilities of science communication by disseminating research knowledge in not-peer-reviewed publications aimed at the academic, professional and general audiences. Both AKA-funded research and universities also show considerable bibliodiversity and multilingualism in peer-reviewed scholarly communication, and both show the same traditional field specific differences in target audiences, publication types, languages, and collaboration. Nevertheless, the AKA-funded research is also more focused than the universities in general on using peer-reviewed publications, articles published in journals, and English as publication language. Also, a larger share of AKA funded research is Open Access.

The Academy of Finland employs international peer-review to select most promising research for funding, with a goal of promoting high quality, renewal and impact of research. Furthermore, the AKA funding instruments included in our analysis are bottom-up funding opportunities with an emphasis on high quality of (basic) research, international collaboration and established position in the international scientific community. Funding for AKA Projects and Fellows is also rather selective, with success rates hovering between 12 and 15 % in recent years (see Table 1 at Academy of Finland, 2020e). It is expected that AKA-funded research would have a strong scientific impact internationally, as indeed shown by Top10 index. Strong emphasis on international impact and application success rates may also explain our findings that AKA-funded research is published in leading journals and book publishers, and with relatively strong preference for English as a publication language. AKA is interested in the societal impact of the research conducted by Projects and Fellows; information about this is requested both in the application and reporting phase. However, our results show that in publishing, science communication is not their priority. AKA funding criteria and policies do not privilege journal publishing as such over conference and book publishing, and indeed our findings suggest that also AKA-funded research follows traditional disciplinary patterns in scholarly communication and collaboration. As a cOAlition S member, AKA is strongly committed to Open Access to research published with its funding (see Academy of Finland, 2020f), and this policy readily explains the larger OA share of AKA-funded research.

One of the limitations of our study is that we were not able to analytically examine the influence of disciplinary variations in comparison of AKA Top10 index and share of JUFO levels 2 and 3 outputs. The main obstacle is the limited number of outputs covered by WoS in some SSH fields, as well as the small number of AKA-funded outputs in VIRTA when differentiated according to the main field. Another challenge for this comparison is due to specific disciplinary grouping used in AKA's WoS-based bibliometric analyses that is difficult to match to disciplinary classification used in VIRTA publication data.

Another possible limitation relates to reporting of outputs by researchers to institutional CRIS, from which VIRTA data is integrated, as well as reporting of outputs of AKA-funded research by the principal investigators (PI). In both cases, reporting may be less comprehensive in case of the other than peer-reviewed outputs, and there may be field-specific differences. In general, universities have a financial incentive to report outputs comprehensively, including publications for professional and general audiences as these are included among the Ministry's funding criteria since 2015. It is not clear, however, if PIs of the AKA-funded projects comprehensively report these types of publications, or if they tend to overreport the output of their projects. In addition, PIs may report only outputs published by the time they submit the final report. Reporting usually takes place several months after the termination of the project, but due to publication delays we have not been able to identify all AKA-funded outputs.

Future analyses could extend comparison to other funding instruments, of which funding programmes of the Strategic research council (STN) - hosted by AKA - would be of particular interest. This is because STN funding programmes emphasise the societal impact and interaction, which might be expected to result in somewhat different scholarly communication profiles compared to AKA funding instruments.

In all, we conclude that national VIRTA data and JUFO levels complement WoS based bibliometric analyses of research performance with a comprehensive coverage of publication output including all fields, publication types and languages. They offer a relevant information source for a responsible macro level assessment and monitoring of publication activity in several contexts in Finland, for example research assessment of organizations and research fields, or analyses of research funded via competitive mechanisms, such as the Academy of Finland funding. Currently institutional and national CRIS data cover the diversity of research outputs, however they do not support international comparisons of research performance and scholarly communication profiles. To enhance international comparisons, we suggest international integration of institutional and national publication data (Sivertsen, 2019; Puuska et al, 2020).

Abstract

Normalized citation metrics are used to analyze, manage, and fund research. The standard category normalized citation index (CNCI) metric, however, obfuscates individual entities and the role of collaboration. Given the increasing importance of collaboration, normalized metrics require additional context for decision making. Here, we compare different CNCI calculation methods for 30 institutions (covering six geo-political regions): the conventional CNCI method, Collab-CNCI (which considers collaboration), and Fractional CNCI (assigning credit). Analyzing article data from 2009-2018 highlights the steady global increase in international collaboration. Normalizing by collaboration type, Collab-CNCI suppresses the impact of multi-lateral-authored articles on CNCI mean for all institutions. Consequently, Collab-CNCI and Fractional CNCI produce comparable results but, crucially, Collab-CNCI does not assign potentially incorrect credit to institutions. Over the period, institutions in developing or newly established research economies generally show the greatest improvement in Collab-CNCI (e.g., Malaysia, China) demonstrating their research base growth; institutions in developed research economies (e.g., USA) generally show low or negative improvement, but still retain high Collab-CNCI values. The breakdown of domestic and international collaborative groups within Collab-CNCI allows managers to better contextualize institutional CNCI data and, therefore, make better informed funding decisions.

Introduction

Research activity data refer to inputs (facilities and money), activity (people and their projects), and outputs (papers and their citations); research evaluation and management require an analysis of the relationship between these. The 'value' of inputs and outputs in relation to activity differs between and within countries, between subjects, and varies temporally. Consequently, if a funder, researcher, or manager is to understand the performance of a research entity they need to adjust the raw values of both input and output data using appropriate benchmarks. Financial data are usually adjusted to Purchasing Power Parity (PPP) via internationally agreed models. Publication data are more problematic.

While the ultimate objective of research investment is the generation of knowledge that benefits wealth creation and quality of life, the proximate unit of research output is a published report of results and their significance. However, research publication rates are not constant between fields and the innate value of each output is unclear. Citations to a published work are conventionally seen as a reflection of the value that is placed on that work through its utility for later publications (Garfield, 1955). There is a growing body of work that has established that, for reasonably large samples, there is a sound relationship between citation counts (specifically, of journal articles) and peer judgments of quality in science, technology, and many social science fields, although this is less evident in the arts and humanities (Evidence, 2007; Waltman, 2016; Aksnes et al., 2019). Citations accumulate over time at a rate that is field dependent. Therefore, to create an index that is more informative for comparisons, raw counts are normalized by calculating the ratio between an observed count and the estimated global average for all papers published in the same year and subject category. This is referred to as Category Normalized Citation Impact (CNCI).

Average CNCI is widely used as a standard indicator for both national and institutional comparisons (Jappe, 2020) and is likely used by research managers within institutions as well. However, a single metric of this kind contains little information. It expresses the average ratio between the observed and expected counts for a set of documents but says nothing about the variance within the set, the proportion of high values, or the nature of the papers that contributed to the high values. It consequently has very limited value for management purposes since it has no explanatory power and suggests no action to improve or mitigate performance.

It has also become evident that collaborative papers are, on average, more frequently cited than single-author papers and that international collaboration is rising (Wagner & Leydesdorff, 2005; Wagner, 2008; Leydesdorff & Wagner, 2008) and associated with higher citation counts than purely national papers (Adams, 2012). There is sound reason to infer that international collaboration should be associated with higher impact research. The costs, as well as benefits, of collaboration are widely acknowledged (e.g., Katz & Martin, 1997; Bozeman et al., 2013) and it is reasonable to suppose that researchers normally engage in collaboration only to further such objectives as they cannot accomplish under their own control. Analysis shows that higher performing institutions typically have higher levels of international collaboration and that they tend to link to other institutions of a similar status; this is associated with exceptionally highly cited research outputs (Adams, 2013).

Some analysts suggest that the effect of collaboration, in raising average CNCI values, is in practice a distortion of the 'correct' citation impact index, if such a ground truth could be demonstrated (Waltman & van Eck, 2015). They suggest that both the credit for publishing and the credit for being cited should be apportioned fractionally among the authors, their institutions, and countries. The central benefit of carrying out such fractional counting is that country counts (e.g., of papers) can be summed to a correct world total (whereas it would otherwise be inflated by double counting) and that national average CNCI values can themselves be subsumed into a world average of 1.0 (whereas it is otherwise feasible for all countries to have a CNCI greater than the world average: Szomszor et al., 2021). This has significant arithmetic appeal and makes some derived calculations more satisfactory.

Because there is no source of truth as to the correct value of a CNCI indicator, however, it is unclear that fractional counting provides a result that delivers any management benefit: it is neither more precise nor more accurate than a full counting methodology. Furthermore, the assumption that a higher value of citation impact brought about by a collaboration should be 'corrected' and reduced by this procedure is a value laden judgment on the part of the analyst from which researchers might reasonably demur. Nonetheless, it remains true that collaborative papers do receive more citations, on average, and that highly collaborative papers (which may have thousands of authors) do appear to be of a different nature (by their authorship and their subsequent citation profile) from the bulk of research outputs (Aksnes, 2003).

The contribution of internationally collaborative papers to a higher average CNCI than a set of domestic papers on their own will not be apparent to an observer who sees only a reported net index value. Fractional counting will suppress the value (through apportionment) but still offer no management information on the result. The Institute for Scientific Information have therefore proposed an alternative approach to calculating citation impact to address the challenge of turning the data into management information (Potter et al., 2020). This variant index (Collab-CNCI) considers different levels of domestic and international authorship collaboration.

Domestic research (where publications carry author addresses from only one country) may belong to a single institution or be collaborative across several institutions, so this is a factor to consider since it may affect an institutional research strategy (Katz & Hicks, 1997). Internationally collaborative research may be bilateral (between two countries), trilateral (involving a third country) or quadrilateral-plus (involving four or more countries). Average CNCI rises from group to group with collaborative diversity (Adams & Gurney, 2018; Adams et al., 2019). The latter group could be subdivided further but they are relatively scarce in any sample. There is, however, an acknowledged argument that papers with large author counts

(~25-30 or more) should be considered as wholly different in kind and excluded from ‘standard’ bibliometric analyses.

Collab-CNCI recognizes the different outcomes of multiple authorship and benchmarks the citation count for each paper against a relevant group in the same way as conventional CNCI, whereas fractional counting apportions counts by author numbers and addresses and thereby reduces the value of authorship as collaboration rises. For example, papers that have a trilateral international authorship are judged as worth only one-third of their natural value to an author-country under fractional counting, but under Collab-CNCI are compared with the world average for similarly trilateral papers in the same Web of Science subject category and publication year. The citation value of a paper is not judged and then reduced by fractional apportionment but instead scaled as a relatively good - or poor - paper of its type. This retains the original logic of normalizing citation counts.

Using a defined group of institutions spread globally, we compare Collab-CNCI results with full (conventional CNCI) and fractional counting methods to investigate improvement over a ten-year period. From this, we examine the disaggregated CNCI values of the different components that make up Collab-CNCI. Finally, we review the management value of using comparative CNCI indices and the enhanced information presented by deconstructed profiles.

Methods

The data source was all documents with type article indexed in Web of Science Core Collection (i.e., including the Emerging Sources Citation index ESCI) over a ten-year period from 2009 to 2018. This is the same source used in Potter et al. (2020).

To cover a range of regions and institutional size, as well as minimizing computation time, five institutions were chosen from each of six geo-political regions (North America, Western Europe, Eastern Europe, Middle East-North Africa-Turkey [MENAT], South East Asia, and China) for analysis. Institutions, based on the Enhanced Organization name labels assigned in address data within the Web of Science, were chosen from those who (co)authored at least 5,000 articles over the ten-year period. These chosen institutions produced a dataset covering ~1.2M articles.

The metrics to investigate performance were CNCI, Collab-CNCI, and Fractional CNCI. CNCI was calculated by normalizing an article’s citation count by document type, year of publication, and Web of Science subject category. For an article in multiple Web of Science categories, the average CNCI of these categories was assigned to the article. Each unique institution listed in the article address was allocated full credit. Thus, if an article with two institutions had a CNCI of 1.3, each institution was awarded an article count of 1.0 and a CNCI value of 1.3. An institution’s mean CNCI was then calculated by summing the CNCI of all the articles on which the institution was recorded in an author address and dividing this by the number of such articles, over the entire dataset.

Collab-CNCI, defined by Potter et al. (2020), uses collaboration type as an additional normalization factor. The collaboration types, based on author address data, are divided into domestic: single (authors from the same institution) and multi (authors from more than one institution within the same country), and international: bilateral (two countries), trilateral (three countries), and quadrilateral-plus (four or more countries), regardless of the number of institutions. Each institution on each article was assigned the appropriate collaboration type. As with conventional CNCI, an institution was given full credit and the full CNCI value for an article, though the mean CNCI was calculated considering each collaboration-type separately (e.g., only an institution’s international bilateral articles were considered when calculating the institution’s CNCI for international bilateral).

Fractional CNCI was calculated at the author level based on the method of Waltman and van Eck (2015); this method assigns credit to each author, institution, country etc. based upon the total, deduplicated number of each on an article. The reader is referred to Waltman and van Eck (2015) for additional information.

As this study uses Web of Science data, it should be noted that an equivalent analysis using other indexing services may yield slightly different results.

Results

The calculated CNCI indicators for the chosen ten-year period are listed in Table 1 for each of the five institutions selected in each region along with the total number of articles considered. Since we are interested in trends relating to perceived improvement in citation impact, we provide the CNCI indicator for the first and last year in the study period (2009 and 2018) along with the percentage improvement (%+ column).

Table 1 - Institutional CNCI indicators (CNCI, Collab-CNCI and Fractional CNCI) and their relative improvement (%+ column) over the 10-year period 2009-18.

There is significant variation in trends over the period, as would be expected from choosing such a diverse set of institutions. When considering conventional CNCI, institutions in most regions have increased their performance, especially in China, MENAT, Eastern Europe, and South East (SE) Asia where CNCI has often risen from below 1.0 (world average). In Western Europe and North America, some institutions show an increase, some are relatively stable, and others decline slightly.

When reading across to compare Collab-CNCI or Fractional CNCI, a different picture emerges. Institutions from China and Eastern Europe still show apparent increases (albeit smaller), but improvement is suppressed (or in fact, negated) in Western Europe and North America. In MENAT and SE Asia, some institutions have contrary trends when comparing CNCI to Collab-CNCI or Fractional CNCI. For example, the percentage improvement for Cairo University with CNCI is 38.4%, but only 6.9% with Collab-CNCI and -19% with Fractional CNCI. Others, such as Islamic Azad University and University of Malaya, show improvement across all three CNCI indicators.

To illustrate these trends over time, we provide a time-series for the CNCI indicator in Figure 1 (left) for a sample institution in each region. Alongside this (right), the relative growth in internationally co-authored papers is plotted. In all cases, significant growth is seen in the abundance of these collaborative papers, but it is not possible to ascertain from this information whether these papers are responsible for the increase in CNCI.

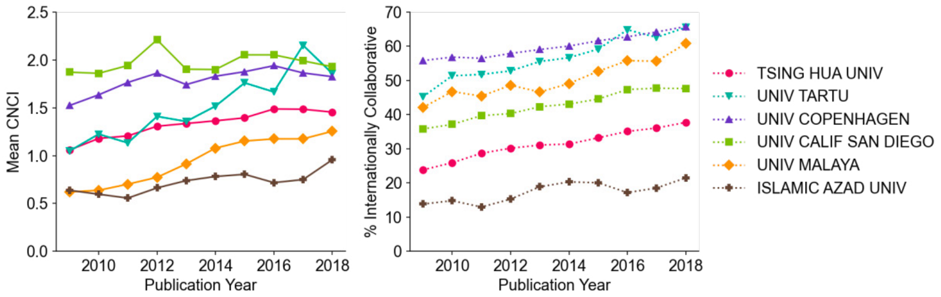

Figure 1 - Mean CNCI (left) and % papers with an international co-author (right) for six sample institutions.

For comparison, a timeseries is plotted in Figure 2 showing the Collab-CNCI indicator (left) and Fractional CNCI (right) over the same time period. Such a plot draws attention to the difference and similarities in trends. For example, Tsing Hua University sees consistent improvement across all CNCI measures, but University of California San Diego changes from relatively consistent performance for CNCI, to a slight decline with Collab-CNCI, and more moderate decline with Fractional CNCI.

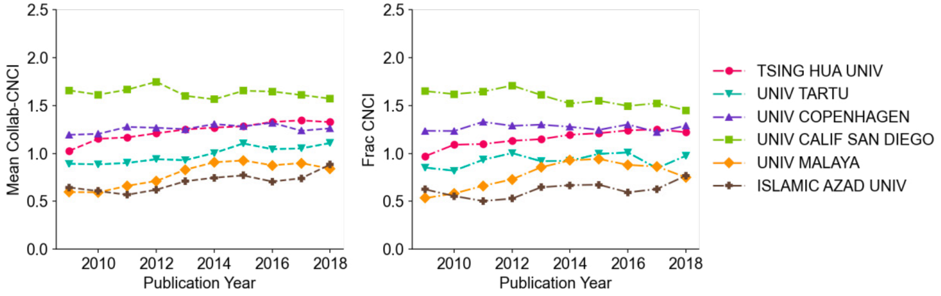

Figure 2 - Mean Collab-CNCI (left) and Fractional CNCI (right) for six sample institutions.

The effect of individual collaboration groups on CNCI values for three sample institutions (Islamic Azad University, Iran; Tsing Hua University, China; University of Copenhagen, Denmark) over the ten-year period is highlighted in Figure 3. As research becomes more collaborative the mean CNCI value increases. This is particularly notable for quadrilateral-plus articles where mean CNCI values are ~1-3 times greater than the other collaborative groups. The quadrilateral-plus articles also have the most variance over the ten years.

The collaboration normalizing effect of Collab-CNCI is clear – the mean for international quadrilateral-plus articles is dramatically suppressed (other international groups are also suppressed) resulting in similar values to the other collaboration types centered approximately around world average (1.0).

The figure also highlights changes in article output between the institutions. The University of Copenhagen, Denmark (the longest established research economy of the three) shows little variation in CNCI over the ten-year period. However, the number and percentage share of quadrilateral-plus articles has doubled (2009 vs 2018) along with a halving of the relative share of domestic single articles. As of 2018, University of Copenhagen had a relatively even share of articles across all groups. Despite its relatively large share of international quadrilateral-plus papers (~23%), this group's (Collab-) CNCI is no better off than its comparators who have a far lower share (<<10%).

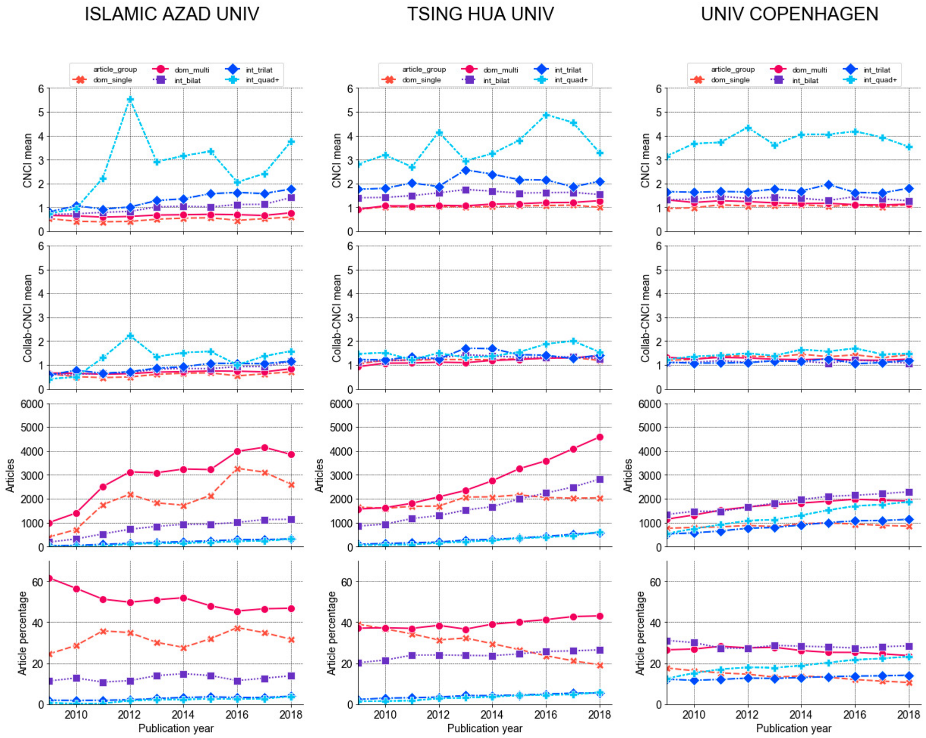

Figure 3 - CNCI and Collab-CNCI mean, and article number and percentage share by publication year for three sample institutions.

Tsing Hua University (China – a growing research economy) shows a two-to-three-fold increase in absolute article number over all collaborative groups, bar domestic single which has remained constant resulting in a relative decrease in its article share (~40% in 2009 vs ~20% in 2018). Domestic multi articles is now the dominant type (~40%), with only incremental changes in international collaboration.

Islamic Azad University (Iran - a developing research economy) has also seen significant increase in article output over the ten years, though in a less consistent manner than Tsing Hua

University. Unlike its comparators, Islamic Azad's domestic single output increased over the period. Domestic multi decreased by a third; international groups again only incrementally improved their share.

Despite their much lower share of international trilateral and quadrilateral-plus articles, Islamic Azad and Tsing Hua have comparable, if not greater, (Collab-) CNCI values for these groups relative to University of Copenhagen. Overall, Copenhagen was the worst improver of these three in terms of Collab-CNCI (5.6% vs 29.2% [Tsing Hua] vs 37.1% [Islamic Azad]).

Discussion

CNCI, while providing a normalized value for institutional comparisons, does not reveal the intricacies of an individual institution's profile, particularly that of collaboration. The Collab-CNCI method does take collaboration into account and can change institutions' metric values (Table 1). Institutions ranked highly by the CNCI metric are more likely to see negative effects in their CNCI improvement when calculated by Collab-CNCI over the ten-year period (e.g., Harvard, MIT, Oxford). This is because such institutions are likely to have strong relative performance across all collaborative groups and already be more internationally collaborative, compared to institutions from developing research economies. This is further highlighted by institutions in Malaysia, Saudi Arabia, Hungary, and China having some of the greatest improvement in Collab-CNCI over the ten-year period. Though well-regarded institutions may show low or negative improvement, when comparing 2009 to 2018, they remain the most highly ranked institutions by Collab-CNCI. Additionally, the (Collab) CNCI improvement metric only considers the raw change in CNCI over the period (i.e., citation pattern changes); interpretation of this in respect to research quality is a separate issue and should be considered along with other performance indicators.

Fractional CNCI, for the chosen sample institutions, provides comparable trends and outcomes to Collab-CNCI (Figure 2). Crucially, however, Collab-CNCI does not assign potentially incorrect credit to each party, while still accounting for collaboration. Due to this, we advocate the use of Collab-CNCI over Fractional CNCI for analysis purposes.

The results further demonstrate the increase in international collaboration over time. In particular, the growth of output in the developing research economies compared to those established ones (Figure 3). Of the individual collaborative groups, international quadrilateral-plus shows the biggest difference between CNCI and Collab-CNCI; the additional normalization demonstrating that these multi-lateral, highly cited articles skew the regular CNCI values. This group also contains the highest variance temporally, due to this group being the smallest by article count (e.g., Figure 3).

The disaggregation of Collab-CNCI into the constituent groups provides an additional level of information and insight that cannot be gained from the single metric value. This, therefore, allows research managers and funders to better contextualize relative performance across and within institutions and, hence, make better informed funding decisions.

Abstract

Although variety of concerns with the postdoc have been growing internationally, scoping or systematic reviews of research on the topic have been limited to a single field and/or a particular concern, and none have considered publication performance per se, which is arguably a central concern of the postdoc. I address this gap through a scoping review of empirical evidence on the postdoc in general, as published over the past five decades, in terms of volume and research design. I also determine, both quantitatively and qualitatively, the contribution of bibliometrics – as an approach to measurement of publication performance – to that body of evidence. All document types indexed in Web of Science and/or Scopus (1970–2020) were searched for spelling variants/derivatives of "postdoc" in the title field. Manual inspection of search results and full-text versions applied predetermined definitions of "the postdoc" and "empirical research". Data on the resulting 260 sources of evidence were analysed, showing an increase in the volume, and the dominance of surveys and secondary analysis, which renders systematic reviews of these feasible. This does not apply to bibliometrics, which has made a small contribution, mostly as part of evaluation studies, and subject to methodological limitations and knowledge gaps.

Introduction

Although there is a lack of a systematic, global definition of the postdoctoral appointment, or "postdoc" (Åkerlind, 2005), for the purposes of this paper it is defined as a temporary position, after completion of a doctorate, taken primarily for additional training, in particular advanced research apprenticeship under supervision (Gaughan & Bozeman, 2019). The earliest postdoctoral appointments (which were in the United States) have been traced back to the 1870s (Zumeta, 1985). In other countries, the postdoc is a comparatively new phenomenon, but viewed globally, the postdoc as an institution has become increasingly common in the past few decades. Its growth has not been without concerns about, for example, their potential or actual status of precarity, and their status as neither staff nor students. There is, however, consensus that postdocs are first are foremost researchers (or at least should be), thus their research production – before, during and after their position – should also be a central concern.

The rationale for this scoping review was informed more generally by my interest in studying the postdoc in South Africa – through a survey and bibliometrically – and specifically by my realisation that only five scoping or systematic reviews have been conducted on the topic internationally (Numminen et al., 2020; Treichler et al., 2020; Nowell et al.; 2019; Nowell et al., 2018; Ranieri et al., 2016). Moreover, these were limited to one field and/or to a particular issue, and did not consider research production per se.

To address these knowledge gaps, I conducted a scoping review of the available empirical evidence on the postdoc, across fields and topics, to determine (1) its volume over the past five decades (1970–2020); and (2) the designs employed to produce the evidence. As a precursor to future systematic reviews, this quantitative part of my scoping review allowed me to assess the feasibility of such future initiatives, but also to determine the extent to which postdoc-related publication performance has been studied using bibliometric data.

I then performed a more in-depth analysis of the instances of bibliometrics this identified, by employing both quantitative and qualitative content analysis to understand, in more depth, why and how bibliometric data were collected and analysed, and in which context (country and field). However, following Peters et al.'s (2020, p. 421) guidelines, I did not undertake thematic analysis or evidence synthesis, as this would be "beyond the scope of a scoping review". Rather, my focus was on methodological limitations as well as possibilities, and knowledge gaps in terms of context studied, that may be addressed by future bibliometricians interested in studying the postdoc.

Methods and procedures

Inclusion criteria

The core concept examined by the scoping review is the "postdoc", and the following definition of a postdoctoral researcher – agreed upon by the United States of America (USA) National Postdoctoral Association, National Institutes of Health, and National Science Foundation – informed my inclusion criteria: an "individual who has received a doctoral degree (or equivalent) and is engaged in a temporary and defined period of mentored advanced training to enhance the professional skills and research independence needed to pursue his or her chosen career path" (Institute of Medicine, 2014, p. 3). I kept in mind that this USA-based definition does not take account of cross-national differences in the definition of the postdoc, as highlighted by Åkerlind (2005), but (as detailed below) it emerged as the most useful operational definition to apply. My review considers not only research on postdocs as individuals, but on issues, other individuals and/or institutions related to "the postdoc".

Based on the assumption that sources of evidence that I was interested in reviewing – those focusing exclusively, or primarily, on the postdoc – would include this term in the title, I searched for two accepted spelling variants, as well as the derivatives, of the term (expressed as the string "postdoc* OR post-doc*") in the (article) title field. As I was interested in empirical evidence of comparable quality, and working within constraints of time and resources, only the Web of Science (WoS) Core Collection and Scopus were searched. These two "world-leading […] citation databases" are "widely used in meta-analysis related studies" (Zhu & Liu, 2020, p. 321). Because of its somewhat broader coverage (Aksnes & Sivertsen, 2019; Mongeon & Paul-Hus, 2016), Scopus was used to augment the results of the WoS search.

However, I recognise that both databases have deficiencies in relation to the social sciences and humanities, and the coverage of literatures in other languages than English. Also, I deviated from Peters et al.'s (2020) three-step search strategy for scoping reviews, namely (1) an initial limited search of at least two appropriate online databases relevant to the topic; (2) a second search, using keywords and index terms identified from the first search, across all included databases; and (3) a search of the reference list of identified sources, for additional sources.

To counteract the potential limitations of my search strategy, I kept my review as "open" (Peters et al., 2020, p. 410) as possible, by placing no limitation on document type, language, contextual setting (e.g., discipline, country) or other criteria. Rather, I applied (manually, to full-text versions) a definition of "empirical research" as conforming to a standard logic, namely the ProDEC framework. "ProDEC" refers to the four elements that are standard in all forms of empirical research: a research problem (Pro), research design (D), empirical evidence (E) and conclusions (C) (Babbie & Mouton, 2001). If at least three of these elements were reported by authors, who themselves conducted the research (i.e., excluding science journalists' reports, usually in trade journals), the source was included.

Sources of evidence published before 1970 were excluded, because WoS searches are limited to publications published from 1970 onwards, and Scopus includes references on publications back to the same year. In addition, postdoctoral training had not been fully institutionalised prior to 1970 (Reskin, 1976). Sources of evidence published up to the end of December 2020 (including early-access publications) were searched, and the time frame is therefore exactly 51 years (approximately five decades).

Search strategy, source selection, full-text retrieval and data extraction

Starting in March 2020, WoS was searched first. Each of the 1 296 results of the search strategy were examined, and two main types of sources were excluded: (1) "noise", e.g., "postdocetaxel"/"post-docetaxel" in the title; and (2) sources that could clearly and unequivocally be considered non-empirical, based on a relatively brief examination (mainly calls for applications for postdoctoral fellowships; announcements of successful applicants for such fellowships; and book reviews). For the remainder of the 444 sources, the following two actions were performed: (1) the full-text was retrieved or requested through an interlibrary-loans service (hard copies received were scanned); and (2) relevant data on each source were extracted from WoS and entered in an Excel spreadsheet. The process was repeated for Scopus, which produced 1 288 results, the majority of which were duplicates of the WoS results. After exclusion of these and the two types on sources referred to above, full-text retrieval and data extraction were undertaken for the remaining 367 sources. These processes were repeated in January 2021, to ensure inclusion of as many sources published in 2020.

The next stage involved assessing the 811 sources in the data set to determine whether they met above-mentioned, predetermined inclusion criterion of "empirical research". The classification was based on the extraction of methodological and other data from the full-text versions that had been successfully retrieved for all but three of those sources (two Portuguese articles and a German one). For these three sources, as much methodological data as possible were extracted from their English abstracts. During full-text examination, the data set was further refined, through the exclusion of 31 sources because they either (1) employed a wider definition of "postdoc/toral" than the one I chose to apply (e.g., academics with a PhD; the general career stage after attaining a PhD); or (2) reported on research concerning postdocs and other groups (e.g., postgraduate students; junior faculty), and did not disaggregate the postdocs from these other groups.

Of the remaining 780, I classified 260 (33%) as sources of evidence produced by empirical research. The majority (220, or 85%) are articles, and the remaining 40 are comprised of relatively similar numbers of editorial material (12); conference papers (9); reviews (8); and book chapters (7). Two books (or, rather, committee reports), one meeting abstract (comprising 13 pages) and one "note" (comprising 26 pages) were also included. The majority of the items (210, or 81%) were sourced from WoS. Six are not written in the English language, but sufficient methodological data could be collected for accurately coding of research design of all but one of these, which was excluded from the analysis of design.

This explicit (and rather lengthy) description ensures that my review is transparent and reproducible. However, it should be noted that I was the only reviewer, while Peters et al. (2020) require that source selection should be performed by two or more reviewers, independently.

Data processing and analysis

One of the aims of my quantitative analysis was to identify and determine the proportion of sources of evidence on the postdoc that were produced, at least in part, by bibliometric research. I therefore classified designs inductively, through immersion with the full-text versions, focusing mainly on the type of data collected and/or analysed. Designs such as case studies, action research, field experiments, mixed methods designs and evaluation studies tend to collect and/or analyse data from various sources, and were therefore coded according to the combinations of types of data collected and/or analysed. In the case of evaluation studies, I focused on the methods used to measure outcomes of an intervention. It should also be noted that this design category (re-)emerged as useful in the in-depth analysis of the sub-set of bibliometric sources of evidence.

Approximately a fifth of the sources report on a wide variety of combination of two or more designs, therefore the individual designs, and not the sources of evidence, were taken as the unit of analysis. After coding had been completed, the data were exported to IBM SPSS Statistics (version 27), to conduct quantitative, univariate analysis. Based on this analysis, the full-text versions of the instances of bibliometric research could be identified, and these were subjected to quantitative and qualitative content analysis, with a focus on when, why, how and in which context (country and field) the bibliometric evidence was produced.

Findings

Quantitative results of an analysis of sources of evidence on the postdoc

The 260 sources of evidence on the postdoc were published over 48 years (1973–2020). Table 1 summarises the distribution of the sources over these (roughly) five decades, showing that two-thirds of the sources of evidence were published in the past 11 years. Percentages decline quite rapidly as one moves back in time, and are very low prior to 1990. On average, in the 1970s and 1980s less than one source was published per annum, increasing to 2,5 in the 1990s, and doubling to approximately five in the 2000s. In the period 2010–2020, however, the average increases more than three-fold, to 15,8 sources published. The past six years were particularly productive in terms of evidence on postdocs published: 2018 leads with 29 publications, followed by 2020 (26), 2016 (23) and 2015 (22).

Table 1. The distribution of sources of evidence (n=260) published in the period 1973–2020.

Year range	*Frequency*	*Percent*	*Mean*
1973-79	6	2%	0,9
1980s	8	3%	0.8
1990s	25	10%	2,5
2000s	47	18%	4,7
2010-20	174	67%	15,8
Total	**260**	**100**	

Figure 1 summarises the 320 designs that were applied in 259 of the sources of evidence in my data set.

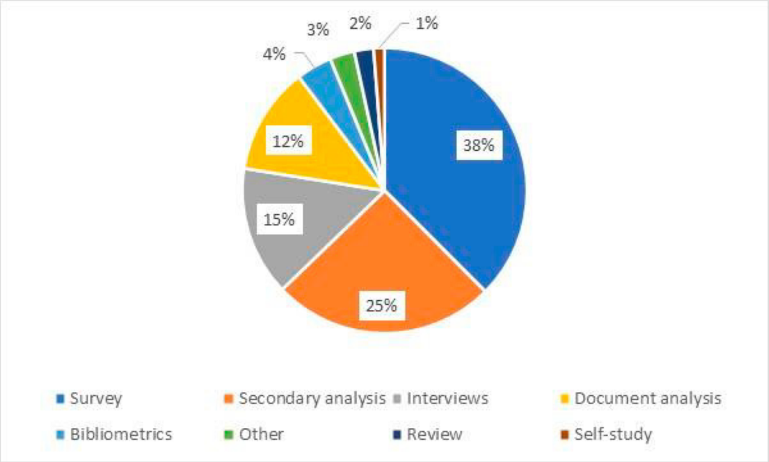

Figure 1. Distribution of research designs (n=320 designs)

As I derived my classification from the data itself, rather than using preconceived categories, some clarification of the categories is provided as part of the results. Of the 320 individual designs that were reported, more than a third (38%) are surveys, using questionnaires (or in very few cases, structured interviewing) to collect quantitative or quantifiable data on more than one case. Another quarter (25%; n=81) of the designs involved the secondary analysis of existing data (or statistics) collected by institutions (ranging from national governments to administrators of a funding programme), or researchers other than the authors. Interviews (n=47) were third-most frequently applied (15%). These ranged from semi-structured to in-depth interviews with a relatively small number of participants, and were coded as such if the data and analysis were primarily qualitative in nature.

Document analysis constitutes 12% (39) of the designs. The term "document" covers a very wide range of different kinds of source, but following Bryman (2012), they can be classified as follows: personal documents [e.g., curriculum vitae (CVs) and funding applications]; official documents deriving from either the state (e.g., policy reports and legislation) or private sources (e.g., funders' guidelines or requirements); virtual outputs (e.g., websites and social-media platforms); and mass-media outputs (e.g., job advertisements).

This defined, document analysis (or even of secondary analysis) may include bibliometrics, but I distinguished it as a unique design, if it conformed to the definitions of Thompson and Walker (2015, p. 551) and of Godin (2006, pp. 109–110), namely "the application of mathematical and statistical methods to scholarly publications" to measure the "output side of science". Only 4% of the designs met this definition, and these 13 instances will be described in more detail in the next sub-section of my findings.

The remaining designs are "review" (a sub-set of document analysis) and "self-study". The seven instances of reviews include the five scoping or systematic reviews on the postdoc that I referred to in my introduction, as well as two (Towns et al, 2017, and Sherry et al., 2103) that do not meet the criteria of such reviews but were used to collect empirical evidence. Self-study (n=4) is "a reflective, analytical approach to understand the authors' individual and shared experiences, practices, and insights" (Ovens & Fletcher, 2014, as cited in Nowell, Grant & Mikita, 2019, p. 306). Nine designs were too unique to be classified into one of these seven categories, and were thus coded as "other". The remainder of this paper provides the results of a content analysis of those 13 sources of evidence on the postdoc that involved, at least in part, a bibliometric component.

Results of a content analysis of bibliometric sources of evidence on the postdoc

Only two of the 13 sources of bibliometric evidence were not published as articles, but as editorial material (specifically a commentary) (Mbuagbaw et al., 2018), or a peer-reviewed conference paper (Zabetta & Geuna, 2019). All but one (De Castro & Porto, 2012) were sourced from WoS, and for this article, only the abstract is available. The summary in Table 2 below shows that, in line with the sources of evidence on postdocs in general, the majority (n=9) of the bibliometric sources were produced in the past decade. After Reskin's 1976 article, almost 30 years passed before the postdoc was again analysed bibliometrically (and then only three times in the 2000s).

The majority (n=10) of the sources may be classified as evaluative bibliometrics (van Leeuwen, 2004), and of these, most (n=7) evaluate one, or a small number of similar, interventions. In these cases, bibliometrics is used to primarily to determine their publication-performance outcomes. These interventions are (in order of earliest to latest publication date): the Burroughs Wellcome Fund Career Awards in the Biomedical Sciences (Pion & Ionescu-Pioggia, 2003); the Canadian Association of Gastroenterology – Canadian Institutes of Health Research – pharmaceutical partner postdoctoral operating fellowship programme (McKay & Daniels, 2003); the Boehringer Ingelheim Fonds (Bornmann & Daniel, 2006); the NIH National Institute of General Medical Sciences Kirchstein-NRSA F32 grant (Levitt, 2010) and the more general NIH F32 grant (Jacob & Lefgren, 2011); two funding instruments of the Council for

Independent Research in Denmark, focussing on three research councils (Schneider & van Leeuwen, 2014); the CIHR Canadian HIV Trials Network international postdoctoral fellowship for capacity building in HIV clinical trials (Mbuagbaw et al., 2018); and three prestigious NASA fellowships (Hubble, Einstein and Sagan) (Pepper et al., 2019). The exceptions are Reskin's study of the impact of postdoctoral fellowships on productivity in one field, and two studies on the effect of appointments or training abroad, i.e., outside of Portugal (De Castro & Porto, 2012) and Italy (Zabetta & Geuna, 2019).

Table 2. Summary of features of sources of evidence (n=13) produced by bibliometric analysis (1976–2019)

Author(s)	*Pub. date*	*Time frame*	*Sample size (publications)*	*Country*	*Discipline/field*
Reskin	1976	1955–1970	450	USA	Chemistry
Pion & Ionescu-Pioggia	2003	1995–2000	101	USA & Canada	Biomedical sciences
McKay & Daniels	2003	1992–2000	87 (247)	Canada	Gastroentorology & related disciplines
Bornmann & Daniel	2006	1990–1995	397 (1 586)	Germany	Biomedical sciences
Levitt	2010	1992–2009	439	USA	Basic life sciences
Jacob & Lefgren	2011	1980–2000	12 189 (13 426)	USA	Biological sciences (predominantly); physical, social & "miscellaneous"
De Castro & Porto	2012	Unknown	86	Portugal	Biology, engineering, geosciences & health sciences
Miller & Feldman	2014	1993–2006	N/A	USA	Life sciences
Schneider & van Leeuwen	2014	2001–2009	632 (6 196)	Denmark	Health, natural & technical sciences
Igami, Nagaoka & Walsh	2015	2001–2006	4 410 (≈10 000)	USA & Japan	Natural sciences
Mbuagbaw et al.	2018	2010–2015	6 (40)	Canada	HIV (clinical)
Pepper et al.	2019	2014–2017	133	USA	Astronomy
Zabetta & Geuna	2019	1986–2015	15 385 (285 283)	Italy	All

The interventions that were studied differ widely in scope (i.e., number of applicants and/or awardees), and all 13 sources of evidence differ widely in terms of the time frame studied. The bibliometric data that were analysed range over six decades (1955–2017); on average (and excluding one unknown time frame), the studies cover 11 years, with a maximum of 29 (Zabetta & Geuna, 2019), and a minimum of three (Pepper et al. 2019). Thus, it is not surprising to find great variability in terms of sample size. Excluding one study that analysed universities (Miller & Feldman, 2014), the sample sizes range from a minimum of 40 publications produced by six postdoc recipients of a single fellowship (Mbuagbaw et al., 2018), to a maximum of 285 283 publications of 15 385 individuals (Zabetta & Geuna, 2019). The median is ≈400. Notably, three of the studies (Pepper et al., 2019; Bornmann & Daniel, 2006; Levitt, 2010) focused on an "elite" population, and one on fast-moving and competitive scientific research (Igami, Nagaoka & Walsh, 2015).

In evaluations, the impact of these interventions on subsequent scientific productivity is a central, bibliometrically evaluated concern. However, the methodological rigour (especially a comparison or control group) required to determine such impact is lacking in at least three evaluations. McKay and Daniels (2003) conclude, based on very little evidence, that the fellows of the programme they evaluated "have performed admirably" in terms of both publication rate and publication quality, and – as the title of their article indicates – they assessed the programme as "an outstanding success that continues to excel!" (p. 437). Similarly, in Mbuagbaw et al.'s (2018) "commentary" (editorial material), the 23 authors conclude, also on the basis of scant bibliometric evidence, that the fellows have built a strong network of collaboration and scientific productivity. Pion and Ionescu-Pioggia (2003) is the third instance of such a practice, but they recognise the limitations of lacking an appropriate comparison group, and temper the veracity of their conclusions accordingly.

Three years later, Bornmann and Daniel (2006) addressed this issue by comparing not only successful and unsuccessful applicants, but also their population's values with international scientific reference values. Jacob and Lefgren (2011) followed suit, with their inclusion of both successful and unsuccessful applicants. Importantly, they warn against "naïve comparisons" in this regard, as these "may be biased upward, reflecting both the causal impact of receiving a fellowship as well as differences in latent scientific productivity (or interest)" (p. 866). Five years later, Schneider and van Leeuwen (2014) again improve in terms of this and other methodological issues involved in the evaluation of postdoc-related interventions. Their conclusion is different from the official conclusion given in an evaluation report, which emphasises the success of the funding programmes (reminiscent of McKay and Daniels, 2003, as well as Mbuagbaw et al., 2018). All three of these studies provide valuable descriptions of empirical strategies that have been used by the authors to increase the robustness of findings.

A need for a "logic of comparison" (Bryman, 2012, p. 58) was addressed somewhat differently by De Castro and Porto (2012), who compared scientific production before and after postdoc training, taking account journal quality, and whether the training was abroad or local. Similarly, Zabetta and Geuna (2019) compared internationally mobile postdocs with a matched control group of their non-internationally mobile counterparts. Interestingly, three studies also compare women and men (Reskin, 1976; Levitt, 2010; Pepper et al., 2019). In addition to the evaluation studies, two econometric analyses utilised bibliometric data to study the contribution of postdocs to research productivity across institutions or countries. The first (Miller & Feldman, 2014) considered research productivity in more general terms, while Igami, Nagaoka and Walsh (2015) focused on postdocs contribution to fast-moving and competitive scientific research.

Next, I consider sources of bibliometric data analysed by the 11 publications for which these were specified. The sources are relatively standardised, with at least half using WoS (or its previous designations, such as SCI and ISI Web of Knowledge, including Journal Citation Reports). Other sources include Chemical Abstracts (1976), PubMed (Levitt, 2010), Google Scholar (Mbuagbaw et al., 2018), Scopus (Zabetta & Geuna, 2019) and the NASA Astrophysical Data System (Pepper et al., 2019).

Two other, less-common sources of bibliometric data deserve mention. Miller and Feldman (2014) sourced average citations per publication from the USA's National Research Council Assessments of research doctoral programmes, to weight publication counts. Pion and Ionescu-Pioggia (2003) collected citation data from SCI, but considered the resulting citation rates difficult to interpret, because "no clear standard exists for judging young faculty's performances on this measure" (p. 184). They therefore also measured the percentage of publications in top-ranked journals, not identified as such bibliometrically, but "by intramural NIH scientists as the 23 most prestigious journals in which to publish basic biomedical and clinical research papers" (Hooper, 1984, as cited in Pion & Ionescu-Pioggia, 2003, p. 184).

Importantly, the bibliometric data that were collected were not only used to measure scientific productivity. A prime example is Zabetta and Geuna (2019), who used (1) affiliation data to deduce a postdoctoral appointment abroad and to build a variable on home country linkages; and (2) publications and citations during the PhD as two of six characteristics on which they matched a treatment group with a control group. Igami, Nagaoka and Walsh (2015) used bibliometric data to measure speed of advancement of research, in terms of citation time lag.

If bibliometric data were used to measure scientific productivity, the unit of analysis was not always the postdoc, as illustrated by Levitt's (2010) study of the influence of mentors' scientific on postdocs careers. However, some uses of bibliometric data involve some precarious assumptions. Zabetta and Geuna (2019) used only affiliation data to identify "researchers who, after the PhD and before the first appointment in Italian academia" published with a non-Italian affiliation for "some time", (p. 4), and equated these academics with those that "undertook a postdoctoral appointment before entering the Italian academic system" (p. 2). Similarly, Levitt (2010) assumed a postdoc's mentor to be the senior author on the publications of the postdoc from the fellowship institution during or shortly after the period of the fellowship.

All the studies depended on other data sources for sample identification and/or further analysis. Some of these data were publicly available, for example online websites and CVs (Pepper et al., 2019), and NIH administrative records (Levitt, 2010; Jacob & Lefgren, 2011). Pepper et al. (2019) used CVs also to verify publication records – an interesting variation on the practice of contacting researchers to validate publication lists, which is considered normal in the design of a bibliometric analysis (van Leeuwen 2007, as cited in Schneider and van Leeuwen, 2014, p. 292). Lists of publications were also verified against online databases (Bornmann & Daniel, 2006). In two other cases, the researchers used data they themselves had collected through previous surveys (Igami, Nagaoka & Walsh, 2015; Zabetta & Geuna, 2019), to create an initial sample.

In a third set of sources of evidence, the research was only possible because of access to data that are not publicly available. One case in point Schneider and van Leeuwen (2014), whose bibliometric analysis formed part of a study they were commissioned, by the Council for Independent Research in Denmark, to conduct. Thus, the authors had access to all postdoc grants from 2001 to 2009, including grant information, names, and demographic data (compiled by the Danish Ministry of Science and Innovation), from which they drew their sample of (matched) funded postdocs. They further mention that they had access to data on a general population of researchers in Denmark for the same period, from which they sampled their control group. In other cases, the sources of non-bibliometric data are vague, and it may be deduced that their availability was dependent on the authors' positionality as evaluators of interventions. For example, CVs that are submitted annually by individuals with active awards from a programme were available to an author who is senior programme officer (Pion & Ionescu-Pioggia, 2003).

Finally, I consider the context (country and field) on which the evidence was produced. As international mobility is often associated with the postdoc, it is sometimes difficult to code studies on the postdoc according to this variable. Other information such as the non-bibliometric data sources used, the country/ies a programme supports, and citizenship or permanent residency criteria that apply to applicants were taken into account. The results show that the bibliometric analyses focused most often on the USA, European countries (Germany, Portugal, Denmark and Italy), and Canada. However, in the case of one "Canadian" study (Mbuagbaw et al., 2018), the six fellows studied are mainly located in African countries (Cameroon, Lesotho, South Africa, Uganda and Zambia), as well as in China. In terms of field, the medical and life sciences dominate, followed by the natural sciences. Only two studies (Jacob & Lefgren, 2011; Zabetta & Geuna, 2019) included other fields, such as the social sciences.

Discussion

This paper reports on the results of the first scoping review of (1) sources of empirical evidence on postdocs across fields and topics; and (2) the contribution of bibliometrics to that evidence. The sources in my data set as a whole range from 1973 to 2020, increasing in small increments from a very low base in the first two decades to the next two, but followed by a significant increase in volume over the past decade. This growth pattern differs from the "exponential growth of global scientific publication output" as measured for the period 1980 to 2012 (Bornmann & Mutz, 2015:2217), and its relationship with wider other developments in science systems internationally would be an interesting avenue for future research.

The numbers of sources of evidence on the postdoc seem to indicate feasibility for systematic review. However, if a particular topic or field were to be selected, the numbers would be quite low, as illustrated by previous reviews. Of Numminen et al.'s (2020) 44 studies of competencies required for a postdoctoral nursing researcher career, the majority concerned not postdocs, but PhD students; Treichler et al. (2020) identified only one study on diversity and social justice training of psychology postdocs, and had to broaden their search to include literature on graduate students in other, closely related fields; Nowell et al. (2019, 2018) found slightly less than 30 articles on professional learning and development initiatives for postdocs; and although Ranieri et al.'s (2016) search resulted in 50 articles on factors that influence career progression among postdoctoral clinical academics, their definition of postdocs is quite broad. Importantly, none of these studies used research design as part of their inclusion criteria.

Were one to do so, without focusing on a particular field and/or topic, the number of surveys on the postdoc are probably adequate for a systematic synthesis of the evidence they produced, and this number may be increased by including some of the secondary analyses of existing survey data. The extent to which this is the case, and the comparability of the survey data in terms of population surveyed, require further analysis that is beyond the scope of this paper.

With regard to the other designs, including bibliometrics, systematic reviews of the evidence produced by these designs would not be feasible at this stage. My search was limited to two databases, did not involve searching the reference lists of publications identified, and additional search terms (e.g. early career scientists) would have probably increased the volume of evidence. However, it is unlikely that a more comprehensive search would increase the volume of bibliometrically produced evidence to a level that allows for systematic evidence synthesis. Such a synthesis would also be hampered by wide variations in scope and the fact that context-specific evaluations of postdoc-related interventions dominate the body of evidence reviewed. Among these instances of evaluative bibliometrics, some methodological standardisation (and improvements) has emerged over time, but it is of concern that bibliometric analyses were still used recently to make unfounded conclusions about the "effect" or "impact" of interventions on postdocs' publication performance. Schneider and van Leeuwen (2014, p. 296) even question the contribution bibliometrics can make to such evaluations, on the basis that "publication activity is a poor parameter for performance evaluation in this context". However, innovative uses of bibliometric data to measure more than publication performance, as illustrated by Zabetta and Geuna (2019) and Igami, Nagaoka and Walsh (2015), shows that bibliometric data and tools can be applied to more than the performance evaluation of postdocs. Although bibliometric analyses contributed only a small fraction of empirical knowledge on postdocs over the past five decades, they are not a recent phenomenon, with the earliest already published in 1976 (analysing data as far back as the 1950s). As publication performance is both a major postdoc and bibliometric concern, what has been limiting the volume of such analyses, when compared to surveys and secondary analysis? One possible explanation is the “meagre” publication history of most postdocs around the time they received their grants (within one or two years after finishing their PhD) (Schneider & van Leeuwen (2014, p. 290). As illustrated by some of the sources of evidence I reviewed, studying postdocs over longer time periods, or as part of mentor-mentee dyads or research teams, would allow for larger numbers of publications to be analysed.

Lack of non-bibliometric data may also be a contributing factor. The results of my content analysis show, quite predictably, that all of the bibliometric studies on the postdoc required access to additional data for sample identification, verification of publication data, and analysis. Although some of these data are publicly available, in most cases the authors were privy to these data because of their positionality as evaluators of interventions. However, my scoping review shows that a large majority of empirical evidence on the postdoc since 1973 has been produced by surveys, leading me to question whether availability of sampling frames from which to construct publication portfolios is a valid reason for the low number of bibliometric analyses.

In addition to the dominance of evaluations of specific interventions, the study of elite populations, and of gender differences, were two interesting themes that emerged. Finally, the context to which the bibliometric evidence pertains, tends to reflect the countries and fields in which the postdoc has been institutionalised for the longest time, namely the medical and life sciences, and the natural sciences, in North America and Europe (Assmus, 1993). Postdoc-related bibliometric research on other countries, and on the social sciences and humanities, is a knowledge gap highlighted by my content analysis.

Conclusions

A central concern with the postdoc is publication performance, the objective measurement of which is the sine qua non of bibliometrics. My review shows that bibliometric data can also be used to measure other issues related to the postdoc. However, compared surveys on the postdoc, the body of evidence that has been produced by bibliometrics since 1976 is still insufficient in terms of volume, standardisation and rigour, for systematic evidence synthesis to be undertaken. In efforts to increase the bibliometrically produced evidence-base on postdocs, current biases towards the medical and life sciences, and the natural science, in North America and Europe should be addressed.

Why university affiliation discrepancies still exist in citation indexes and how to resolve them

Abstract

Research managers benchmarking universities against international peers face the problem of affiliation disambiguation. Traditional bibliometric data sources such as Scopus and Web of Science each conduct a manual process to describe organization relationships between academic institutions which allow the user to search a single unified name. This study used digital object identifiers (DOIs) as the common attribute for publications indexed in four bibliometric databases to retrieve publications from 18 Arab universities. We then determined the overlapping coverage and identified discrepancies between databases that were due to different ways of treating affiliation names. We found the larger databases, Dimensions and Microsoft Academic tended to have more affiliation discrepancies with each other and with the more selective Web of Science and Scopus. Finally, we manually examined sample records that revealed the reason for the affiliation discrepancies. There was an even spread between missing affiliations, unification differences, and assignation to the wrong institution. We conclude by calling for renewed efforts to develop a global, open-source disambiguation system which should be maintained by universities and incorporated into all bibliometric data sources.

Introduction

The problem of affiliations

The research community understands to varying degrees the importance of getting its university affiliation names right. Individual researchers are now routinely assessed at least in part on their ability to produce published articles and their institutions are at least partially ranked on those very same papers. The single factor tying the paper to its author's employer is the affiliation name given by the author when they submit the manuscript to a journal.

There are many ways of acknowledging a university and one can easily confuse a rudimentary database by simply swapping My City University with University of My City. Other common variations involve acronyms, MCU, UMC, or partial acronyms, MC University, Univ MC. The list easily extends to dozens of variants when authors introduce their faculty or department name sometimes at the expense of the university name. Add to that the common practice of incorporating one institution into another or splitting part of a university away from its main organization, along with larger mergers and creation of international branch campuses and we have a complex problem for those assessing the university.

Indeed, nowadays journal and authors names are relatively constant while it is not uncommon for university names to change. Although there have been several initiatives to address the problem by using unique identifiers for research institutions, none have been universally adopted to the same extent as for journals (ISSN), individuals (ORCID), or documents (DOI). These efforts have mainly been made by the major citation indexes such as Scopus (Affiliation Identifier or AFID), Web of Science (Organization Enhanced), Dimensions (Global Research Identifier Database or GRID). A new community-led collaboration of multiple organizations has been launched and is known as the Research Organization Registry (ROR). It holds promise because it is closely linked to GRID and is to be incorporated into Crossref metadata (Lammey Rachael, 2020).

Databases used in such assessments have made strides into resolving this problem using different solutions including manual submission of affiliation variant lists by universities to database owners or automated unification systems. The degree of accuracy is still unquantified and policy makers who rely on bibliometric analysis often overlook an inherent level of error when using these data sources.

The importance of affiliations

Many universities driven by increased external competition (Brankovic, Ringel, & Werron, 2018; Espeland & Sauder, 2016) seek to maximize their position in the various international ranking tables. The ranking organizations in turn typically assess institutions' performance against a set of criteria that usually include the quantity and impact of research publications (Centre for Science & Technology Studies Leiden University, 2020; QS Intelligence Unit, 2019; Shanghai Ranking Consultancy, 2019; Times Higher Education, 2019; US News & World Report LP, 2019). These ranking systems use either Elsevier's Scopus or Clarivate Analytics' Web of Science (Web of Science) to compute the bibliometric component of their tables.

The level of accuracy of those databases and their ability to assign papers to the correct affiliations consequently becomes one of the limiting factors in an institution's performance (Orduna-Malea, Aytac, & Tran, 2019). Any 'missing' papers can cost a university valuable places in the ranking table and authors are routinely encouraged to use the official institution name when publishing. Nevertheless, each year universities complain to the ranking systems of missing papers, but the rankers are constrained by the limitations of the citation indexes. Disgruntled universities are usually referred to the database owners to resolve their affiliation-related complaints.

This study focused on those records found in overlapping database coverage but with discrepancies in the university affiliation name between databases. We manually examined two dozen records from each surplus and attempted to explain the mismatch in the context of affiliation indexing. This has major implications for any university benchmarking study and particularly the international university rankings. We chose to make this a regional study because it requires close knowledge of university names, and we selected 18 universities from the Arab region because of our familiarity with this region.

Affiliation disambiguation policy

In Scopus, we used the Affiliation identifier (AFID) which is a unique identifier for the institution to which records are tagged. In many cases however, Scopus includes multiple AFIDs for a single university treating medical schools and other faculties as separate entities. This does not appear to be consistent and for some universities there is only one AFID while for others there are many. Although there is a search option that unifies the AFIDs for one single institution, some of the component organizations appear less related to the main institution than others and we therefore used only the main AFID for each university. From Web of Science, we used organization enhanced (OE) which is a preferred institutional name searchable in the database and to which records from that organization and its component parts are unified. The OE unification process is performed by the database owner with voluntary input from the institutions themselves. Dimensions and Microsoft Academic each use GRID which was developed by Digital Science to describe both parent-child relationships between institutions and external related organizations. GRID disambiguates affiliation names for approximately 100,000 organizations and we therefore used the GRID record linked to the generally accepted name for each of the 18 university names.

Research questions

1. How prevalent are affiliation discrepancies between citation indexes for Arab universities?

2. What causes affiliation discrepancies and what are the implications for databases and bibliometricians?

The answers to these questions will be useful in our understanding of the extent to which research outputs are covered by the different databases. Since many decisions are based on the outcome of bibliometric studies, comparisons, and university rankings, policy makers will be better informed about the limitations of bibliometrics studies and comparisons. The ranking bodies may take these limitations into account when they publish their league tables. Database owners may incorporate these finding into their development plans and algorithms to improve the accuracy of their products and make them more competitive.

Literature review

Work on author affiliations was documented at Leiden University in the mid-1980's. Indeed the LISBON Institute, the predecessor of CWTS already used affiliation data from the Science Citation Index (SCI) to report the changes in academic collaboration in the Arab region following the geopolitical developments in the 1980s (DeBruin, Braam, & Moed, 1991). The problems of author affiliations became more important as bibliometric reports gained popularity and started being offered as a service (Calero-Medina, Noyons, Visser, & De Bruin, 2020) and the development of in-house citation indexes at CWTS in the 1990s were constructed in a manner that facilitated address disambiguation.

Interesting applications of author affiliations included delimitation of scientific subfields using terms in corporate addresses in scientific publications and assessing whether European funding had spurred increased co-operation between EU Member States using the country name in the author address fields. The problem of missing author affiliations has been largely addressed but still in 2015 the Web of Science indexes contain sizeable quantities of publications without any affiliations whatsoever (SCIE: 7.6%, SSCI: 6%, and A&HCI: 35%) (Liu, Hu, & Tang, 2018).

The Web of Science OE feature attempts to overcome the affiliation disambiguation problem and has been selectively used in bibliometric studies to improve accuracy (Baudoin, Akiki, Magnan, & Devos, 2018). A recent study (Donner, Rimmert, & van Eck, 2020) showed widely varying recall and precision across institutions between Web of Science OE, Scopus AFID and a German institution affiliation disambiguation system described as 'near-complete' for German public research organizations. Taking the German system as ground truth, the authors concluded the resulting inconsistencies in publication and citation indicators using the commercial vendor systems should be taken into consideration by policy makers.

One of the first large-scale studies comparing database coverage across a multi-institution dataset between Scopus, Web of Science, and Microsoft Academic examined the publication overlap of 15 universities with DOIs serving as the common attribute (Huang et al., 2020). The authors created a Venn diagram for each university showing the proportion of DOIs indexed by all three data sources. The diagram also revealed the extent to which DOIs were covered by only one of the three databases, that we term a surplus. For instance, DOIs found in Web of Science but not in Scopus or Microsoft Academic count as Web of Science surplus.

Method

This study examines the overlap of indexed DOIs from for 18 universities (Table 1) of all document types, in four international, multidisciplinary citation indexes often used in bibliometric studies, namely Scopus, Web of Science, Dimensions, and Microsoft Academic. From Scopus we used the main affiliation ID only because of the differences in the level of disambiguation performed for the universities. Within the Web of Science, we used five editions; the Science Citation Index Expanded, Social Sciences Citation Index, Arts & Humanities Citation Index, the Conference Proceedings Citation Index-Science, and the Conference Proceedings Citation Index-Social Sciences & Humanities. Neither the Book

Citation Index (BkCI), nor the Emerging Sources Citation Index (ESCI) were used because we do not have access to them. We refer to our version of this database henceforth as CWTS Web of Science. From Dimensions, we extracted only publications because these are comparable with the documents in the other databases, but not grants, patents, datasets, clinical trials, or policy documents. We did not use Google Scholar because of the difficulties in accessing its data, especially for large bibliometric studies. All data were retrieved from the versions of the databases available in the database system of the Centre for Science and Technology Studies (CWTS) at Leiden University. The data was received in March 2020 (CWTS Web of Science), April 2020 (Scopus and Dimensions), and July 2020 (Microsoft Academic).

Table 1: The universities used along with their abbreviations

Abbreviated name	*Full institutional name*	*Country*
Ain Shams	Ain Shams University	Egypt
Alexandria	Alexandria University	Egypt
Assiut	Assiut University	Egypt
AUB	American University of Beirut	Lebanon
Babylon	University of Babylon	Iraq
Baghdad	University of Baghdad	Iraq
Bahrain	University of Bahrain	Bahrain
Carthage	University of Carthage	Tunisia
Jordan	University of Jordan	Jordan
Khalifa	Khalifa University	United Arab Emirates
King Abdulaziz	King Abdulaziz University	Saudi Arabia
King Saud	King Saud University	Saudi Arabia
Kuwait	Kuwait University	Kuwait
Qatar	Qatar University	Qatar
Lebanese	Lebanese University	Lebanon
Sfax	University of Sfax	Tunisia
Sultan Qaboos	Sultan Qaboos University	Oman
UAEU	United Arab Emirates University	United Arab Emirates

We subsequently manually analyzed 24 samples of affiliation discrepancies from each of the database pairs. For each pair we selected the university with the highest proportion of affiliation discrepancy provided that university had not already been used. If so, we moved on to the university with the next highest proportion. Examination was performed by manually searching for the records on the web interface versions of each database and checking the published PDF documents as the ground truth.

Results and discussion

Differences between databases

It was not possible to approach this study from the overlapping coverage between databases for any given university. Overlapping coverage would necessarily contain the correct affiliation name in each database, otherwise it would not be retrieved. Instead, we searched for DOIs containing affiliations from each of the selected universities in one database that we referred to

as the primary database. Then we searched the comparator databases to determine first, whether the DOI was covered, and second whether it was assigned the same affiliation name as in the primary database. Consequently, for each database pair we present our results as a series of stacked bars. At the ends of each bar are those records with affiliation discrepancies between the two databases while overlapping affiliations are found in the central portion of the bar.
In Table 2 we present the overall overlapping DOI count for a cumulative dataset of the 18 selected universities for each pair of databases. The right-hand portion of the bar represents those DOIs found in the primary database with one of the university affiliations that is also present in the comparator database but not assigned to the same affiliation. Without closer examination of the individual records, we cannot say whether the affiliations are correct or erroneous in either of the databases. Also, if an affiliation is incorrect in both databases, then it would be missed from the entire dataset.

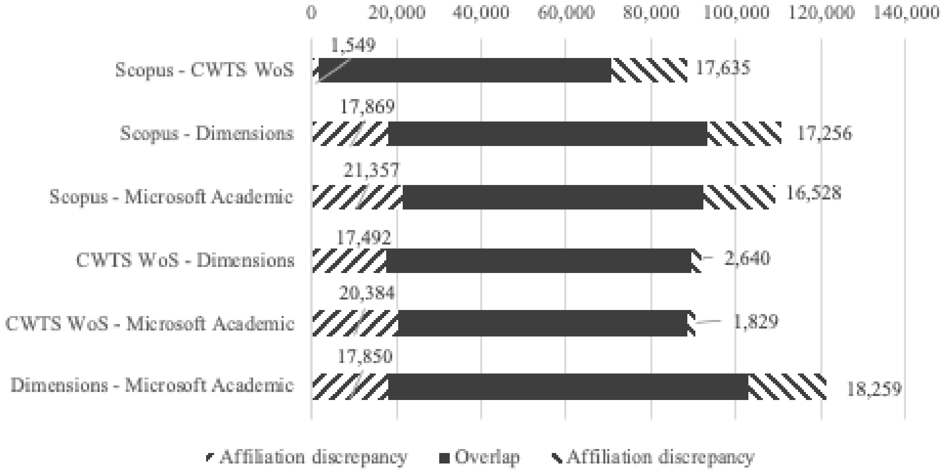

Figure 1. Affiliation discrepancies by database pair

The first bar shows that 1,549 CWTS Web of Science records for the 18 universities were also found to be covered in Scopus but not with the same affiliations. This is a small proportion of the overall overlapping DOIs found when compared with the proportion of Scopus records found to be present in CWTS Web of Science but with affiliation discrepancies. The fourth and fifth bars show a similar pattern with a small proportion of CWTS Web of Science papers showing affiliation discrepancies with either Dimensions or Microsoft Academic. The third bar shows a larger proportion of Microsoft Academic records that do not agree with their corresponding record in Scopus than there are Scopus records with affiliation discrepancies in Microsoft Academic.
These differences might be explained by CWTS Web of Science and to a lesser extent Scopus having more accurate affiliation data than Dimensions and Microsoft Academic resulting in fewer discrepancies. Alternatively, the differences could be related to the extent and type of sources these databases cover as that might impact their likelihood to have DOIs or complete and accurate affiliation data. For instance, CWTS Web of Science is only a subset of the full Web of Science database. Our version of the database excludes the BKCI and its component document types, books and book chapters which frequently lack a DOI (Gorraiz, Melero-Fuentes, Gumpenberger, & Valderrama-Zurián, 2016). It also excludes the ESCI that comprises several thousand regional or peripheral journals that might well be present in the larger databases but less frequently be associated with DOIs. As only those records with DOIs are

included in the study, there is increased likelihood of finding them in CWTS Web of Science. Indeed, Web of Science and Scopus are smaller and more selective databases and consequently more likely to comprise journals articles from publishers that register DOIs for their articles. Any article in a comparator database without a link to its DOI would be missed in this study. Dimensions and Microsoft Academic are both considerably larger than Web of Science and Scopus and divergence is therefore more, rather than less likely. Two recent large-scale comparisons of these data sources reveal closer overlap between Scopus and Web of Science than between Scopus and Microsoft Academic (Huang et al., 2020; Visser, Van Eck, & Waltman, 2021). The Visser study also showed Scopus to hold closer overlap with Web of Science than with Dimensions. The leaves us with the probability that affiliation discrepancies are greater between Scopus on the one hand and Dimensions and Microsoft Academic on the other than they are between Scopus and Web of Science.

Reasons for mismatches on affiliations

We manually examined two dozen records from each of the database pairs using the web interface for each database. For each of these examples, we attempted to discover the reason the affiliation was responsible for the DOI not being retrieved in the search. The main reasons are summarized in table 2.

Table 2. Affiliation discrepancies

Database pair	*Institution*	*Missing affiliation*	*Missing second affiliation*	*Assigned to wrong institution*	*Unification*	*Inconclusive*	*Total*
Scopus-CWTS WoS	Lebanese			1	22	1	24
Scopus-Dimensions	Sfax	11			11	2	24
Scopus-Microsoft Academic	Khalifa	2			20	2	24
CWTS WoS - Scopus	Saud	6	1	13		4	24
CWTS WoS - Dimensions	AUB	6	1	1	14	2	24
CWTS WoS - Microsoft Academic	Assiut	6	12	5	1		24
Dimensions - Scopus	Carthage	3			21		24
Dimensions - CWTS WoS	Bahrain	1		19	4		24
Dimensions - Microsoft Academic	Babylon	9	6	7	2		24
Microsoft Academic - Scopus	Kuwait					24	24
Microsoft Academic - CWTS WoS	UAEU	4	1	3	15	1	24
Microsoft Academic - Dimensions	Qatar	20		2	2		24

Missing affiliation

The author affiliation has not been captured by the database and therefore a search for the affiliation name did not retrieve the record. We found almost all (20 of the 24) Qatar University affiliation discrepancies in the Microsoft Academic–Dimensions pair were caused by missing affiliations in Dimensions. In most of these cases all author affiliations were missing, and the papers were conference proceedings or book chapters. Similarly, we found where CWTS Web of Science has missed author affiliations, the majority were meeting abstracts.

Missing second affiliation

The author's first affiliation has been listed but not the second. This is similar to the above category but worth separating as it appears that Microsoft Academic has distinct groups of papers for which the additional affiliation is missed while the first is captured. As an example, on 10.1166/asl.2017.7424 the PDF shows University of Babylon as second affiliation for one author that is omitted from the record in Dimensions and Microsoft Academic, but included in Scopus and Web of Science. In other cases (e.g., 10.1016/j.asoc.2016.06.019), the second affiliation is listed separately from the first on the PDF under categories such as 'Author's current address' or in this case, 'Correspondence address'. Scopus and Web of Science included this as second affiliation, while Dimensions and Microsoft Academic did not.

Assigned to the wrong institution

We found seven records from University of Babylon erroneously assigned in Microsoft Academic to either the College of Information Technology or the Information Technology University in Pakistan, or the University College of Engineering in India. Each of these are in fact sub-units of the University of Babylon. Lots of universities have a College of Information Technology and we found several other examples of papers from e.g. College of Information Technology, UAEU that were also assigned to the College of Information Technology in Pakistan. Due to erroneous assignments the publication counts for these universities will be too low and the publication count for the College of Information Technology in Pakistan will be too high.

Other examples showed records assigned to UAEU in Web of Science OE were in fact published by authors at a Moroccan institution called Université Abdelmalek Essaadi sometimes abbreviated to UAE University and mistakenly unified to the wrong institution.

Similarly, authors from LaSTRe Laboratory in Tripoli, Northern Lebanon, which is affiliated to the Lebanese University in Beirut, had been erroneously affiliated to the University of Benghazi in Tripoli, Libya in the Web of Science. Two further records from the same university were assigned to the United States of America due to confusion over the tiny town of Lebanon in Grafton County, New Hampshire. It appears therefore that the presence of a city name or country name might sometimes trigger unification to the wrong organization enhanced name in the Web of Science.

Unification

An affiliation is listed but it has not been unified to the main or correct university. For example, 10.1002/2015gl066534 features the affiliation Masdar Institute which has been unified to Khalifa University in Dimensions but not in Microsoft Academic. Khalifa University is the result of a merger between three institutions, the Petroleum Institute, Masdar Institute and Khalifa University of Science and Technology in 2017. Microsoft Academic's approach is not necessarily wrong because Masdar Institute existed when the article was published but highlights decisions that have to be made when handling organization mergers.

Many authors in Tunisia have acknowledged their institution as Faculty of Sciences at Sfax. We found that Scopus unified these papers to the University of Sfax while Dimensions treated it as a separate organization. In a similar case, 10.1002/ajh.25075 the American University of Beirut Medical Centre has correctly been unified to AUB in Web of Science but not in Dimensions.

Also in Tunisia, we found several records affiliated to the National Institute of the Applied Sciences and Technology and several other research centers which Web of Science and Dimensions unified to the University of Carthage while Scopus did not. In most of these cases, the university was not mentioned on the PDF, but Scopus has made the link through its disambiguation process.

Inconclusive

We classified as inconclusive cases where there was no obvious reason for the DOI not being retrieved, a human indexing decision involved, or access to PDF proved impossible. An example of a human indexing decision is a book preface with a DOI (10.1016/B978-0-12-800887-4.00034-1) but no authors or affiliations. While Scopus had assigned the book editors as authors, Dimensions had not. Another interesting case was a letter to the editor published by three authors with a long list of additional signatories at the end. Scopus had counted all the signatories as authors of the letter while Dimensions limited authorship to the three at the top of the paper. Neither of these cases is clear cut, if one accepts the book editors in the first case, and letter signatories in the second should be named as authors then their affiliations are missing in Dimensions. If they should not be named, then they are phantom affiliations in Scopus.

Conclusions

Each database uses a different method of disambiguation and unification. That makes comparison difficult. Scopus AFIDs and Web of Science Organization Enhanced records are very useful because they allow the user to analyze the whole university or any of its components and affiliated institutions. When comparing institutions, we make the assumption the disambiguation process has been performed to the same level for all institutions in the analysis. Our results show this is not always true and that some comparisons will produce misleading results. In Scopus, the relationship between the 'Affiliation only' AFID and those included in the 'Whole institution' appear to vary widely in their level of unification. In Web of Science, there is evidence of errors brought into affiliation assignation by the presence of certain city and even country names. Dimensions has missing affiliations in some conference proceedings paper and book chapters while Microsoft Academic has mistakenly affiliated many records to the wrong institution.

A considerable limitation to the present and most previous studies on affiliation disambiguation is the fact that university names change over time. Changes result from a number of factors including mergers and splits but also for reasons of government naming conventions, changes of country leaders, city names, and other factors. Once an address is unified to an affiliation, all its prior papers will be found when searching the new unified affiliation. Studies are therefore a time-frozen shot of the current unification and do not take account of unification dynamics over time.

Some university rankings providers assume responsibility for disambiguating affiliations in their league tables to different degrees. This is especially true in the case of the Leiden Ranking which disambiguates all affiliations from its proprietary database (Calero-Medina et al., 2020), while both QS (QSIU, 2019) and Times Higher Education have begun supplementary work on Scopus unification in special cases. This practice is welcomed and providers of products that derive from bibliometric data sources should be encouraged to increasingly take stewardship of the analytical process and responsibility for the accuracy of the resulting publication.

There is a need for a universal unique identifier for academic institutions that should reflect the current and historical organization relationship tree. The ideal indicator will be supported by input from the institutions themselves in the same way that researchers maintain their own ORCID records. That way the accuracy, maintenance, and historical record will be maximized. There will be scope for non-maintenance or misuse especially where an institution can benefit from a certain interpretation of its organization, but these will be outweighed by the benefits. Universities and their stakeholders should still decide their own names and they are still the most appropriate managers of the public record of their relationships with sub-units and external entities. However, a global initiative is required to provide an integrated platform for such relationships to be presented. The Research Organization Registry is a promising initiative that will fill that need especially if adopted by all data source providers.

Abstract

This paper reports research in progress on a PhD project to investigate how cancer research is reported in some newspapers in China and the UK during the six years 2014-19. The stories were selected if they cited identifiable cancer research papers recorded by the Web of Science, whose details were appended to those of the news stories in a big spreadsheet. We are comparing the coverage by cancer site (*e.g*., lung, breast) with the disease burden from different cancers in the two countries, and also with the amount of research taking place. We are also examining the location of the researchers whose work is being cited to see how much own-country work is being described, and whether research outwith the main cities is being neglected. Many research stories also quote commentators who can put the results in context. Finally, we are planning to determine if citation of research in newspapers leads to more than expected numbers of citations from researchers in the country of their publication. Some early results from the popular Chinese newspaper, *Global Times*, and *New Scientist,* are presented.

Introduction

Cancer is now one of the leading causes of death world-wide and its burden in the population has increased over the last 30 years, see Figure 1. This is because major improvements in infant and maternal mortality, and reductions in many infectious diseases have combined to increase life expectancy. Consequently, more people survive into old age where they are more susceptible to cancer.

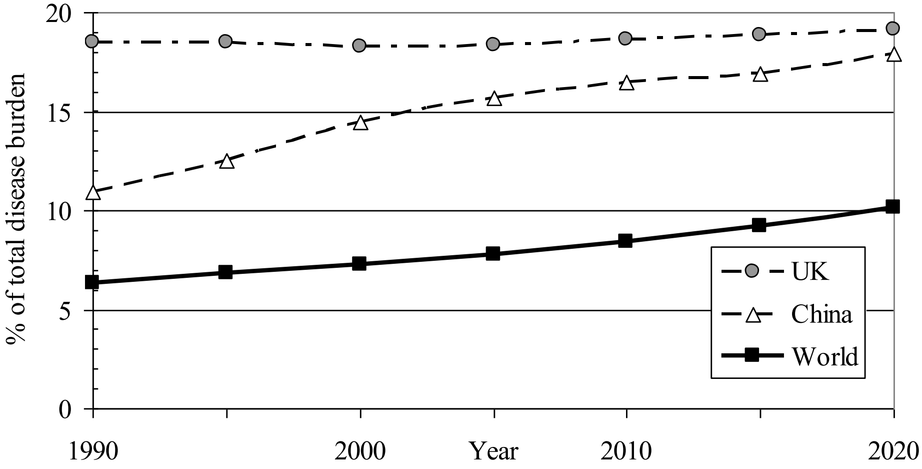

Figure 1. Cancer burden as a percentage of the total, Disability-Adjusted Life Years (DALYs), for the world, China, and the UK, from 1990 to 2020. ***Data from the Institute for Health Metrics and Evaluation at the University of Washington (GBD Compare | IHME Viz Hub (healthdata.org)).***

As China has developed economically over this period, its population has become more susceptible to cancer, and its relative cancer burden has increased and is now close to that of the UK. It is therefore as major a concern for the Chinese government as it is in the UK.

The causes of cancer are numerous, and over a thousand have been listed by the International Agency for Research on Cancer (IARC), part of the World Health Organization Table 4 (who.int). Genetics plays a large part, and some of these environmental causes are hard for people to avoid, but there are several causes of cancer that are to a large extent under the control of individuals. These include whether to smoke or drink alcohol, what to eat, and how much exercise to take. There are public health campaigns on each of these in many countries, some sponsored by the government, and in the UK, some by charities. However, one of the main means by which people obtain health information is from the mass media.

This project, therefore, seeks to assess how information about cancer research is reported and presented to the public in two very different countries, China and the UK. They are different because the media, particularly newspapers, are controlled in very different ways: by the communist central government in China, and by their capitalist proprietors in the UK. [An exception which we are studying is *The Guardian*, which is owned by a private-non-profit organisation, the Scott Trust.] These countries also differ because the distribution of cancers differs between the two countries, see Figure 2.

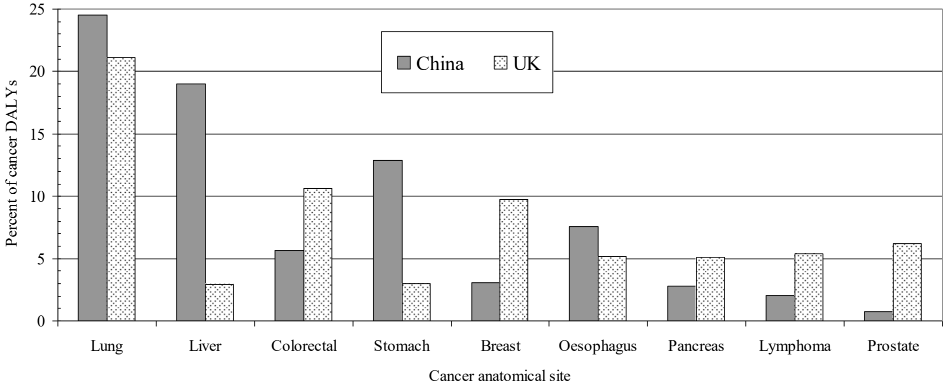

Figure 2. The percentages of total cancer DALYs in 2015 from different cancers in China and the UK. Data from the World Health Organization (Indicators (who.int))

Lung cancer is the cancer with the greatest burden in both countries, while liver, stomach and to some extent oesophageal cancers are more important in China. Colorectal, breast and prostate cancers also contribute to relatively larger burdens in the UK. One of the objectives of our research is to assess whether media reports take account of and reflect these different epidemiological patterns.

Both China and the UK are now very active in cancer research. China's research output, measured by papers in the Web of Science (WoS), exceeded that of the UK in 2009 (Figure 3), and that of the USA in 2018. [The slowdown since 2015 is probably an artefact caused by the addition of the Expanded Sciences Citation Index to the WoS in that year.] So we will also be investigating whether the newspapers in each country choose to cite preferentially cancer research from their own countries, relative to research from the world total, and whether they tend to favour regions of each country where research is concentrated. These regions include the big cities of the eastern provinces in China, especially Beijing and Shanghai (Li & Lewison, 2020), and the "Golden Triangle" of Cambridge, London and Oxford in the UK (Begum *et al*., 2017).

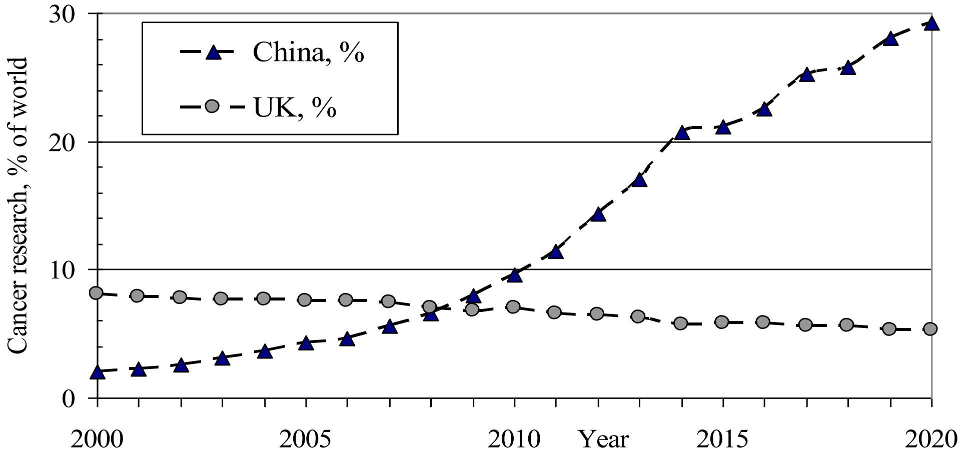

Figure 3. Cancer research outputs of China and the UK in the WoS, 2000-20.

Media reports of medical research have become somewhat polarised recently, with many false stories appearing, notably about the COVID-19 vaccines. We therefore consider it important to check whether journalists writing articles are seeking outside independent commentators who can put the research in context, and verify that it is good science. Previous studies of the UK media (Lewison *et al.*, 2008; Pallari *et al.,* 2020) have shown that British journalists frequently quote external experts, particularly from the cancer charities, to validate the results that they are reporting. One question is therefore, Do Chinese journalists use external experts, and if so, where do they find them? The tone of the stories is also of concern, as (at least in the UK) newspapers often over-hype their stories so as to grab the attention of their readers and increase circulation. Our question for China is, Does the Chinese Communist Party (CCP) control of the media provide an opportunity to demonstrate to its citizens the superiority of Chinese cancer research?

A final investigation will be to assess whether reportage in the mass media has any measurable influence. It is only one of the many factors that can influence health-related behaviour, but it has been shown that news reports can lead to more citations in journals (Phillips *et al.*, 1991; Lewison *et al.*, 2008). In the absence of an unusual "before and after" scenario such as the one Phillips investigated when *The New York Times* employees went on strike and then resumed work, it will be necessary to see if reportage in a country's media increases the proportion of citations to the cited papers that are from that country. There are, of course, many other possible effects of media reports on people's behaviour, but these are much harder to demonstrate.

Methodology

The first task was to select the media for study. In China, we chose eight mass media, seven of which are newspapers, and one popular online medical daily, *Dr. Ding Xiang*. They are normally read in their online versions with printed editions available (see Table 1). The newspapers are all controlled by the Chinese Communist Party (CCP) so they are expected to reflect the views of the Government. For example, the *People's Daily* is the largest newspaper in China, and the most important wind vane for the party's theory, line, principles, and policies (People's Daily, 2017). But some, such as the *South China Morning Post* and the *Beijing News,* try to maintain a certain degree of independence. *Global Times* is very widely read, and its original intention was to present mainly foreign news with a large network of correspondents from all over the world (Global Times, 2019). Currently it has become the key platform to cultivate and shape the popular consensus according to China's will (Lee, 2010). Three of the newspapers, the *Beijing News, Xin Min Evening News* and *Heilongjiang Daily*, are regional, so might be expected to take the local cancer burden and the regional differences in potentially modifiable cancer risks (Chen *et al*., 2019) into account. *Dr Ding Xiang* is the only Chinese medium we selected without a printed version. It is the most popular and influential WeChat Public Account for health in China now, with professional contributors, and more than 10 million followers. It also explicitly aims to fight health misinformation, such as that garlic can prevent cancer, and to bridge grassroots advice and that from medical experts. (Wang, 2018).

Table 1. List of news media in China selected for study

Title (CN)	*Title (English)*	*Area*	*Language*
人民日报	*People's Daily*	Mainland China	Simplified Chinese
环球时报	*Global Times*	Mainland China	Simplified Chinese
中国日报	*China Daily*	Mainland China	English
新京报	*Beijing News*	Mainland China	Simplified Chinese
南华早报	*South China Morning Post*	Hong Kong	English
丁香医生	*Dr Ding Xiang*	Mainland China	Simplified Chinese
新民晚报	*Xin Min Evening News*	Shanghai	Simplified Chinese
黑龙江日报	*Heilongjiang Daily*	Heilongjiang	Simplified Chinese

[The Chinese written language was simplified in 1949, but the original script is still used in Hong Kong and Taiwan.]

In the UK, where the news media are independent and the market is segmented by education level and politics, we selected ones that represented a wide range of views, shown in Table 2. Data were already available for *Daily Mail* and *The Guardian* for the years 2002-13, and for *New Scientist* for some of the study period, and for five years before then. The others were chosen to represent an intellectual and financial readership, one that is "middle-of-the-road", and one that is distinctly popular and un-intellectual.

Table 2. List of news media in the UK that were selected for study

Title	*Circulation*	*Characteristics*
Daily Mail	1,134,184	Right-wing tabloid, middle-market readership
Financial Times	155,009	Centre-right business broadsheet, international readers
The Guardian	111,155	Left-wing Berliner format, intellectual
i	215,932	Centre-left tabloid, parent is online only
The Sun	1,206,595	Right-wing populist tabloid, low education level readers
New Scientist	118,009	Centre-left popular weekly science magazine

The individual stories were first identified through their headlines and brief synopses on the Factiva database by means of a simple search statement:

> *(cancer OR leukaemia* OR melanoma* OR lymphoma* OR tumour* OR sarcoma*) AND (research* OR study OR scientist* OR expert*)*

and these details were downloaded to an Excel spreadsheet. They were first formatted so that all the data for each story (including date, the name of the journalist, and length in words) were on a single line. Then they were filtered to remove any that did not have one of some 16 words in their headline or synopsis indicating that they cited published research. The full texts of those that remained were then individually downloaded *via* Factiva and read. Further details were added to the spreadsheet, including those of the cited research paper (author, institution, journal) and of any commentator(s).

The next stage was to identify each cited paper in the WoS and download all its bibliographic data to individual files, numbered to correspond to the index number of the citing story, and then transferred to the spreadsheet. These data could then be analysed by a series of macros (all written by Philip Roe of Evaluametrics Ltd) to show the fractional counts of countries involved in authorship, the research level (from clinical to basic), the cancer anatomical site, and the type of research involved (*e.g*., epidemiology, surgery) (Pallari & Lewison, 2019).

Results

At this stage we have detailed results only for the few cancer research stories in *Global Times*, together with those in *New Scientist* for part of the six-year study period, and five previous years (2009-13). Because its objective is to cover mainly foreign news, the *Global Times* cited overseas newspapers frequently. Overall, 36% of the research that it cited was from the UK, 24% from the USA, and only 16% from China (including Hong Kong, and, curiously, Taiwan). Its stories were often focused on the relationship between lifestyles and cancer risks (48% of stories) and eye-catching medicines (24%). Screening and diagnosis were relatively rarely reported (8%). Much of the research mentioned was applicable to any type of cancer (44%).

There were more cancer research stories (n = 318) from the *New Scientist*. Research from the UK itself was over-cited (compared with its integer-count presence in all cancer research in the same years) by a factor of 4.5, and most European countries' research was also over-cited, by between 1.4 and 4 4 times. That of the USA was over-cited by a factor of 2.1, but research from East Asia was relatively ignored, with Chinese cancer research receiving only one quarter as many mentions (13 instead of 53) as would have been expected.

Stories within *New Scientist* over-emphasised breast cancer, with 33 of them mentioning it (10%), whereas it accounts for less than half the burden measured in DALYs than lung cancer (WHO, 2015). However, it is the most researched cancer site, both in the UK and the majority of other industrial countries (Begum et al., 2018). Other cancer sites prominently featured were the prostate (22) and the brain and central nervous system (21). The stories also concentrated on genetics, with 54 (17%) the most popular research domain, followed by drug treatment (40) and epidemiology (36). There were very few stories on the two other main cancer treatments, namely surgery (6) and radiotherapy (5), reinforcing the public view that drugs, and not these two latter treatments, are the way to defeat cancer.

Discussion and conclusions

China and the UK are very different countries, but they have a common interest in reducing the toll of cancer on their citizens. Since about half of the causes of cancer are to some extent under their control, it is important to see how news of the research that should underpin both their decisions and governmental regulatory actions is being presented to the public. This is an important component of the relationship between research and its public acceptance, which is one of the criteria for research evaluation in the forthcoming UK Research Excellence Framework for 2021 (https://www.ref.ac.uk

We have selected a wide range of newspapers and a popular science magazine in each country to study. The major part of the work remaining will be to collect all the details of the media stories and then of the papers that they cite in a spreadsheet; the analysis can be done very quickly with existing software. Once the results are clear we plan to conduct interviews with some of the key actors, such as science journalists, cancer researchers, and the funders of this research, in order to learn more about how research articles are selected for coverage, any constraints on this, how commentators on the new results are chosen, and perceptions of the impact the stories may have on the various groups of readers.

A limitation of the study is the relatively small number of newspapers and magazines that can be covered, and in the UK the lack of regional diversity. However, this is almost inevitable because of the decline of regional and local media. In China, the strict censorship imposed by the CCP makes this less of an issue, although we might still find some variation in the content of the stories in provinces where the cancer burden, or its treatment, differ markedly from that in the major cities of the east of the country.

Abstract

Analysts are rapidly developing methods to map publications to SDGs in the face of policy demands. However, as reported by Armitage et al. (2020), a high degree of inconsistency is found when comparing the bibliometric corpora obtained with different approaches. These inconsistencies are not due to minor technical issues, but instead they represent different interpretations of SDGs. Given the variety of understandings regarding the relationship between research and SDGs, we propose that bibliometrics analysts should not assume that there is one single, preferred or consensus way of mapping SDGs to publications. We propose instead that, since different stakeholders have contrasting views about the relationships between science and SDGs, the contribution of bibliometrics should be to provide a plural landscape for stakeholders to explore their own views. We describe here the beta-version of an interactive platform that allows stakeholders to scrutinise in a global map of science the clusters potentially related to SDGs.

Introduction

The shift in S&T policy from a focus on research quality towards societal impact has led to a demand for new S&T indicators that capture the contributions of research to society (Wilsdon et al., 2017), in particular those aligned with SDGs. The use of the new 'impact' indicators would help monitoring if (and which) research organisations are aligning their research towards certain SDGs.

Responding to these demands data providers, consultancies and university analysts are rapidly developing methods to map projects or publications related to specific SDGs. These 'mappings' do not analyse the actual impact of research, but hope to capture instead if research is directed or related towards problems or technologies that can contribute to improving sustainability.

Yet this quick surge of news methods raises questions about the robustness of the mappings and indicators produced, and about the effects of using questionable indicators in policy making. The misuse of indicators in evaluation has been one of the key debates in science policy this last decade, as highlighted by initiatives such as the San Francisco Declaration on Research Assessment (2013) and the Leiden Manifesto (2015).

In a new study that aims to map publications to SDGs, we have found a high degree of inconsistency using different approaches, as recently reported by Armitage et al., (2020). In this contribution, we propose that these inconsistencies are not due to minor technical issues, but instead they represent different interpretations of SDGs. In other words, there is no a single objective 'truth' about which research is relevant for reaching SDGs. Since different stakeholders have contrasting and often conflicting views about the relationships between science and SDGs, the contribution of bibliometrics should be to provide a plural landscape for each stakeholder to explore which areas are 'really' related to SDGs according to his views

(Rafols and Stirling, 2020). We describe here the beta-version of an interactive platform that allows stakeholders to explore in a global map of science the relationship between publications and SDGs.

Recent efforts for mapping research to SDGs

The first public analysis of SDG impact, released in 2020 by the Times Higher Education (THE, 2019), should be a motive for concern. For almost two decades, the THE has offered a controversial ranking of universities according to 'excellence'. The THE has now produced a new ranking of universities according to an indicator that sums dimensions of unclear relevance. For example, the indicator of the impact on health (SDG3) of a university depends on the one hand on its relative specialisation on health (as captured, e.g. by the proportion of papers related to health, 10% of total weight), and on the other hand on the proportion of health graduates (34.6%). The score is also based on (self-reported) university policies such as care provided by the university, e.g. free sexual health services for students (8.6%) or community access to sports (4%). Such an heterogenous and arbitrary composite indicator is likely to cause more confusion than clarity and it is potentially harmful as it mystifies university policies for the SDGs.

One may thus believe that it is better to stick to objective measures such as 'relative specialisation on health' as captured by the proportion of papers related to health. In the THE ranking, this bibliometric data is supported by an Elsevier analysis of the publications that are related to the SDGs – which might seem more reliable than those based on data self-reported by universities (Jayabalasingham et al., 2019).

However, mapping publications to the SDGs is not straightforward. Bibliometricians are aware that while some consensus can be soon reached regarding the delineation of a traditional scientific fields, fields defined by policy issues such as environmental research are ambiguous. Following policy demands, there is currently a profusion of initiatives aiming at mapping publications to SDGs. The approaches developed by Bergen University (Armitage et al., 2020), Elsevier (Jayabalasingham, 2019), the Aurora Network, SIRIS Academic or the STRINGS project are based on searching for strings of keywords, in particular keywords found in the UN SDGs targets or other relevant policy documents. These searches are then enriched differently in each case. The hypothesis is that publications or projects containing these keywords are those best aligned with the UN SDG discourse. The question is then which keywords should be included, and which not. For example, why in some lists zika virus is included in the list of health SDG3, but not the closely related dengue virus, with a much higher disease burden?

An alternative approach being developed at NESTA and Dimensions (Wastl, 2020) uses policy documents and keywords to train machine learning algorithms in order to identify articles related to the SDGs instead of creating a list of keywords to search the articles. The alleged advantage of this algorithm is that machine learning is assumed to be more accurate than search strings. The downside of this approach is that is it a black box regarding the preferences (or biases) of the machine learning algorithms – and this is serious handicap for transparency.

In terms of consistency across approaches, an article recently published by a team at Bergen University sounded the alarm by showing that slightly different methods may produce extremely different results (Armitage et al., 2020). When comparing the papers related to SDGs retrieved with their own analysis with those by Elsevier, they found that there is astonishingly little overlap – in most SDGs only around 25%-35% as illustrated in Figure 1. The differences also affect the rankings of countries' contributions to the SDGs. The Bergen team concluded that 'currently available SDG rankings and tools should be used with caution at their current stage of development.' We have conducted exploratory comparisons between the Bergen, SIRIS and STRINGS approach and can confirm major differences.

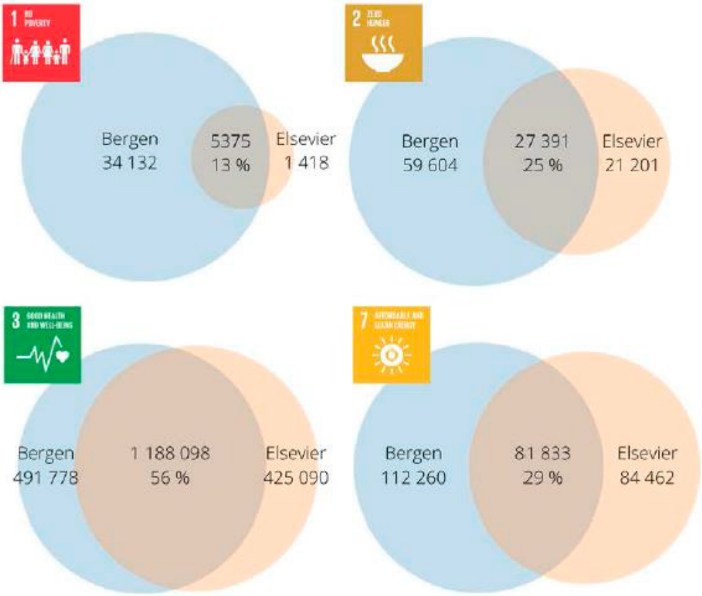

Figure 1. Comparison between Bergen and Elsevier approaches to mapping SDG-related publications. Based on WoS Core collection, 2015-2018. Source: Armitage et al. (2020).

Conceptual framework: a multiplicity of possible mappings of SDGs

However, from a conceptual point of view, perhaps we should not be surprised that different methods yield so different results. The SDGs refer to policy objectives in multiple dimensions – ending poverty, improving health, achieving gender equality, preserving the natural environment, etcetera. Innovation studies have shown that the social contributions of research are often unexpected and highly dependent on the local social contexts in which knowledges are created and used.

Nevertheless, most research is funded according to the expectations of the type of societal benefits that it may generate – and thus one can try to map these expectations or promises according to the language used in the (titles and abstracts of) projects and articles. However, the expected social contributions are often not made explicit in these technical documents because the experts reading them are assumed to know the potential applications.

As a consequence, the process of mapping projects or articles to the SDGs is ineluctably carried out through an interpretative process that 'translates' (or attempts to link) scientific discourse into potential societal outcomes. In other words, the analyst has to make assumptions regarding which terms are uniquely related to SDGs. Of course, such translation is dependent on the analysts' understandings of science and the SDGs. There is consensus on some of these understandings. For example, most analysts would agree that research on malaria is important for achieving global health. However, other translations are highly contested: should nuclear energy research be seen as a contribution to clean and affordable energy? Should all educational research be counted as contribution to the SDG on 'quality education'?

Furthermore, in a number of SDGs such as zero hunger (SDG 2) or reduced inequalities (SDG 10), there are stark disagreements on what the benefits of potential contributions: some stakeholders believe that GM crops (or organic farming) will help, while others believe that they will make the situation worse. Moreover, there is relatively little research explicitly mentioning issues such as gender or inequality in comparison to research whose innovation outcomes may affect these issues.

Another challenge is that many bibliometric databases used for analysis are not comprehensive, having a much larger coverage of traditional fields and rich countries (see Chapter 5 in Chavarro, 2017). This is particularly problematic, given that some research agendas relevant to developing countries are likely to be highly underrepresented (Rafols et al., 2015).

In summary, there is lack of consensus and many ambiguities on how publications relate to SDGs, and in these cases, the mappings will depend on the particular interpretation of the SDGs adopted in the methods for searching publications.

Given these ambiguities, we have developed an interactive mapping tool that aims to help stakeholders pick and choose which research lines they consider relevant in their context for each SDG. The map shows publication clusters of potentially relevant publication clusters for each SDGs with some interaction for users to understand the research contents of each cluster. This approach is introduced in the following sections.

Data and methods

We developed a search string extracting terms from policy documents explicitly mentioning SDGs. These search-strings were applied to retrieve publications (articles and reviews) for the period 2015-2019 from the CWTS in-house version of Web of Science (WoS) after an iterative process of refinement to avoid false negatives. This process was informed by comparisons with searches carried out by other initiatives, in particular SIRIS and Bergen. Details of this retrieval methodology are presented in the 2021 ISSI proceeding by Confraria et al.

On the other hand, we rely on an article-level classification based on direct-citation clustering of about 4,000 categories. These clusters are positioned in a science map based on citations across clusters according to a *VOSviewer* layout. This information is imported on a *Tableau* visualisation interface. The *Tableau* interface shows the clusters retrieved for each SDG with information on the cluster and the publications related to SDGs, as detailed below.

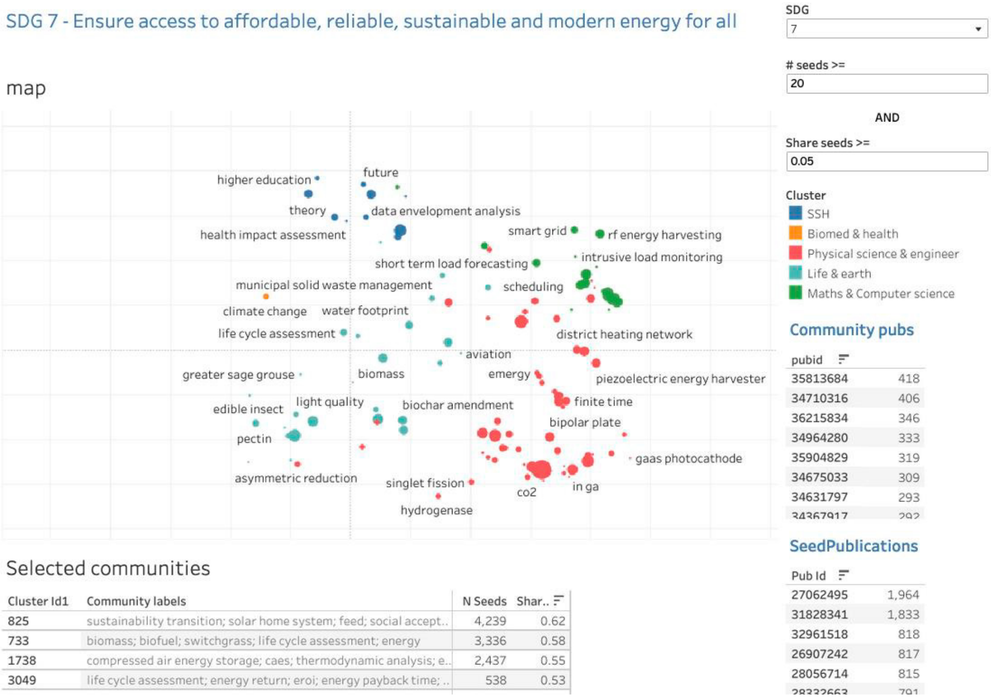
Results: a visualisation interface to explore plural mappings of SDGs

In this proceeding we introduce the beta-version of a visualisation interface aimed at facilitating the exploration of publication clusters related to SDG. The interface allows to choose one SDG (top right). Then the user can set the thresholds for considering if a cluster is related to this particular SDG: the minimum number of publications retrieved by the search string of this SDG (seed publications), and the minimum share of seeds in a cluster.

The clusters with figures above these thresholds are displayed in a science map according to their position in the global map of science. The colours of the clusters represent broad disciplines. Clusters in *Social science and humanities* (blue) are in the top left, *Biomedicine and health* (yellow) are in the left, *Physical sciences and engineering* (red) are in the bottom right, *Maths and computer sciences* (green) are in the right, and *Life and earth sciences* (light-blue) are in the centre-left.

The contents of specific clusters can be explored by placing the pointer of the mouse over the cluster of interest. For each cluster, you can see the 5 most relevant labels (where the labels are terms with high frequency and high cluster specificity) and the 5 most frequent journals. By clicking on the node or by clicking on the corresponding row in the list of 'Selected communities', the right column 'Community Pubs' allows to click into specific publications, which are linked via DOI to website of the publication. In this way, it is possible to read titles and abstracts and better understand the content of clusters.

Let us take for example, the cluster labelled as 'greater sage grouse' (centre-left) in SDG 7 (energy). This may seem a false positive since a grouse is a type of bird, rather than energy. However, the other labels of the cluster are wind farm and turbine. By clicking at the community publications, we then see that the article contents is related to bird collisions with wind turbines and power lines. Interestingly this cluster is about energy, but it shows a trade-off between SDG7 (Energy) and SDG15 (Life on Land).



SDG 7 - Ensure access to affordable, reliable, sustainable and modern energy for all

The map illustrates the many different types of research trajectories that may be related to sustainable energy, from higher education (top left), to smart grid management (top right) to thin solid films for photovoltaics made out of copper indium gallium selenide solar cells (InGa, bottom right), to diesel engines (centre-right) and alternative fuels in aviation (centre). This large variety of research trajectories shows that science can contribute to sustainable energy in very different (sometimes conflicting) innovation pathways.

However, stakeholders in specific contexts may think that some research trajectories are not as relevant for them as other trajectories. For example, developing countries might object to considering that cancer research as a priority for SDGs, given the relative under-investment in infectious diseases – the latter issues having a much higher burden for them. Therefore, the proposal of an interactive map is aimed at facilitating that different stakeholders find and choose those research trajectories that they consider y relevant for SDGs. Instead of having one single delineation of each SDG, the use of the interactive visualisation by stakeholders makes it possible to develop a plural and conditional mapping between SDGs and publications (Rafols and Stirling, 2020).

We can thus think of research over a given SDG in terms of a variable portfolio of research options as shown by clusters, with different stakeholders having different perspectives, values and needs regarding the balance between options, and the options that should be prioritized (Wallace and Rafols, 2015; Ciarli and Rafols, 2019). A given SDG will not be achieved by having more research on this SDG – but by having a balance of research options that is conducive to achieving the SDGs. In contrast, we think that having only rankings of universities according to their SDG is not a meaningful source of information for policy decisions.

Conclusion

In summary, given the variety of understandings regarding the relationship between research and SDGs, we propose that bibliometrics analysts should not assume that there is one single, preferred or consensus way of mapping SDGs to publications. Such assumption is likely to reproduce hegemonic perspectives on SDGs – often given by rich countries at influential institutional actors (Stirling, 2019). Instead, we propose a mapping tool which suggests publication clusters potentially related to a given SDG, thus allowing plural interpretations.

Protégé-advisor gender pairings in academic survival and productivity of German PhD graduates

Andreas Rehs[1]

Abstract

Female underrepresentation is a severe problem in academia and challenges the principle of merit-based selection. Previous studies have found protégé-advisor gender pairings to be associated with scientific survival and early career productivity for young scientists. In this study, I add to these results and focus on the disentanglement of temporal patterns after completing a PhD. I link a dataset of German protégé-advisor pairs scraped from online dissertations with disambiguated publication data from the Web of Science. My analysis is based upon time-discrete survival regression and explores the duration until the final publication after completing a PhD. I show that for protégés of female advisors, the yearly risk to drop out of academia after completing a PhD is about 38% lower than for protégés of male advisors. This effect is not different between female and male protégés. Women generally have a higher yearly dropout rate after completing a PhD.

Introduction

Doctoral advisors are often the most influential persons at the beginning of an academic career. They transfer knowledge, attitudes, norms, and behaviour to their protégés and influence their academic socialization and success (Barnes & Austin, 2009). Several studies have addressed the various scientific and socioeconomic characteristics of the advisors and their protégés to point out what makes these relationships mutually successful. Gender pairing in protégé-advisor relationships repeatedly stands out in this regard. It has diverse effects on career attainment and publication output of protégés (Gaule & Piacentini, 2018; Hilmer & Hilmer, 2007; Pezzoni, Mairesse, Stephan, & Lane, 2016).

In this paper, I want to investigate the role of protégé and advisor gender in German PhD graduates' academic outcomes. Especially for pairings involving women, this issue is of high societal and scientific interest in Germany. As observed in other countries, women are underrepresented in advanced career stages in German academia (Larivière, Ni, Gingras, Cronin, & Sugimoto, 2013). Although they accounted in 2017 for 51.7% of graduate students, their share of PhD holders was 45.4%. Women account for only 25.6% of university professors in Germany (Statistisches Bundesamt, 2020). This departure of women from the academic workforce indicates a misallocation of talent (Acemoglu, 1995). The consequences of this departure imply decelerated scientific progress with negative spillovers to industry and the economy in general. Women may also be personally affected. If they are equally qualified with men to start and pursue an academic career, but at some point quit, their educational investment cannot be fully utilized (McGuinness, 2006).

Gaule and Piacentini (2018) argue that this underrepresentation of women in academia perpetuates itself through the lower availability of female advisors for female students. They argue that underrepresentation works through a productivity channel or a preference channel. In the productivity channel, students are less productive when collaborating with an advisor of the opposite gender. As productivity is generally the primary driver of academic career success, this leads to higher rate of dropout from academia for female PhD graduates who were advised by men. In the preference channel, the authors argue that working with an advisor of the opposite gender is less enjoyable and leads to lower career satisfaction and a higher chance of dropping out early. Gaule and Piacentini show that a PhD student's research productivity, and propensity to become faculty after graduating, are both related to the gender of the advisor.

In this paper, I build on Gaule and Piacentini's findings. In the first step, I test whether productivity during a PhD in German academia is also linked to protégé-advisor gender pairings. In the second step, I focus on the disentanglement of the temporal patterns related to career outcomes and advisor gender after completion of a PhD. From the temporal perspective, academic careers, and careers in general, are non-dichotomous processes. They include multiple decisions and promotions that differ in their duration and in their point of time. The investigation of fixed points in time, as done in Gaule and Piacentini (2018), does not exploit the temporal dimension to its full extent. In this sense, it is an open question of how long protégés in different gender pairings remain in academia and which dropout "risk" they assume after their PhD. My study tries to address this gap and therefore adds to the methodical and empirical literature on academic labour market exit of junior researchers.

The durations one remains in academia can be considered as survival times and allow to utilize related models such as Cox proportional hazard or complementary log-log regression (c-log-log). The c-log-log regression used in this paper estimates covariates' effect upon the time a specified event takes to happen and assumes time to be discrete (Tutz & Schmid, 2016). Therefore, I can investigate how an advisor's gender and other characteristics affect the time a PhD graduate remains in academia after finishing his or her PhD. A similar methodology was applied by Sabatier, Carrere, and Mangematin (2006) to investigate the time it takes for female and male postdocs to attain professorship.

In the subsequent section, I discuss previous findings on gender pairings in academic protégé-advisor relationships. In the Data and methods section, I present my three data sources: doctoral advisor information scraped from German online dissertations, the German National Library's catalog, and publication data from the Web of Science that I have previously disambiguated (Rehs, 2021a,b). In the Results section, I describe the specification of my econometric approach and use negative binomial regression to estimate the effect of advisor gender on PhD student productivity. While I found that women were less likely to publish during the PhD, being advised by women did not have any effect on publication productivity. The probability of academic exit from academia by gender and advisor gender, as measured by the last year of publication after completion of a PhD, is investigated with a c-log-log regression and represents my main finding. I find that PhD graduates who had female advisors are about 37% more likely per year to continue publishing after PhD completion; this effect is not different between male and female graduates. In line with the observable female underrepresentation in academia, I also find that women are about 38% more likely per year than men to exit from research after completing a PhD. I end this paper by discussing the results, showing limitations, and, finally, concluding.

Gender pairings and outcomes of doctoral advisory

The topic of gender in doctoral advisory belongs to the greater literature on protégé-advisor relationships. This literature is divided into business research (Feeney & Bozeman, 2008; Noe, 1988), undergraduate (Bettinger, Long, Ehrenberg, Jacob, & Murnane, 2005), and postgraduate protégé-advisor relationships. Central to all these literature strains is some success outcome, like establishing business networks (Feeney & Bozeman, 2008) or influencing women to major in scientific fields of female academic role models (Bettinger, Long, Ehrenberg, Jacob, & Murnane, 2005; Canaan & Mouganie, 2019). In summarizing the literature across all those subdomains, I find that there is no clear support for the hypothesis that female advisors positively affect the outcomes of their female protégés.

The relation of advisor and protégé gender in postgraduate outcomes has been addressed in several studies and is central to the debate of female underrepresentation in academia (Pezzoni et al., 2016). When discussing those studies, one must account for the various disciplinary, institutional, and regional backgrounds in which the studies were conducted. The German context – which is subject of this study – is special in many regards (Kehm, 2006). German universities produce one of the highest proportions worldwide of doctorates in relation to the population (OECD, 2019). About 50% of those doctorates are awarded in the field of medicine, where dissertations are very different from other disciplines (Konsortium Bundesbericht Wissenschaftlicher Nachwuchs, 2017).

The sorting process of advisors and their protégés is the natural starting point to investigate the effects of advisor gender and gender pairings. It has repeatedly been found that same-gender pairings are clearly overrepresented (AlShebli, Makovi, & Rahwan, 2020; Gaule & Piacentini, 2018; Pezzoni et al., 2016). The causal mechanisms for this overrepresentation, however, remain unclear. The qualitative study from Gray and Goregaokar (2010) on executive coaching suggests that women prefer women because they act as a role model for business success. This can lead to empirical problems as the matching process may not be random. Azoulay, Liu, and Stuart (2017) especially point towards this issue of "partially deliberate" social matching. Some social factors, like the rationales for forming the advisor-protegee relationship (e.g., same gender role models) are endogenous to the matching process. However, other factors are incidental and are therefore conditionally exogenous to the matching process. Azoulay, Liu, and Stuart (2017) indicate that geography and thematic focus are the main drivers of matching between advisors and protégés. For my study this implies that self-selection bias related to same gender can be present in the data but is probably not the main driver of matching.

The international literature comes to different conclusions on the effects of postgraduate advisor gender and protégé-advisor pairings. Starting with productivity outcomes, Pezzoni et al. (2016) find for protégé-advisor pairs of the prestigious California Institute of Technology that students working with female advisors publish 7.7% more articles per year while earning their PhD than those working with a male advisor. Using male students with male advisors as the reference group, Pezzoni et al. show that gender pairing matters in this regard. They find that male students working with female advisors publish 10% more articles per year than the reference group, and female students working with male advisors publish 8.5% less. They find no difference between women advised by women and the reference group of men advised by men. The results are robust for using the journal impact factor as a proxy for the quality of articles. Gaule and Piacentini (2018) study the productivity of PhD students in US chemistry programs. In opposition to Pezzoni et al., they find students with an advisor of the same gender tend to be more productive during a PhD program. Women profit more strongly from same-gender advisors than men do.

The recent study from AlShebli, Makovi, and Rahwan (2020) on protégé-advisor gender pairings is controversial (Retraction Watch, 2020). They use a different notion of advisor, considering all senior coauthors on a paper as the focal PhD student's informal advisors. Using 3 million protégé-advisor pairs, they find same-gender pairings do not benefit the impact of papers (measured by number of times cited by other papers) written after completing a PhD. Their findings suggest that female protégés who remain in academia profit more strongly when mentored by male advisors rather than equally impactful female advisors. Their findings also suggest that advisors more strongly benefit in future impact when working with male protégés rather than comparable female protégés. This especially holds if the mentor is female. The paper from AlShebli, Makovi, and Rahwan has been criticized because advisor quality, as measured by previous papers, is an inadequate matching variable. The advisor quality is central in finding comparable female-male, female-female, male-male, and male-female pairs that are later used for analysis. Since there is empirical evidence for gender citation bias, matching via this citation-based criterion may also be biased.

Hilmer and Hilmer (2007) and Neumark and Gardecki (1998) investigate protégé-advisor gender pairings in economics and consider activity-based success measures. When examining the first jobs of new PhD graduates, Hilmer and Hilmer (2007) find that female graduates who had male advisors are significantly more likely to accept research-oriented first jobs than male graduates who had male advisors. Neumark and Gardecki (1998) focus on time spent in and completion of graduate school. They find limited empirical evidence for the positive impact of female advisors on the probability that female students finish graduate school. However, female advisors are associated with female students spending less time in graduate school. Gaule and Piacentini (2018) address the likelihood of PhD students becoming university faculty based on different gender pairings. They find female students working with female advisors are considerably more likely to become faculty; for male-male pairings they do not find an effect. In summary, the empirical evidence on the effects of gender pairings and advisor gender is ambiguous, scattered, and may depend strongly on the data, context, and operationalization of outcomes. I therefore abstain from forming a hypothesis about the protégé-advisor gender pairing effects in German academia.

Data and methods

My data rest upon two pillars: disambiguated Web of Science publication data, and PhD advisor info scraped from online dissertations. A schematic of my databases and their relations is depicted in Figure 1. I use the German National Library's 2015 electronic catalog and university library servers to build my online dissertations database. The German National Library has the legal mission to collect and archive all printed publications issued in Germany and works written in German or relating to Germany. German PhD graduates are therefore required to supply a copy of their dissertation to the German National Library. The German National Library's electronic catalog features information on their authors, the university name, the year of publication, subject, and, if available, a link to an online dissertation.

Figure 1. Database schematic

I use the provided online dissertation link and download the underlying PDF document. The download from the German National Library was successful in 40,000 cases. To further increase my online dissertation dataset, I repeat the same exercise for dissertations stored at 20 different university library servers, collecting 80,000 online dissertations. All scraping has been done in 2017. I match the 40,000 dissertations from university library servers back to the German National Library's catalog by the author name, year, and university name. I search dissertation front pages and acknowledgments for text patterns like "doctoral advisor" and its German variants in the next step. These patterns indicate the subsequent occurrence of advisor info. A similar approach was used by Fuchs and Rehs (2020) to scrape birthplaces from the same dataset of online dissertations. I find 13,315 protégé-advisor pairs where the found advisor has a unique name in the German National Library catalog. The restriction to unique advisor names ensures correct protégé-advisor pairs.

To retrieve publication data of the protégés and their advisors, I use the database from Rehs (2021b). Rehs (2021b) builds on Rehs (2021a), which develops a machine learning approach to disambiguate author names in the Web of Science. Rehs (2021b) uses this algorithm to establish a data base of about 11 million author-name disambiguated publications and links them to 50,000 out of one million dissertation authors stored in the German National Library's catalog. Using the publication profiles of German dissertation authors, I investigate how long they continue to publish in Web of Science journals after completing their PhD and how this duration is related to their gender and the gender of their advisor.

Productivity during the PhD and other related indicators are also calculated from this dataset. For a random set of 100 persons, I check whether the year of the final publication after completing a PhD corresponds to the actual year of dropout from academia. I retrieve the dropout year from online research on Xing, LinkedIn, university homepages, and other websites. The year of the final publication correlates with the actual dropout by 0.7 and validates the year of final publication as a dropout proxy.

Table 1 reports summary statistics for my final datasets. In line with Gaule and Piacentini (2018), I find that women disproportionally often advise women. Advisors also differ substantially in their numbers and their characteristics by gender, although advisors have, on average, the same academic age (see advisor characteristics: *Dissertation year*). My earliest dissertation from protégés is from 2001; the mean dissertation year is 2005. The availability of online dissertations is the driver of this bias towards younger doctoral cohorts in my dataset. The high popularity of online dissertations may explain the sharp increase in the coverage rate of advisor info in my dataset. The difference between the PhD graduate's dissertation year and the advisor's dissertation year (see advisor characteristics: *Difference to diss. year of protégé*) is a measure for the advisor's academic age. Female and male protégés have no differences in this regard.

Figure 2 shows the temporal distribution of the mean number of (accumulated) publications of a protégé by gender pairing. The descriptive patterns suggest that productivity differences are established early, before completion of a PhD. Male protégés advised by men have the highest mean productivity and women advised by women, the lowest. After $t = 0$ the publication number averages may include survivor bias and can therefore not be interpreted in a meaningful way.

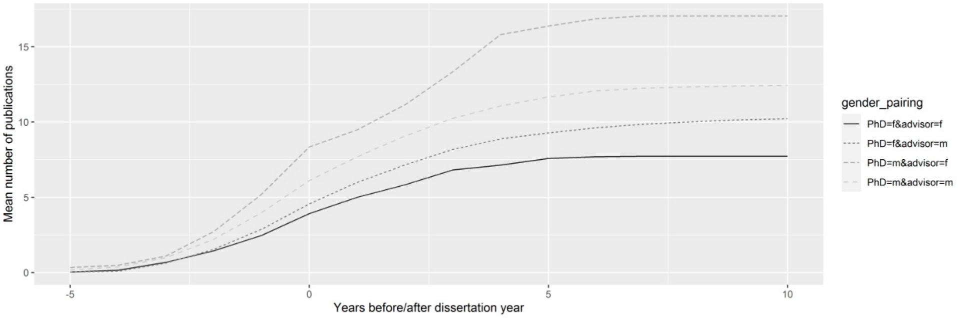

Figure 2. Mean number of cumulated publications before and after dissertation by gender pairing

Years till last pub. after diss. is my main outcome with respect to academic survival. I can observe that PhD graduates advised by men survive on average half a year longer than those by female advisors. In further differentiating the effect of female advisors, I find that their female students produce their final publication half a year earlier than male students. I observe no difference between male and female PhD graduates with male advisors in the mean number of years until the final publication.

Difference to diss. year of protégé	962	0	20,5	41		-4	21,4	99		6	20,4	41
Number of papers	59	2	59,1	208		2	63,4	189		6	52,9	208

In my econometric setup, I will first investigate a student's productivity during the PhD program to address whether early productivity differences by gender and gender of the advisor exist. The number of papers written until the year after the PhD is my dependent variable. The main variables of interest are the gender of the protégé and the gender of the advisor. Since the outcome variable is a count, I use a negative binomial regression to estimate my regression and control for discipline and year effects using dummy variables.

The next step is modeling academic survival after completing a PhD. I use the year of the final publication after PhD completion as a proxy for academic survival. This outcome's operationalization is restricted in my dataset by the period of graduation cohorts from 1995 to 2015. Older cohorts can therefore be active longer than younger cohorts. My solution is to censor persons who were still active in 2017. A PhD graduate from 2014, still publishing at the cutoff of my database in 2017, is treated as right-censored after three years. In the following description of my economic approach, I will orientate on the methodology of Tutz and Schmid (2016) and van de Schoot (2020).

In my time discrete survival models the risk of event builds on the hazard h_{it}. The hazard is the conditional probability that a researcher i will exit from academia in the time period t, given the researcher did not exit earlier. The hazard function can be stated as follows:

$$h_{it} = P(T_i = t \mid T_i \geq t) \tag{2}$$

In (2), T is a discrete random variable. The equation represents the probability that the exit of a given researcher will occur in the current time period t under the constraint that it will occur now or sometime in the future. Now, the hazard in time period t can be estimated as follows:

$$\hat{h}_t = \frac{Number\ of\ exits\ from\ research_t}{Number\ of\ researchers\ at\ risk\ to\ exit_t} \tag{3}$$

In order to build a regression framework, the hazard h_{it} now needs to be linked to a linear predictor η. The relationship of the hazard function and a linear predictor can be represented as:

$$\eta = g(h_{it}) = \gamma_{0t} + x_{it}\gamma \tag{4}$$

Here, g is a link function that links the linear predictor to the hazard. In my case, the linear predictor includes a set of covariates for researcher i in period t. These covariates are protégé gender, advisor gender, and year and discipline controls. To disentangle the effects of advisor gender, I also estimate interactions of advisor gender and protégé gender. In (4), γ_{0t} represents the time-variant intercept and shows the baseline hazard. In the next step, I use a c-log-log function to link the hazard to the linear predictor. Therefore, my model refers to a time discrete c-log-log regression. The hazard function changes and becomes:

$$h_{it} = 1 - \exp(-\exp(\eta)) \tag{5}$$

Results

Table 3 shows the regression results and average marginal effects for productivity as measured by the number of papers published during PhD study. I do not find an effect of advisor gender in any of my full sample models. However, the coefficients and the marginal effects of protégé gender arrive at statistical significance in the baseline, in the full model, and in the full model with advisor productivity. According to the full model's marginal effects, female PhD students write 1.6 papers less than male PhD students. When including advisor productivity, as done in the full model 5, this discrepancy disappears. The advisor productivity has a statistically significant impact on the number of papers at the dissertation year. An additional publication from the advisor leads to an increase of about 0.04 publications by their protégés. Since this result is based on 59 observations, including only nine female advisors, the robustness is questionable.

Figure 3 shows the Kaplan Meier survival curve for the four different protégé-advisor constellations and a table that shows the number of graduates at risk of leaving academia each year after PhD completion (t = 0). I observe a substantial decline in the number of persons at risk in the first two years. The dominant share of scientists, therefore, do not stay in academia after PhD. P = 0.21 indicates the log-rank test result and indicates that the time to the final publication is statistically not different between the four groups.

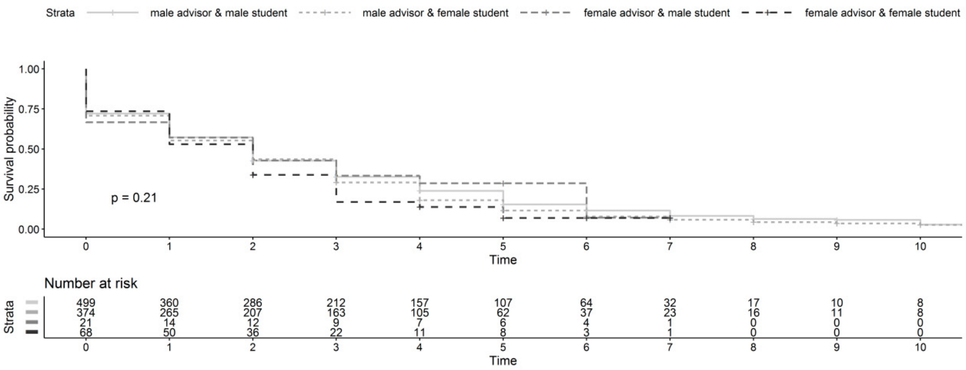

Figure 3. Kaplan Meier Curve and risk table for final publication after PhD completion

Table 2 shows the c-log-log regression results. The hazard for women to write their final paper is, according to Model 1, 1.37% higher than for men. A female advisor is generally beneficial and leads to a 38% lower hazard of dropout from academia. Model 3 includes year and discipline dummies; it shows that women's higher hazard remains robust when including these dummies. Models 2 and 4 display the interaction of advisor gender and protégé gender. I find no statistically significant effect for the interaction.

Discussion and conclusion

In this paper, I have investigated the effect of advisor gender on protégé productivity during PhD study and on academic survival after PhD completion. In my investigation of productivity, I aimed to find if early productivity differentials are related to advisor gender. Using negative-binomial regression, I do not find any such relation. However, I find that female PhD students publish about 1.6 papers less than male students during their PhD study. My data cannot explain if this profound effect is related to other advisor and PhD student characteristics. For instance, it is still unknown if advisor productivity, quality, and protégé-advisor collaboration play a role. Also, I could not account for publication quality and number of co-authors. In future studies quality can be addressed by weighting the publications on the basis of the journal impact factor. My second outcome, the time between PhD completion and final publication, addresses academic survival after earning a PhD. The time until the final publication is one of the main contributions of my approach. Unlike in previous literature, which concentrates on examining outcomes at fixed points, I fully utilize the temporal dimension after PhD completion.

My application of time-discrete c-log-log regression delivers two main findings on advisor and protégé gender. First, I find that female advisors positively affect academic survival of PhD graduates, leading to a 38% lower dropout hazard. The causal mechanisms underlying this result remain unclear and are beyond the focus of my study. My results potentially suffer from self-selection bias. Therefore, the initial matching process between protegees and advisors may not be random. Descriptively, the disproportionately high number of women advised by women may indicate such bias. However, Azoulay et al. (2017) point out that spatial proximity and thematic focus are the main drivers for matching advisors and protégés. In further studies the potential self-selection bias should therefore be addressed by using more advanced econometric setups (e.g., Azoulay et al., 2017).

The female advisor effect is statistically not different between male and female PhD students. My results contrast with previous findings, such as those of Gaule and Piacentini (2018), who find that same-gender protégé-advisor pairings increase the likelihood of PhD graduates becoming university faculty. The reason for my lack of result may be a problem of low statistical power. PhD graduates advised by women make up only 89 observations in my dataset, and the effect just fails to reach the 10% statistical significance level. To obtain more observations from female advisors, one can improve the advisor scraping and linking and author name disambiguation strategy in the future. The underlying dataset of Rehs (2021b) only covers a fraction of German dissertation authors who have published.

An explanation of the low number of female PhD graduates and female advisors could also be attributed to name changes after marriage. My approach does not account for women who marry and change their family name after their doctorate. Since they are then no longer observable, they are considered to have had their final publication. This problem could be solved by bibliographic coupling. If I no longer observe publications from the focal female scientist, and if a previous coauthor of hers publishes together with a person of the same first name, but different last name, this may indicate that the focal scientist has changed her name. The positive female advisor effect may be conditional to unaddressed advisor characteristics. I did not control for team characteristics, informal advisors, graduate school characteristics, funding characteristics, socioeconomic background, and many others.

The second main result I find is that women are 37% more likely per year than men to exit from research after completing a PhD. In light of the female underrepresentation, this finding is unsurprising. Nevertheless, it adds to the literature by quantifying the female dropout risk for the first time. Concerning the name changes mentioned previously, this result needs further robustness analysis. There are other factors unaddressed in my study that lead to female dropout. In particular, the effect of private events and factors, such as childbirth and motherhood, lead to an omitted variable bias in my study. It is also unclear whether there are differences in the preference for careers in science or industry between men and women after completing their PhD, which could explain the female departure from academia.

Finally, my study is limited to young German scientists in disciplines where publication in Web of Science index journals is traditionally dominant. Therefore, I miss arts, humanities, and parts of social science where journal publications are not (or have not been) popular and which are only partly covered by the WOS (Mongeon & Paul-Hus, 2016). In these disciplines, women also make up higher shares of PhD graduates in Germany, potentially leading to different productivity and survival patterns.

I conclude that female underrepresentation and its relation to advisor gender in academia is a complex empirical phenomenon of high scientific and societal relevance. My study contributed to the literature by trying to disentangle the temporal and productivity dimensions before and after completion of a PhD in the German context. The survival operationalization offered a new perspective on female underrepresentation and may help to design policies that help to reduce female underrepresentation in academia.

Abstract

ANOVA models in general are valid only insofar as both homoscedasticity and multiple comparisons between groups are controlled for. While recent studies suggest that researchers in various disciplines seldom comply with these requirements, lack of rigor in methodological reporting makes a proper, large-scale, and transdisciplinary assessment of the situation impossible. Given this situation, the present paper attempts a large-scale and transdisciplinary assessment of statistical reporting transparency in ANOVA-related papers, using customized regular expressions on the full-text of articles published in Elsevier journals. Results show that, beyond important variations at multiple disciplinary levels, reporting transparency in the testing of ANOVA statistical assumptions is generally lacking, as a minority of ANOVA-related papers refer to either homoscedasticity or multiplicity correction. Also, articles from higher-quartile journals tend to report statistical assumptions more thoroughly than those from lower-quartile journals, regardless of discipline or subdiscipline.

Introduction

Alongside scientific misconduct, questionable research practices (QRPs) have the potential to undermine science, its reputation, and human knowledge in a considerable, extensive, and durable manner (John, 2012; Martinson et al., 2005, Fiedler and Schwarz, 2016; Sacco et al., 2018; Steneck, 2006). What makes QRPs such as post-hypotheses, conveniently-rounded numbers or selective literature reviews particularly insidious, resilient, and prone to escalation is that they can be done unknowingly, in good faith, and offer “considerable latitude for rationalization and self-deception” (John, 2012: 524): “QRPs can waste researchers’ time and stall scientific progress, as researchers fruitlessly pursue extensions of effects that are not real and hence cannot be replicated. More generally, the prevalence of QRPs (…) threatens research integrity by producing unrealistically elegant results that may be difficult to match without engaging in such practices oneself” (John, 2012: 531).

Amongst the different issues pertaining to QRPs, statistical misreporting certainly features amongst the most benign-looking, yet deceptive ones: despite the foundational and historical role of thorough reporting in science (Hardwicke, 2019), empirical research in certain fields has shown that reporting inconsistencies are increasing (Leggett, 2013), can have important consequences (Chalmers, 1990), and persist despite publication of guidelines (Clayson, 2019). Even when stemming from honest mistakes, selective or incomplete reporting of statistical protocols results in publications that “fail to capture all of the findings generated by the scientific enterprise” and thus provide “a skewed impression of the evidentiary landscape” (Hardwicke, 2019: 15). Perhaps more importantly, statistical misuses cannot be properly identified, assessed or dealt with if scientific narratives tell only part of the story.

This deadlock is perhaps nowhere more obvious than in the case of analysis of variance (ANOVA) procedures, which figure amongst the most popular Null Hypothesis Significance Testing (NHST) models in science. Regardless of the number of independent or dependent variables considered, from a parametric or nonparametric perspective, ANOVA procedures are only valid insofar as both homoscedasticity of variance and multiplicity of comparisons between groups are both controlled for. While studies presented in the following section show that both requirements are seldom met and that non-compliance in both regards can greatly impact research results, lack of rigor in methodological reporting makes a proper evaluation of the situation impossible. In light of this, the present research attempts a first large-scale and multidisciplinary assessment of homoscedasticity and multiplicity reporting in ANOVA-based research, using customized regular expressions on the full-text of articles published by Elsevier journals in 2015. In the next section, the different types of analysis of variance models are briefly presented, along with a description of their homoscedasticity and multiplicity control prerequisites. Following this, data collection and analysis procedures are detailed and their results reported and discussed.

Analytical models and statistical assumptions of variance

Analysis of variance refers to a collection of NHST models used in order to compare the differences among normal group means or medians in a sample. More precisely, ANOVA models test the null hypothesis that all group means or medians are equal by comparing the amount of systematic or explainable variance in the data to the amount of unsystematic or unexplainable variance. ANOVA models are thus omnibus tests: they tell us if the groups differ, but do not provide specific information about which groups differ and the magnitude of these multiple differences. In experimental terms, they allow us to determine if experimental manipulation has had some effect or not, but don't tell us specifically what the effect is.

Three fundamental types of ANOVA tests can be distinguished: parametric analysis of variance (ANOVA), parametric multivariate analysis of variance (MANOVA), and nonparametric analysis of variance. In the specific case of standard ANOVA tests, only one dependent variable is considered, and all models are variations on two common dimensions: how many independent variables they compare ('one-way' for one, 'factorial' for more than one, 'two-way' for two, ...) and what type of groups the test considers ('repeated measures' if the same participants are used in each variable group, 'independent' if the variable groups include different participants, and 'mixed' if both variable group types are used).

Multivariate analyses of variance (MANOVA) can be considered a generalization of ANOVA tests, as they can be used regardless of the number of independent variables involved, and are as such able to provide more information than univariate tests. "*If separate ANOVAs are conducted on each dependent variable, then any relationship between dependent variables is ignored. As such, we lose information about any correlations that might exist between the dependent variables. MANOVA, by including all dependent variables in the same analysis, takes account of the relationship between outcome variables. Related to this point, ANOVA can tell us only whether groups differ along a single dimension, whereas MANOVA (...) has greater power to detect an effect, because it can detect whether groups differ along a combination of variables*" (Field, 2012, p. 664).

Both standard ANOVA and MANOVA models are however parametric tests, in that they assume that the variables to be analyzed follow a given (normal) distribution. In contrast, nonparametric ANOVA models like the Kriskal-Wallis test obviate the need for distribution normality: by focusing on ranks and medians instead of absolute values and means, nonparametric tests represent an ingenious way to compare central tendencies between groups in cases where the data does not allow for parametric comparisons. Despite this versatility, nonparametric tests are however just as dependent as their parametric counterparts on their compliance with two fundamental statistical assumptions, without which no valid analysis of variance is possible: homoscedasticity and multiplicity.

Homoscedasticity

Like many other statistical tests, ANOVA models must comply to the rule that the groups whose means they compare are homoscedastic, that is, have similar variances (as opposed to heteroscedastic groups): "*as a rule of thumb, the largest and the smallest variance within groups should not differ by more than one order of magnitude. The reason for assuming equal residual variance (homoscedasticity) is that the variances are pooled to give an estimate of the variance that can be used for all groups simultaneously. (...) Slavish adherence to the formulae in the face of a violation of homoscedasticity assumption is one of the most common mistakes in the use of ANOVA which often result in a tragic abuse of really good data*" (Ståle, 1989, p. 270). Past research has indeed shown that violation of the homoscedasticity assumption for both ANOVA and MANOVA models has a nonnegligible impact on statistical significance; this has been observed in both unequal (Bishop, 1978; Box, 1954) and equal (Rogan, 1977) sample size contexts as well as under a wide variety of variance heterogeneity conditions (Bishop, 1976; Dajani, 2002; Krutchkoff, 1988; Lee, 2003; Lu, 2007). As for non-parametric tests, these are first and foremost statistical dominance tests, that is, procedures for identifying partial order between variables (Fishburn, 1964; Kmietowicz and Pearlman, 1979); as such, they are adequate for median difference testing only insofar as the groups being compared have similar shape and variance (Kasuya, 2001; Moser et al, 1989; Neuhäuser, 2002; Ogenstad, 1998).

Multiplicity

Multiplicity is for its part intrinsically linked to the scientific method itself. While science is often portrayed as a piecemeal investigative process, one which consists in asking nature "one question at a time" (Fischer, 1926, 511), actual scientific practice usually proceeds "familywise", by conducting large experiments designed to answer a collection of related claims. What is often forgotten however is that such batch testing and comparing increases the probability of detecting a nonexistent effect: for example, using a standard significance level of $\alpha = 5\%$ in a consecutive series of independent tests, one might expect to get a significant effect at the 20th test, regardless whether or not this effect is true (Bender, 2008). In addition, this inflation effect does not only concern the hypotheses of interest, but is instead tributary to all the potential inferences that can be drawn regarding the problems and data at hand. In other words, "familywise" statistical inferences are valid only insofar null hypotheses are scaled up accordingly. In the case of ANOVA, MANOVA, and nonparametric tests, this multiplicity problem emerges as soon as more than two variables are involved, one test being needed for each pairwise variable combination (Albers, 2019; Armitage, 1969; Cramer, 2016; Fletcher, 1989; John, 2012; Smith, 2002). As with NHST in general, the two most prudent and used statistical strategies to deal with false positives resulting from multiple comparisons are to control either the familywise error rate or the false discovery rate (Cramer, 2016). Both tests have proven their efficiency in a famous neuroimaging study, in which the authors showed that neglecting both tests enabled them to detect statistically significant signatures of brain activity in a dead Atlantic salmon during "mentalizing" tasks (Bennett, 2012). Despite this, researchers rarely use these tests: in a recent study of 819 articles published in six leading journals in psychology, it was shown that while almost half of all articles used a multiway ANOVA, only 1% of them used a correction procedure. Such a situation may stem from the fact that the multiplicity problem and its solutions are often not presented by mainstream statistical textbooks and statistical software packages, especially as regards to factorial, multivariate, and nonparametric tests (Cramer, 2016). Due to these omissions, not only are scholars not reminded to avoid considering the statistical significance of each mean comparison individually, but many might not even be aware of this necessity.

Methods

Article metadata for the corpus used in this research was obtained through the Web of Science (WoS) database, along with Scimago journal ranking statistics and the National Science Foundation disciplinary and sub-disciplinary classification of journals. Following this and with the use of various Python and R scripts, all WoS articles with digital object identifiers, published in 2015 in Elsevier journals from Life Sciences, Physical Sciences or Social Sciences & Humanities disciplines were kept. For each article of this data set, the full text was obtained using the Elsevier Full Text API, from which 321312 articles published amongst 1438 journals were extracted; WoS proportion and article frequencies by best quartile and discipline are shown in Figure 1. It is important to stress here that, while there are few Elsevier Journals in the lower quartiles of many disciplines, the total amount of articles within each discipline remains substantial and will allow for interesting analyses and comparisons.

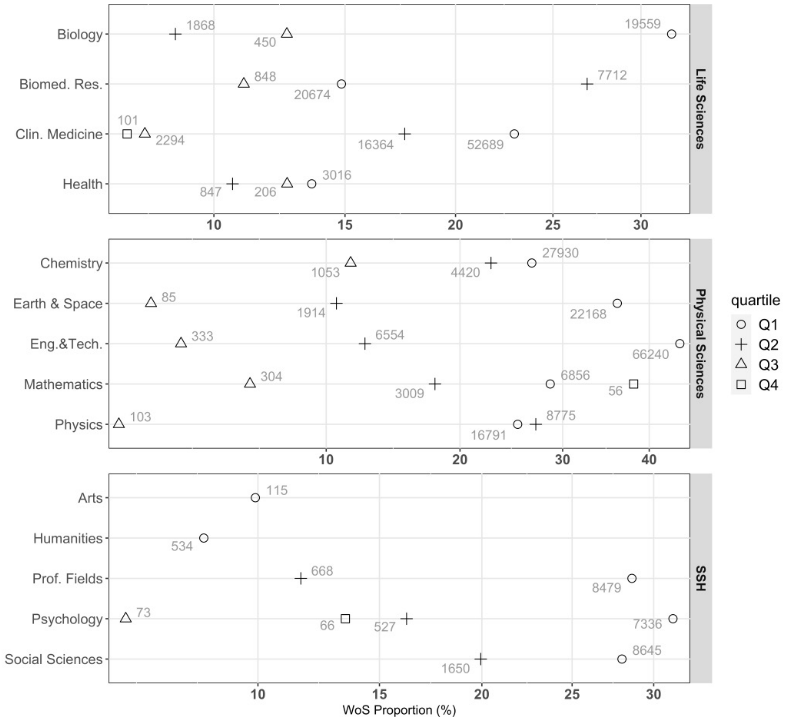

Figure 1. WoS proportion (%), along with article frequency of harvested Elsevier articles, by discipline and journal quartile.

In order to identify papers that use terms related to analysis of variance, homoscedasticity, and multiplicity, various regular expressions were designed and applied to the corpus. A first set of 3 regexes was aimed at identifying articles containing orthographic variants of expressions related to various analysis of variance tests. The first regular expression aims to capture all mentions of parametric analysis of variance in the corpus; negative lookaheads and lookbehinds were added to the regex in order to exclude all cases referring to MANOVA and non-parametric considerations. The second regex aims to capture references to multivariate or multiple analysis of variance (MANOVA). The third regular expression aims to catch expressions referring to the following non-parametric analysis of variance tests: Jonckheere's trend test, Friedman test, Kruskal-Wallis test, permutational ANOVA, non-parametric ANOVA as well as ANOVA on ranks. The last two regexes were designed to capture strings related to homoscedasticity and multiplicity considerations respectively. In the first case, references to either hetero- or homoscedasticity were considered relevant for the present study, hence the ulterior use of the expression 'scedasticity' to refer to such cases. This scedasticity regex was designed in order to capture variants of the following expressions: *homoscedasticity*, *heteroscedasticity*, *equal/similar/comparable variance*, *Levene's test*, *Bartlett's test*, *Hartley's fMax*, *Glejser test*, *White test*, *Cochran's C test*, *Box's M test*, *Breusch-Pagan test*, *Goldfeld-Quandt test*, *Brown-Forsythe test*, *Cook-Weisberg test*, *Harrison-McCabe test*, *Fligner-Killeen test*. As for multiplicity considerations, variants of the following strings were captured: *Bonferroni correction*, *family-wise error rate (FWER)*, *false discovery rate* (*FDR*), *Dunn's test, Dunnett's test*, *Šidák correction*, *Tukey's range test*, *Holm-Bonferroni step-down procedure*, and *Hochberg's step-up procedure*. In the case of ANOVA-related expressions referring to last names, regular expressions were designed in order to ignore citations; this was done by excluding all expressions followed by substrings characteristic of various citation formats, namely the abbreviation *et al.*, digits surrounded by brackets or parentheses as well as the conjunction *and* followed by a proper noun followed by digits surrounded by brackets or parentheses, as in *Smith (2008)* or *Johnson [3]*. Application of these regex to the corpus resulted in the extraction of 178818 expressions distributed over 55746 articles; frequency distribution of all captured strings for each regular expression are shown in the Appendix.

Results

The Venn diagram shown in Figure 2 classifies the articles containing strings captured by the above-mentioned regular expressions. Of the lot, 11 articles contain strings matched by all regular expressions, while 37043 articles match only one of the above regexes. Of particular interest for the present research are the set-theoretic equations shown below the figure: of the 13.6% of extracted papers containing parametric ANOVA mentions, 8.2% of them also contained expressions referring to scedasticity, 37.2% contained multiplicity-related expressions, and only 3.8% of them referred to both statistical assumptions. As regards to both MANOVA and nonparametric ANOVA test types, while the proportion of extracted papers is considerably smaller than in the case of ANOVA-related papers, proportions regarding statistical assumptions remain similar, with respectively 16.7% and 10.5% for scedasticity, 31.8% and 32.9% for multiplicity, as well as 6.4% and 5% for both assumptions. In sum, while around a third of all papers dealing with analysis of variance include considerations related to multiplicity correction, that ratio drops drastically in the case of scedasticity reporting, even more so in the case of papers alluding to both statistical assumptions. Finally, with the sole exception of multiplicity, proportions are higher in the MANOVA and nonparametric cases than in the parametric ANOVA one; this trend suggests that reliance on more sophisticated or marginal analysis of variance tests or considerations might be positively correlated to both the awareness of and commitment to the tests' underlying statistical assumptions.

Percentages for ANOVA-related articles (A), ANOVA-related articles that contain either scedasticity or multiplicity (SorM) references, and ANOVA-related articles that allude to both assumptions (SandM) were compiled for all extracted articles; results by disciplinary group, discipline, and journal quartile are shown in Figure 3. Overall, 14,3% of extracted Elsevier journal articles contain expressions referring to analysis of variance. Life Sciences papers have the highest proportion of such papers (27.7%), followed by Social Sciences & Humanities (17.3%) and Physical Sciences (3.6%), the latter containing more than half (51.8%) of all extracted papers. At the disciplinary level, Psychology (41.7%) and Biology (40.5%) have the highest proportion of ANOVA-related papers, while Physics (0.6%) and Mathematics (0.8%) have the lowest ratios. Given the disciplines involved and with the exception of Mathematics

Q4, it seems reasonable to conclude here that disciplines that rely more on NHST-based experimental procedures show a higher proportion of ANOVA-related papers.

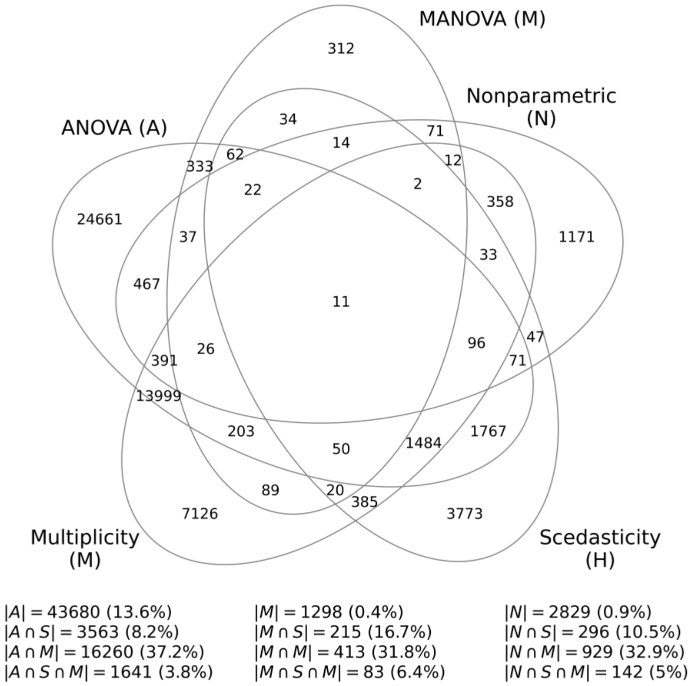

Figure 2. Article Frequency by Regex captured.

Regarding statistical assumptions, 39.7% of papers referring to analysis of variance include either scedasticity or multiplicity considerations; at the disciplinary group level, Life Sciences disciplines (42.4%) have on average a higher ratio than both SSH (34.1%) and Physical Sciences (28%), with Clinical Medicine (44.9%) and Biomedical Research (44.3%) leading the disciplinary landscape. Results are however markedly lower for papers alluding to both assumptions. Overall, only 3.6% of ANOVA-related papers refer to both scedasticity and multiplicity; proportions are uniformly distributed amongst disciplinary groups (Life Sciences: 3.4%, Physical Sciences: 4.4%, SSH: 3.6%) and disciplines, Mathematics Q3 (25%) and Earth & Space (8.7%) being the odd ones out in that respect. In sum, while the above Venn diagram showed that assumption testing was not thoroughly reported globally, analysis at both disciplinary group and discipline levels shows that this underreporting is not specific to a disciplinary group or a few disciplines, but rather pervades the whole scientific community, regardless of the subject matter and its formal complexity. It is also interesting to point out that higher-quartile journals tend to contain higher A, SorM, and SandM ratios than lower-quartile journals from the same discipline. While hinting at the appeal and impact of ANOVA-based research, this trend also suggests that more scrupulous peer-review in higher-quartile journals may help foster thorough statistical reporting in these publications.

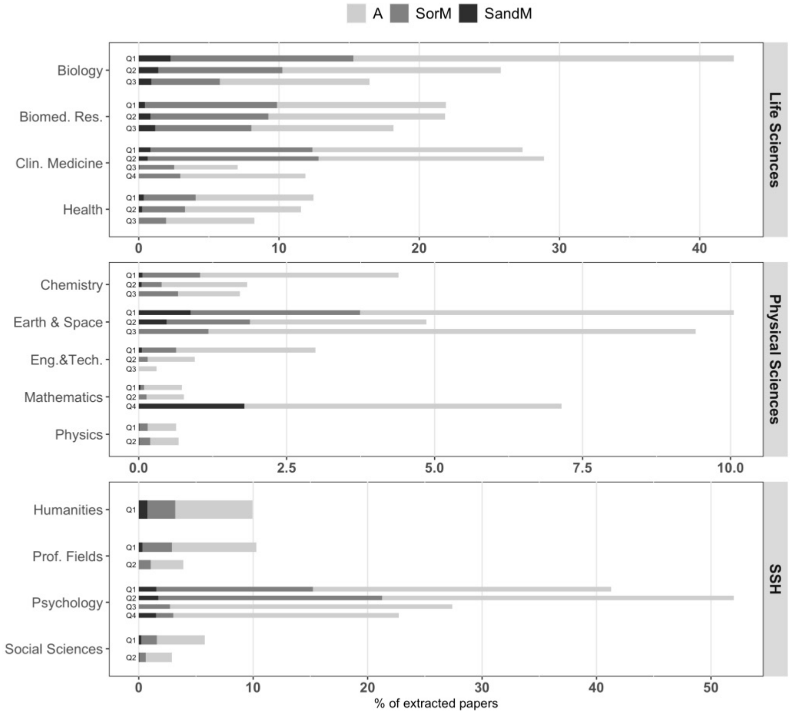

Figure 3. % of ANOVA-related papers (A) and ANOVA-related papers referring to either (SorX) or both (SandX) scedasticity and multiplicity, by discipline and journal quartile

At the finest granularity level, Figure 4 shows percentile proportions for the 5 subdisciplines of each disciplinary group that have the highest proportion of ANOVA-related papers. At first glance, the disciplinary composition of the group gives additional support to the hypothesized enmeshment of NHST-based experimental research and ANOVA testing. Also interesting is the fact that a few subdisciplines from Life Sciences and Psychology have a majority of papers referring to ANOVA models and tests, namely Physiology (67%), Experimental Psychology (59.2%), Behavioral Science & Complementary Psychology (52%) as well as Zoology (51.4%). As for assumption testing, Physiology (61.4%), Marine Biology & Hydrobiology (59.8%) as well as Pharmacology (53.9%) have a majority of ANOVA-related papers that include considerations referring to either assumption. However, ANOVA-related papers referring to both assumptions remain pretty low at the subdiscipline level, with perhaps the exception of Marine Biology & Hydrobiology (18.1%), Physiology (16.1%), Industrial Engineering (13.6%), and Oceanography & Limnology (12.8%). At the other end of the spectrum, journals from some subdisciplines and sub-disciplinary quartiles refer heavily to ANOVA, while scarcely mentioning anything about assumption tests; this is particularly true of Social Psychology, whose high proportion of ANOVA-related papers (37.9%) markedly contrasts with its relative silence as regards to assumption tests, with respectively 18.1% and 0.6% of ANOVA-related papers in that field containing references related to either and both statistical prerequisites. As for comparisons between subdiscipline quartiles, much variation can again be observed for the different ratios, and a pattern similar to the one observed at the discipline level seem to emerge from the data: papers published in higher-quartile journals tend to have higher ratios than papers published in lower-quartile journals. However, too many disciplinary quartiles are absent from the current dataset to make definitive statements in that regard. Overall and perhaps more than the previous analyses, these latter results show that, in the same manner as the use of ANOVA models itself, the reporting adequacy of these models' assumptions varies widely between subject matters, journal quartiles as well as between the very specific scientific subcultures that pertain to them.

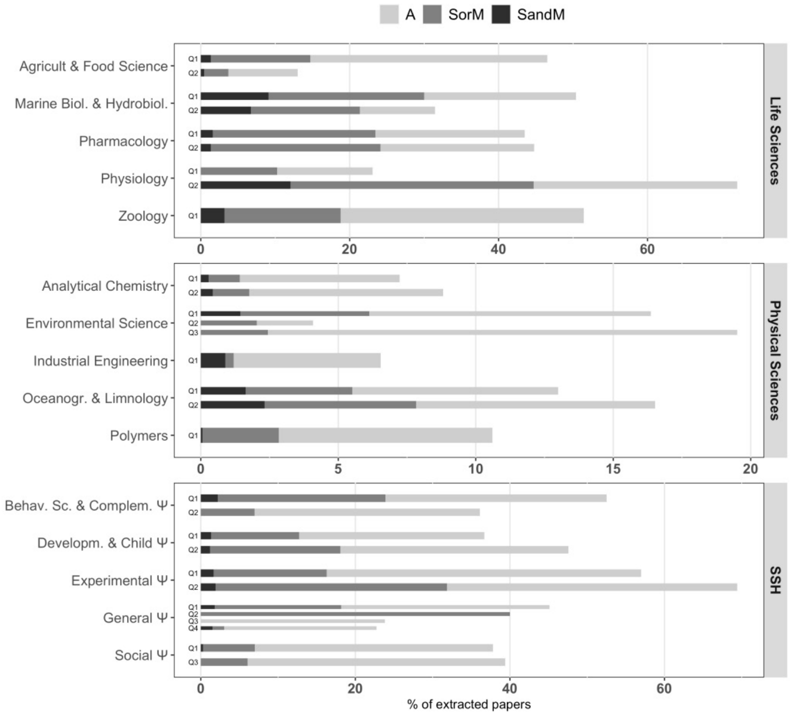

Figure 4. Percentage of ANOVA-related (A) papers and ANOVA-related papers referring to either (SorX) or both (SandX) scedasticity and multiplicity, by subdiscipline and journal quartile.

Conclusion

Overall, the present research shows that, beyond important variations at the different disciplinary levels, reporting transparency in the testing of ANOVA statistical assumptions is generally lacking, as a minority of ANOVA-related papers contain expressions referring to multiplicity, and even less to homo/heteroscedasticity or to both. Disciplinary groups, disciplines, and subdisciplines that have the highest proportion of ANOVA-related papers tend to be experimentation-prone and to refer more systematically to both statistical assumptions, with the notable exception however of social psychology. As regards to journal quartiles, a certain pattern can be observed at the different disciplinary levels, as articles from higher-quartile journals tend to report statistical assumptions more thoroughly than those from lower-quartile journals, regardless of discipline or subdiscipline; however, given that most Elsevier journals are to be found at the upper quartiles of each discipline or subdiscipline, more data is needed in the lower quartiles before drawing any conclusion in this regard. Despite these data gaps, the general picture presented here remains clear: efficient and thorough statistical reporting is still a long way ahead, being so far hinted at by only a few subdisciplines.

Of course, lack of reporting transparency does not any way imply lack of testing: it could be the case that in many non-reporting cases, statistical assumptions for the corresponding ANOVA models were actually tested. However, in the absence of any mention to that effect, nothing can be known about the completion of these procedures nor their outcome. In fact, non-testing is but one possible explanation of non-reporting; the possibility that tests were made but not reported due to negative or inconclusive results is also an equally if not more likely hypothesis, hence the importance of establishing thorough statistical reporting practices. On a related note, it might also be objected that non-testing is not necessarily indicative of malicious intent, but could also be attributed to lack of proper knowledge regarding statistics or their reporting. However, such a hypothesis is not only untestable, but also neglects the fact that, in matters of scientific integrity, practices that are the result of ignorance and negligence are indiscernible in their effect from those stemming from unhindered malevolence.

While these considerations and the results that trigger them are certainly grim, the dice are not yet cast in matters of statistical integrity. Indeed, the fact that so many authors from different and often unrelated fields explicitly comply to the testing of these statistical assumptions as well as the reporting of the latter's results suggests two things: first, that the scientific criticality of statistical assumption testing and reporting is acknowledged in practice by certain scientific groups; second, that collective awareness of and adherence to these issues is possible and can be fostered. On this matter, given both the inefficiency of guidelines in addressing statistical reporting issues (Clayson, 2019) and the high interquartile variability reported here, it could be argued that thorough peer reviewing would go a long way in rectifying the situation.

Acknowledgments

This work is supported by the Practices, Perceptions, and Patterns of Research Integrity (PRINT) project, funded by the Danish Agency for Higher Education and Science (Danish Ministry of Higher Education and Science) under grant No 6183-00001B. Abstract

Funding agencies (FAs) have increasingly engaged in international cooperation agreements (ICAs) to encourage world-class research and achieve more promising outcomes in the context of increasing competition for research resources. The main research question we want to address is the influence of institutionalized ICA (meaning between funding agencies and universities, and other research organizations) on scientific and technological outputs. Our research design is based on a comparison between granted researchers under ICAs (treatment group) and granted researchers not carried under ICAs (control group). Using a quasi-experimental evaluation design, we show that ICAs have a positive and significant impact on the quality of scientific production and the number of national and international collaborations. Different results were found in terms of the number of scholarly and technological outputs.

Introduction

Funding agencies (FAs) have played an irreplaceable role in promoting the generation and diffusion of scientific knowledge when examining recent history[1]. The performance of these organizations has been observed in terms of conventional research outputs, such as citation impact of publications (Yan et al. 2018), but also in its ability to modify the rate and direction of inventive activity (Corredoira et al., 2018). Positive effects are widely reported in the literature, although variations in efficiency between different funding systems are observed due to factors such as research evaluation system, competition for granted projects, and institutional autonomy (Aghion et al., 2010; Sandström and Van den Besselaar, 2018).

Given the need to enhance the results from funded research, FAs have increasingly engaged in international cooperation agreements (ICAs) (Reale et al., 2012). These agreements aim to encourage world-class research and achieve more promising outcomes in increasing competition for research resources. Moreover, in a world where scientific discovery increasingly relies on wide-spread connections, the agreements reduce institutional distances that represent obstacles to interaction among those involved in academic research (Sergi et al., 2014).

Arguments in favour of the engagement of FAs in institutional agreements with foreign research organizations could be relying on two main rationales. First, the quality and quantity of funded research may be enhanced when they are undertaken in collaboration, which is the mechanism that allows the exchange of ideas required for generating new knowledge, solving complex problems, and enabling innovative practices (Sergi et al., 2014). This rationale is adequately discussed in the literature since the study on research collaboration, including international

[1] These organizations are often quasi-public and "financed by the State in order to define and execute a large part of the science policy" (Braun, 1998).

collaboration, has received increasing attention from the scientific community, research institutions, and policymakers (Bammer, 2008; Narin et al., 1991; Wagner and Leydesdorff, 2005). More recently, the "International Research Collaboration" has been perceived as an emerging area of innovation studies (Chen et al., 2019). This research agenda covers topics such as the effects of international collaboration on research outputs (Bozeman et al., 2013; Lee and Bozeman, 2005), the role of international knowledge networks (Adams, 2013; Guan et al., 2017; Zhao and Guan, 2011) and collaboration patterns (Leydesdorff and Wagner, 2008; Todeva and Knoke, 2005; Wagner and Leydesdorff, 2005).

The second rationale is based on a relevant causal argument that a better outcome would not have occurred in the absence of the cooperation agreements. A pertinent question in the counterfactual language is: "Would the researchers be less collaborative or productive if they had collaborated out of institutional agreements?". The counterfactual evaluation of the magnitude of this specified causal effect is scarce. Yet, it is usually assumed among policymakers and scientists that FAs should be encouraged to engage in numerous agreements. The use of counterfactuals in policies has been the subject of disagreement among scholars; however, many issues for which causal inference would be feasible and useful.

This article contributes to the literature by evaluating the impacts of research granted under ICAs on scientific and technological outputs and the intensity of collaboration. Particularly, we employ a panel of researchers granted by The São Paulo Research Foundation (FAPESP) to compare those carrying collaboration under and out of ICA. Accordingly, we designed a quasi-experimental evaluation with samples of researchers granted by the Foundation between 1990 and 2018.

Literature review

The literature allows us to identify two distinct and complementary research streams. The first pay attention to the relationship between collaboration – often measured through the proxy of co-authorship (especially international co-authorship) – and research outputs measured by the number of papers and citations. The positive correlation between these variables has been confirmed by many studies (Glänzel and Schubert, 2001; He et al., 2009; Katz and Hicks, 1997; Moya-Anegon et al., 2018; Narin et al., 1991; Zhou and Bornmann, 2014). Furthermore, the comprehensive study by Wuchty et al. (2007) revealed that research produced by teams is frequently more cited than those that individuals do, and this prevalence has been increasing over time.

Nevertheless, the effect of international collaboration on increasing the citation impact of publications tends to vary significantly when analysed at the national level and depends mainly on the partner country's scientific development phase (Moya-Anegon et al., 2018). For instance, collaboration with the US increases the research impact, mostly when US researchers serve as corresponding authors (Bote et al., 2013; Lancho-Barrantes et al., 2013; Sud and Thelwall, 2016). Despite the positive effects of research produced through international collaboration in citations, Wagner et al. (2019) also reveal that international collaboration seems to have less novel and more conventional knowledge combinations.

The second group of studies emphasizes the relationship between funding and research collaboration and reveals that these dimensions interact with each other since funding enables international collaboration (Cimini et al., 2016; Clark and Llorens, 2012; Liu et al., 2018; Ubfal and Maffioli, 2011), and international collaboration facilitates access to funding (Zhou and Tian, 2014). Zhou et al. (2020) argue that this interaction produces a more complex effect on citation impact.

In terms of evidence, a study using a panel of top US universities' departments found that scientists who have earned prestigious awards tend to collaborate with larger research teams (Adams et al. 2005). The panel with scientists from the European Union reveals that the impact of collaboration on productivity is positive and significant (Defazio et al., 2009). The study also proposes that future research should include a control group of researchers applying for the same fund but not selected.

Further evidence shows that research grants in the United States have a substantial and significant impact on the number of collaborators affiliated with university research centres, although the net impacts of collaboration are less clear (Bozeman and Corley, 2004; Lee Bozeman, 2005). Other studies on the Argentine experience reveal that grants have a positive effect on the quantity and quality of the publications (Chudnovsky et al., 2008), and also impacts on collaboration, which is measured in terms of the number of co-authors for publications in peer-reviewed journals (Ubfal and Maffioli, 2011). These arguments lead us to conjecture:

Hypothesis 1. *The impact of the scientific outputs of granted researchers associated with ICAs is greater than granted researchers with international activity but not associated with ICAs.*

Hypothesis 2. *The impact of the technological outputs of granted researchers associated with ICAs is greater than granted researchers with international activity but not associated with ICAs.*

Hypothesis 3. *Granted researchers associated with ICAs have more scientific production in collaboration than granted researchers with international activity but not associated with ICAs.*

Methods

We use a unique dataset of 11.787 granted researchers, representing all FAPESP research grants between 1990 and 2018. These researchers were divided into two groups: granted researchers associated with ICAs (treatment) and granted researchers not related to ICAs but with some form of international collaboration (control). Therefore, from a population of 11,787 granted researchers, 572 are associated with ICAs, and 2,055 are not, but had carried various sorts of point-to-point collaboration. Table 1 – Describes the secondary data sources that supported this study.

Table 1 – Description of the databases.

Although some authors refer to this as a quasi-experimental approach (Ferraro and Pattanayak, 2006) we rather take it as a comparison group using estimation of Average Treatment on the

Treated (ATT) effects, likely less biased than traditional ATE in this type of selection process. This approach is particularly necessary when one intends to measure the funding instrument's difference (Ferraro, 2009; Ferraro and Pattanayak, 2006; Frondel and Schimidt, 2005). Quasi-experiments require the consideration of four main aspects (Ferraro; Pattanayak, 2006), namely: 1) consider that the effects are the same for both groups; 2) conjecture what are the potential effects resulting from the intervention (of the program); 3) design a simple control group (those who did not receive the intervention) and 4) collect data on the effects and key inputs before (baseline) and after the intervention.

The evaluation adopted the Coarsened Exact Matching (CEM) method, which proved to be adequate compared to Exact and Nearest Neighbour. The observable baseline variables used in the pairing were: Year of first FAPESP research grant not related to ICAs; Year of the first FAPESP research grant associated to ICAs; time-period of the project under analysis; Responsible institution; Areas of knowledge; and Total FAPESP research grant. Variables as for number of publications and citations before the period of comparison were adjusted. After matching, the balance reduced the heterogeneity between the groups, and the Standardized Average Differences practically zeroed after matching, maintaining a sufficient sample size for inferences.

Results

The estimates of impacts on scientific, technological, and collaboration outputs are presented in tables 2, 3, and 4, respectively.

Table 2 – Impact on scientific outputs

	Effect	*p-value*	*CI 95 %*
Number of articles (Lattes)	0.927	0.432	[0.766 – 1.121]
Number of articles (Dimensions)	1.008	0.944	[0.813 – 1.249]
Number of citation (Dimensions)	1.041	0.889	[0.595 – 1.821]
Number of citation (Scopus)	1.964	<0.001	[1.468 – 2.628]
H-index (Scopus)	1.181	0.008	[1.045 – 1.335]

Note: Number of articles and citations in the 5 years before and after the first grant.

Table 3 – Impact on technological outputs

	Effect	*p-value*	*CI 95 %*
Number of Patents (INPI)	0.582	0.293	[0.213 – 1.594]

Table 4 – Impact on national and international collaboration

	Effect	*p value*	*CI 95 %*
Single authorship (Scopus)	1.096	0.651	[0.736 – 1.633]
International collaboration (Scopus)	1.567	<0.001	[1.245 – 1.973]
National collaboration (Scopus)	1.301	0.019	[1.045 – 1.619]

The main findings can be summarized as follows:

a. It **was not possible** to state that ICAs produce a quantitative impact on scientific production when comparing the number of articles in journals.
b. It **was possible** to conclude that ICAs make a qualitative difference in scientific production based on citations and H index: 96% more citations and H index 18% higher in the treatment group.
c. It **was not possible** to state that ICAs produce higher technological production when comparing the number of patents.

d. It **was possible** to confirm that collaboration under ICAs produces higher international collaboration (by 56%). This cooperation effect also extends to national cooperation, which is 30% higher in the treatment group. In other words, researchers participating in ICAs are more cooperative than those who collaborate internationally outside institutional agreements.

Abstract

Editors exert a significant influence on journal's mission and governing the strategic direction of outlets. They are the channels gatekeepers not only by ensuring the quality but also by guaranteeing the integrity of novels produced. For being such an important piece of scientific puzzle, they are a research object of utmost interest which is rather fragmented. This paper aims to better understand the relationships between editors seated on boards of 20 innovation top-tiers. The sample considered comprised 2,440 editors occupying 3,005 editorial positions and assuming 122 different duties. No single journal is free from this interlocking editorship phenomenon and 18.6% of the scholars serve on multiple boards. We deploy social network analysis to further inquire and model the editorial relationships in which innovation journals are embedded. Our results offer new insights on how the field is organised: 627 lines linking the journals were found with a 41.6% interlocking density. Research Policy has the highest number of direct links to other boards (degree) and the shortest distance from all network journals (closeness) while Industrial and Corporate Change is the one bridging the largest number of other pairs of journals (betweenness), followed by Small Business Economics and Research Policy.

Introduction

Elite boards memberships are crucial agents in scientific governance. For being seen as critical the role they play and thus, an appointment to a journal board is considered an important career stepping-stone as it provides opportunities for intellectual growth and networking (Topaz & Sen, 2016). The critical mentality and decisions of scientific editors have so far safeguarded and will also warrant the social and intellectual integrity of science for the upcoming years. For being consulted about research agendas and strategic directions for the outlets, the elite board membership become of paramount interest (Bedeian, Van Fleet, & Hyman, 2009; Feldman, 2008). Their positions and editorial affiliations provide a chance to study the underlying direction of journals (Morton & Sonnad, 2007; Wilkes & Kravitz, 1995).

As prominent scholars with a robust track of publications (Teixeira & Oliveira, 2018) and highly appreciated by peers (Andrikopoulos & Economou, 2015), editors are commonly seat in more than one board. Such phenomenon was previously identified by Baccini & Barabesi (2010) and may be responsible for the establishment of subgroups of scholars linked to some core journals, who may exert influence on the vision and main paradigms of such journals.

Taking advantage of commonly described academic boards on journal's website, we aim to ponder about journal governance as already done for other scientific fields (Bakker & Rigter, 1985; Brinn & Jones, 2008; Burgess & Shaw, 2010).

In this work, we draw a social network analysis to discuss about the social structures and independence of journal's EB. Through the assessment of Boards composition of the twenty most important innovation journals identified by Fagerberg et al. (2012), we examined how the memberships of EB interact and identified the most influential ones in the field. We believe this study may introduce some pertinent knowledge for those interested social structures in the innovation studies context.

The editorship network

In modern science governance literature, editors validate their role legitimacy through high academic standing and further signal their intellectual and social capital resources through board member affiliations. In this sense, the editorial process becomes an important professional network. To investigate the relationships between editors and journals, we have employed principles from network science to study complex systems composed of relationships between entities (Vespignani, 2018).

A social network was defined by Wasserman and Faust (1994), p.20, "as a finite set or sets of actors and the relationship or relationships between them". With social network analysis (SNA), we can find groups of elite board memberships surrounded scientific outlets or as bridges connecting them. Social network analysis characterizes networked structures in terms of nodes and ties (edges). Networks can be conceptualized organizationally, as networks of journals connected by editors. In this work, we model the relation between editors from innovation-oriented journal Boards based on data collected on outlets' webpages.

Considering editors seating on more than one journal Board is a proxy of intellectual similarity between editorial policies, we may perceive journals have closer policies according to the number of scholars they have in common on their Boards. The interlocking phenomenon puts outlets closer to each other and facilitates the communication. In other words, the closeness of the editorial policies of two scientific journals can be assessed by the number of common editors sitting on their Boards. We will not focus on the editorial policies adopted by the Boards of innovation-oriented journals. Instead, we will infer about the similarity of editorial policies through the detection of recurrent scholars as common editors between Boards.

Exploring editorial teams in "Innovation Studies" periodicals

Innovation studies is an evolving interdisciplinary field focused on producing systematic and reliable knowledge about how best to influence innovation and to exploit its effects to the full (Fagerberg, Martin, & Andersen, 2013). Born from plural contexts like Economics (Nelson, 1959), Management (Burns & Stalker, 1961) and Sociology (Rogers, 1983), it became a global research community world-wide (Martin, 2012). Fagerberg et al. (2012) analysed the development of innovation studies and through an empirical approach based on analysing the chapters contained in authoritative handbooks on innovation studies, identified which publications had most impact (Fagerberg and Verspagen, 2009). This proved to be consistent with later studies from Cancino, Merigó, & Coronado, (2017), Kotsemir (2013) and Rakas and Hain (2019). With the purpose of understanding the editorial community, we studied the emergence of the innovation studies field from an editorial point of view (Fagerberg, Mowery, & Nelson, 2004). In this study, we restricted our analyses to the twenty most influential journals identified (Fagerberg et al., 2012).

Our research explores structural properties of the network generated by the editorial population of leading innovation studies journals (de Andrade & Rêgo, 2018). The general aim of this study is to investigate the relationships between editors and journals. Taking advantage of centrality measures such as degree, betweenness and closeness, the most central outlets and their roles in the network were also identified.

The Boards of "Innovation Studies"

Data collection and methodology

From outlets' editorial pages, we collected scholars' names, institutional affiliations, gender and their roles inside the Board. A summary about the editorial memberships found is provided in Table 1, including the number of editorial positions available, the number of different scholars seating on the Board and shared editors with other outlets. In total, 2,440 different persons were found for the 3,005 editorial positions available. Repeated names allowed the identified the ones in charge of multiple duties inside a journal or among different journals.

Table 1. Editorial Boards descriptive characteristics.

Short name	Journal	No. of editorial memberships	Total distinct scholars	Shared editors	No. of duties
AMJ	Academy of Management Journal	328	328	145	5
AMR	Academy of Management Review	312	310	149	5
ASQ	Administrative Science Quarterly	115	111	62	5
CJE	Cambridge Journal of Economics	53	52	1	4

Tec	Technovation	58	58	12	12

Source: Scimago, as of March 2019 and journals' homepage.

Among those top-tier outlets, it was noticed the editorial memberships available differ greatly between journals. Some of them revealed to have small numbers of editorial positions such as RDM and IJTM while other Boards reported more then 300 of duties entrusted to scholars. For 12 outlets, these duties were assigned to different personalities while 8 top-tiers made some editors responsible for multiple roles. All outlets also share at least one editor with other Board, actually, scholars shared range from 2% to 56%. For this interest, duties and the proportion of shared editors is addressed apart.

Editors' duties

Among different journals, diverse internal organisations within EB were found. There are journals with only one title for all editors, such as observed for HR where everyone is “editor” while MS exhibited 35 different titles within the Board. According to the titles assigned, different internal organisations were supposed: journals like HR, where the same title label is given to all editors without further hierarchies contrasted with other Boards which presented more defined internal structures with five or more different categories.

It is noteworthy that outlets have different numbers of scholars on Board. With the exception of MS, all journals have one title ascribed to a majority of the editors. Editorial duties' labels were kept exactly as recorded from official journals' webpages with exception of plural descriptions which were converted to singular. The lack of uniformity in the similar positions' titles across journals makes it harder to compare editors' responsibilities. As expected from Table 1, MS counts with a large number of memberships while RDM has a very small editorial team. ICC and IJTM have also a geographical organisation for editors on Board which is not found in the other outlets.

Although AMJ and AMR exhibit a similar editorial structure, with a team encompassing mainly scholars as part of Editorial Board, in general, outlets from the same publisher did not present a similar editorial organisation. Considering the ones published by John Wiley & Sons (JMS, RDM and SMJ), it is clear the heterogeneous labels used for the group of scholars on their Boards. The main editorial assignment in JMS, named as “Editorial Board”, includes 279 scholars while RDM has five different categories and the largest one, “Editorial Advisory Board”, has only eleven memberships. SMJ organises editors among six different categories involving 33 as “Associate Editor”.

The same editorial title is also found between Boards with different frequencies, suggesting dissimilar commitments. In HR, those 99 scholars on its Board are assigned as “Editor” and no other group of editors are disclosed. However, in RDM, the one assigned as “Editor” seems to be the main gatekeeper in this top-tier, sustained by 18 additional scholars to direct the journal's outputs. SBE reveals one individual as “Editors-in-Chief” assisted by a group of 28 memberships designated as “editor” and 120 among the “Editorial Review Board”. For being a designation, which could be applied to all members of a Board, to a medium group of editors or only to a single editor, it is possible to deduce it has different connotations and thus, heterogenous responsibilities.

Shared editors, inter and intra-journals

Since editors are prestigious researchers, the more prominent one editor is, the higher the recognition level and more invitations will get for further responsibilities. Within our sample, we searched for scholars taking the editorial job for multiple journals. Among the memberships from our study set, 47 were assigned to editors already on the same Board, i.e. the name appeared more than once in EB and they became responsible for more than one duty in the internal editing process. In order to understand the outlets assigning one, two and three concomitant duties within the same top tier the same personality, Figure 1 was developed.

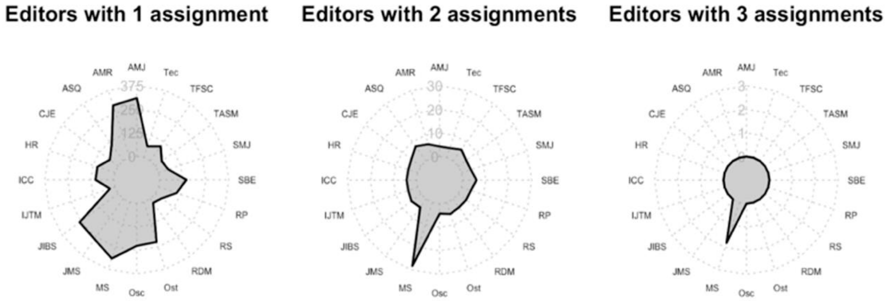

Figure 1. Number of editors in each country, per number of duties.

With exception of MS, all outlets have less than ten editors with two simultaneous assignments. MS has also two editors responsible for three simultaneous assignments in the same Board. Some editors were also found common to more than board. For this journals’ set, the highest number of simultaneous Board memberships held by one individual, is five; thirteen academics hold four Board memberships, 82 have three and 348 have two. From 361 editors in the UK and 1.131 in the US, there are more than 60 and almost 180 editors assuming two duties, respectively. Other studies have also found five as a common number of Board memberships individuals accept simultaneously. Brinn and Jones (2008), in the accounting field, identified two individuals assuming editorial duties for six journals simultaneously and Chan and Fok (2003) found scholar with eight as the maximum number of memberships, in international business.

Clustering of editors based on Boards coupling

In order to address the degree of EB overlapping, we applied some SNA techniques to study the cross-presence of editors within Boards. Based on the so-called ‘interlocking editorship’ phenomenon described by Baccini and Barabesi (2010), the editorial proximity was measured. When a scholar is found in two different Boards, then the two Boards are ‘interlocked’. The interlock bridges the two journals and allows social interaction and communication.

Journals are linked by 627 connections and the density of the interlocking editorship network (i.e. the ratio of the actual number of lines to the maximum possible number of lines in the network) is 41.6%. This is quite superior to the trend previously determined by Baccini and Barabesi (2010) for economic journals and Baccini, Barabesi, & Marcheselli, (2009) for statistical journals.

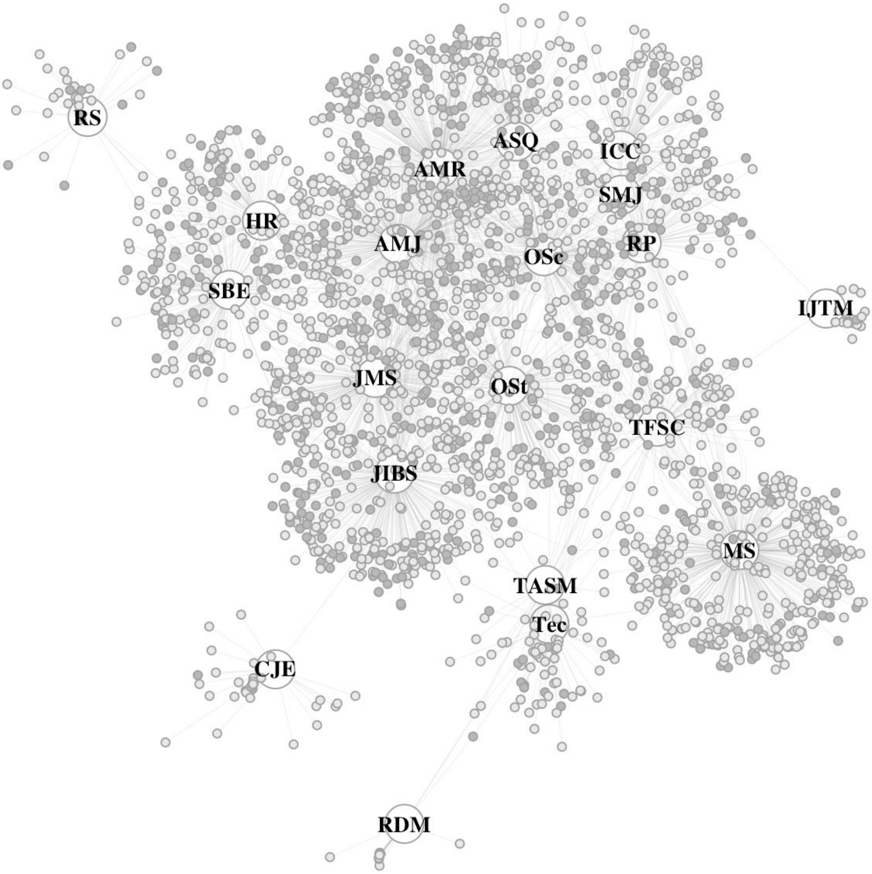

Figure 2. Social network of EB members of innovation-oriented journals.

Using the data from the twenty journals previously identified, we constructed the affiliation network database ad hoc. The average number of seats per journal was 150.25, while the average number of seats occupied by each scholar (i.e., the mean rate of participation) was 1.22. We also investigated the female presence on Boards. The graph of the network is reported in Figure 2, where editors are connected to the journals they work for. Distinct scholars are represented by small nodes (light grey for women and dark grey for man) and their memberships are represented as edges to the big white nodes, the top-tiers.
No journals were found to be completely independent from the others as all outlets are connected, suggesting a strongly connected network. It was also possible to perceive one main group, a giant central which shows close ties formed by editors shared between journal Boards. It is possible to see the high number of scholars holding editorial positions in MS, JIBS, HR and SBE.

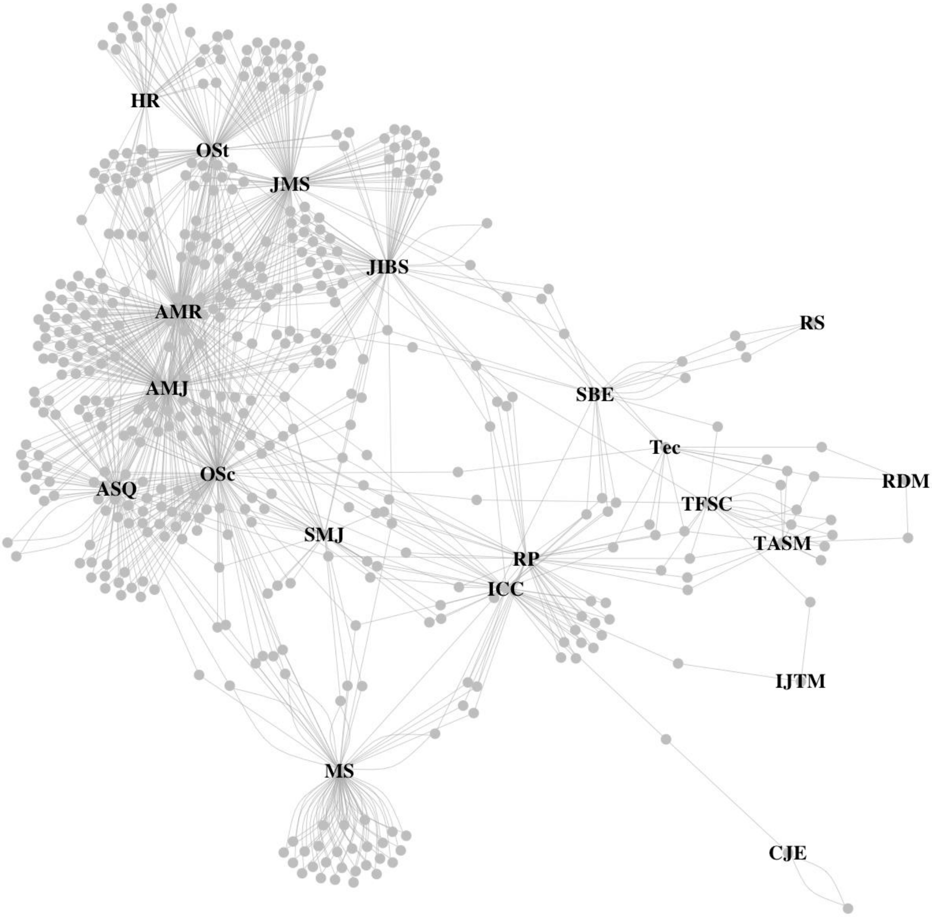

Figure 3. Network illustrating Boards highly connected having staff in common.

More isolated are those journals with lower numbers of editors shared with other journals from the sample: RDM, CJE, RS, IJTM. Actually, CJE shares only one scholar, only with JIBS. Among those more isolated, it is also noticeable the differences on Boards' size. These four outlets have a small number of editors compared to the ones in the central group. Among this network, 73% are men (n=1.783) while 27% are women (n=657). Most female editors are presented in the giant centred sample. Outlets like JIBS, ASQ and SBE show a large number of dark spots surrounded, illustrating the female underrepresentation on those ones. Considering only the editors shared between journals, we plotted Figure 3 to illustrate which outlets share the most scholars.

It is possible to see pairs of journals sharing more editors with larger numbers of edges or larger width edges. Pairs of journals like OSt and MS, ASQ and OSc, RP and ICC share a great number of editors. Regarding the most isolated ones, five journals can be identified: RS, RDM, TASM, IJTM and CJE. The last one, CJE, shares only one editor with ICC. In MS, ASQ and CJE's Boards, it is possible to find some nodes with multiple edges to the same outlet illustrating the multiple editorial roles scholars are assigned to.

The power structures in the interlocking editorship network

One main purpose in SNA is to distinguish between the most central from the peripherical components of a network. In our case, the goal is to perceive which journals are in a central position from those in the boundaries. Centrality analysis may reveal the power and status of the individual or organisation in the social network. As suggested by Wasserman and Faust (1994), three centrality measures may be used: Degree, Closeness and Betweenness.

The simplest measure for the centrality of a journal is represented by the degree of overlap among Boards. Degree centrality is the number of direct connections (lines) a director has with the other journals and measures network influence. It proxies individuals' ability to access, share knowledge or other resources and thereby influence the wider network. Thus, the more ties a journal has to other journals, the more central will be its position in the network.

The Closeness centrality is based on the distance between a journal and all the other journals. This measure calculates the shortest paths between all nodes. A journal is central if its Board can quickly interact with all the other Boards. The more direct and indirect connections a journal has with others, the more central it will be in the network. Journals occupying a central location are best placed to quickly influence the entire network.

Finally, the idea behind the Betweenness is that similar editorial aims between two nonadjacent journals might depend on other journals in the network, especially on those outlets lying on the paths between the two. The number of times a node lies on the shortest path between other nodes is measured as Betweenness centrality. It highlights nodes acting as 'bridges' in a network, proxying for a director's ability to control information and resource flow and to coordinate otherwise disparate parts of the network. In Table 2, centrality measures are provided for all the outlets in the railway network to identify significant top-tiers.

Within our network, we realised both RP and OSc are the outlets with the highest Degree, i.e. with more connections. Considering the normalised degree, which is obtained by dividing the number of connections by the maximum possible number of journals, we realise there are twelve top-tiers showing a normalised degree above 1. In this network encompassing twenty top-tiers, the maximum number of journals an outlet could be linked to is 19. Those twelve exceeding 1 reveal they share more than one editor with some other Boards. Figure 4 provides a graphical representation of the network according to journals' degree, betweenness and closeness. Journals with the average shortest distance (closeness) to all other outlets are represented with greater nodes. Grey scale is applied to illustrate betweenness centrality measure where darker colours represent top-tiers linking higher number of other non-adjacent outlet pairs. Edges between journals are larger for journals with higher number of common editors which justifies the degree score.

Table 2. Journals' centrality measures.

Journal	Degree	Degree normalized	Betweenness	Betweenness normalized	Closeness	Closeness normalized
AMJ	26	1.368	11.35	0.033	0.037	0.704
AMR	26	1.368	11.35	0.033	0.037	0.704
ASQ	20	1.053	2.65	0.008	0.030	0.576
CJE	4	0.211	0	0	0.022	0.422
HR	14	0.737	0	0	0.027	0.514
ICC	24	1.263	61.02	0.178	0.037	0.704
IJTM	6	0.316	0.80	0.002	0.024	0.463
JIBS	24	1.263	9.58	0.028	0.037	0.704
JMS	22	1.158	12.85	0.038	0.033	0.633
MS	20	1.053	3.01	0.009	0.033	0.633
OSc	28	1.474	21.71	0.063	0.038	0.731
OSt	20	1.053	6.09	0.018	0.031	0.594
RDM	6	0.316	0	0	0.021	0.396
RS	4	0.211	0	0	0.021	0.396
RP	28	1.474	36.71	0.107	0.040	0.760
SBE	20	1.053	40.81	0.119	0.033	0.633
SMJ	20	1.053	2.40	0.007	0.032	0.613
TASM	10	0.526	6.28	0.018	0.027	0.514
TFSC	16	0.842	20.72	0.061	0.031	0.594
Tec	18	0.947	36.69	0.107	0.032	0.613

Through the closeness centrality, we understand how long it will take to spread information from a given node. For being the ones with the highest closeness scores and shortest average distance to other nodes, RP and OSc are the outlets represented by larger nodes. Occupying such a position may suggest they are a reference for other outlets. The smallest nodes found are those representing RS and RDM. ICC is the one bridging the bridge for the highest number of other pairs of journals. Its central position may be explained by its interdisciplinary nature, we mean by the presence of many influential editors who enlarge the number of different links with other top-tiers. ICC seems to have an important role facilitating the communication between innovation-oriented journals as it presents the biggest size on its node. For being the most isolated ones, CJE, IJTM, RDM, RS and TASM have a null betweenness as they cannot be a path for other outlets to interact.

Considering the edges, it is possible to understand the degree scores journals obtained. RP and OSc, the ones with higher score, have the largest number of connections. RP has several edges to other outlets and the one with ICC with a larger width. OSc has also multiple edges connecting other top-tiers, three of them representing a great number of shared editors. The most isolated ones are CJE, IJTM, RDM and RS sharing only one or two editors with other outlets from the network. Interesting to remark is that no journals are isolated or completely apart from the network (i.e. they do not present a zero degree).

Figure 4. Projection of journals closeness and betweenness centrality and shared editors.

Discussion

In this paper, an overview of editors behind the twenty-top innovation-oriented journals identified by Fagerberg et al. (2012) was provided. We tried to analyse which scientific outlets had the greatest number of editors, which ones share the highest number of scholars with other journals and which top-tiers are the most central ones.

With reference to the internal Board's organisation, the different assignments labels were determined and the heterogeneity in the numbers became manifest. This proliferation of titles without settings description makes it harder to compare the proportion of scholars responsible for the same duties among Boards and responsibilities accepted by an editor present in two Boards. Apart from the Editor-in-Chief role, which may be the single title with the same definition, all the others may entail several different duties and levels of knowledge.

Even though editors have some power shaping the editorial policies and thus, journals sharing editors may have common interests. By measuring the degree of overlap among Boards, the editorial proximity was compared. As an example, AMJ and AMR share 65 Board members, so greater affinity may be expected on their articles published. On the other hand, journals like RDM and CJE have no common editors and no further similar interests are predictable. Actually, by the articles published, we realise the first one is dedicated to Management while the other one to Economics.

Our special interest was to investigate the social relationships between EB members using network techniques. Based on the public data available on journals webpages, we draw our sample of editors from the top twenty innovation-oriented journals and establish co-editorship links between these scholars. Applying a social network methodology, it was possible to provide a rare insight about the dependency of journals through their editors. All outlets were connected at least with another, sharing at least one scholar as editor. This method of research field mapping using co-editorship allowed us to compute centrality measures and provide many novel insights about the relationships between journals' EBs.

By measuring the average geodesic distance, which is the average distance between pairs of nodes in the network, we discovered RP plays a central position for having on Board twenty-eight editors shared with other journals (degree). This journal as well as OSc are able to reach swift communications with other Boards. In addition, RP also revealed to be the closest Board for all the others (closeness). We also determined some journals act as a bridge between others. ICC was the journal occupying the most strategic position facilitating the communication between other pairs of outlets in this twenty journals network (betweenness), followed by the SBE, RP and TFSC. These outlets play a pivotal role connecting top-tiers which do not share editors between their boards and thus, we may infer, with unlike publish policies. By bonding those more distinct channels, these outlets are bringing closer other heterogeneous components which otherwise would be out or disregarded from such a group.

A few limitations should be acknowledged: the official list of EB members on journals' web pages might not be the most updated since a time lag is common between the time a member enters or exits the Board and the appearance of the information in a journal's masthead. Regarding the editorial duties, more detailed analysis of different functions within EB were not possible because of the diversity of positions and the inconsistency of their distributions among journals. Some editorial designations used in one Board are not used in the others, so common assignments are not matchable.

Conclusions

This work analysed the social structure of EB membership in innovation-oriented research based on twenty leading innovation journals in 2019, previously identified by Fagerberg et al. (2012) from 1989 to 2013. The network generated highlighted the presence of shared editors who are responsible for getting journals closer without any independent outlet among this sample.

Regarding the duty's scholars are responsible for, the lack of formalism defining duties allow each journal to decide how to label them. Thus, comparison is not possible. In addition, we considered the number of editors without considering the effort each one of them dedicate to the editorial job.

We can also discuss potential uses of such an approach for science policy purposes and academic governance in our global science system. Co-editorship networks seem prone to reflect intellectual influence of current gatekeepers rather than those who have made significant past contributions but are no longer affiliated to those journals. Comparisons with past Boards' composition may bring more details about outlets' common views and journals connections. Key advantages of social networks encompass the chance to map knowledge wardens in interdisciplinary fields. It could be also used for research fields where literature outputs are published in non-English languages or to map intellectual influence around issues like government policies and scientific processes involving inputs from non-scientific stakeholders but lay experts and others.

In the innovation field, a promising issue to address in the future relates to knowing deeper about those important gatekeepers shared between journals (i.e. where they work or which journals they work with) and determining how common editorial Board composition has put closer editorial policies and similar outputs.

Abstract

In this paper, we address the problem faced by researchers attempting to decide the appropriate journal to submit their works for. Based on content analysis, we studied how semantically similar are journals blurb's sections with the articles published by the outlets. By considering such a methodology, we propose a new strategy for journal's selection for manuscript submission decision based on endogenous outcomes instead of traditional ones like journal's scores centered on dissemination achievements. Throughout, we illustrate our analysis with data from twenty current innovation-oriented journals. We use the articles published from 2010 to 2019 to develop a framework for understanding how historical contents shape publication opportunities for researchers. We emphasize the usefulness of contents already published to understand journals' selection practices. Current statistical approaches to content analysis can grasp the usefulness of already published abstract articles or journal blurbs section as a path to drive further submission decisions and offer reliable measures of influence that may have potential policy implications.

Introduction

Turning a scientific manuscript into a published article and reaching multiple stakeholders is the greatest desire of any scientist. However, it is a tough decision to select an appropriate outlet to submit a research work. In the modern world where both knowledge and technology progress promptly, delays in the publication or wrong audience envisioned might negatively impact a yearly academic review and prevent a pioneering idea from entering the desired field.

By their side, journals publish articles selected by editors who ultimately depend on reviewers' opinions. Expert reviewers evaluate the rigor and value of new discoveries to gauge how they advance the field. Such peer-review constitutes an important approach to evaluating scientific output and it will continue to play a critical role in many forms of evaluation. For having an inbuilt quality filter, journal articles seem to be the most appropriate unit to count.

However, peer review is limited by its subjective nature and weakly correlates with the manuscripts true value (Starbuck, 2005). As a result, highly prestigious journals are publishing a considerable number of low-value articles while lower prestige ones are distributing some admirable papers. This random editorial selection process is also making outstanding manuscripts receive sequential rejections from different journals before being accepted.

The first attempts to describe the motivations of authors reassemble to the 1950s and 1960s when De Solla Price (1963) treating science as a measurable entity, developed some quantitative techniques and introduced the scientometrics concept. Later and to realise the main interests of authors when selecting a journal for submission purposes, Kochen and Tagliacozzo (1974) identified five basic factors which intervene in the choice of a journal: relevance, acceptance rate, circulation, prestige, and publication lag. Within the years, many other studies contributed for the corpus of knowledge in multiple perspectives. For instances, it was perceived publication timelines are field-dependent. Björk and Solomon (2013) determined submission-to-publication times were approximately twice as long in business and economy as in chemistry and the same happened also for earth sciences and chemistry (Garg, 2016).

The number of factors driving this judgement also changed as well as their importance. Rowlands and Nicholas (2005) found the top factors for senior authors were the journal's reputation, readership, and impact factor (IF). Solomon and Björk (2012) also surveyed authors to evaluate the importance of different factors when considering a journal. The most important factor was whether the research fit the scope of the journal, followed by the journal's quality/impact, speed of review and time-to-publication, type of readership, open access option, and likelihood of acceptance. Salinas and Munch (2015) reported journal prestige, likelihood of acceptance, turnaround time, target audience and IF.

Along with those studies, multiple web services were developed to support authors selecting a publishing venue. Besides of being free to use, they support scholars offering multiple measurements of performance to be used as filters for journals selection. Cofactor Journal Selector, created by the London-based firm Cofactor, leads users through a detailed list of filters to match author's publishing requirements (*Journal Selector | Edanz Group*, n.d.). Others like Elsevier Journal Finder or EndNote Match developed by Elsevier and Thomson Reuters respectively, requires user to input key pieces of information about the article to publish (e.g. title, abstract, keywords/phrases) and uses it to find the best matching journals (Kang et al., 2015). However, services provided by publishers are limited to their own pool of publications, assuming authors begin their decision process by first picking a publisher (Forrester et al., 2017).

To the best of our knowledge, scholarly journals are currently compared through four different means: 1) based on directly available information like IF calculated yearly by the Institute of Scientific Information; 2) data from publishers including acceptance rates, number of subscribers and Web load statistics; 3) data calculated from openly available information such as publishing fees and mean time from submission to publication; and 4) data obtained via surveys with authors who have experienced in publishing in a specific journal (Björk & Öörni, 2009).

Since all these methods are not content sensitive, we propose to match descriptive data ('external') with the 'real fine content' ('internal') of a set of journals based on semantic document classification strategies. Taking advantage of the short promotional statement self-prepared by the journals, the blurbs, as well as the journals' portfolio made available through the acknowledged sources of scientific information like the Web of Science platform, we aim we propose a novel recommendation system for those seeking to publish their scientific work.

Bringing some content-sensitivity to journals' comparison

The exponential growth of the number of scientific publications accompanied with the huge progression on the number of scientific outlets makes it difficult for researchers to decide about the journal to choose for publishing their works (Bornmann & Mutz, 2015; Evans, 2013; Gu & Blackmore, 2016; Shiffrin et al., 2018). Several metrics were developed to measure journals impact, importance and ultimately to guide science makers about the channels to submit their novels (Bornmann & Marx, 2015).

Journal IF, proposed by Garfield (1972), was one important metrics guiding authors (Eugene Garfield, 2006). In ecological field, 85,6% of authors revealed that a journal with a high IF is a 'very important' to 'important' criterion when selecting an outlet to submit their works (Aarssen et al., 2008). And, in a large-scale survey, covering 923 scientific journals between 2006 and 2008, it was found a resubmission pattern suggesting a flow from higher to lower IF journals (Calcagno et al., 2012). Seeking to maximize citation counts, researchers choose to submit their works to the journal with the highest IF and then work down the IF list as the manuscript is rejected. However, this kind of strategy ignores the value of following actions and the opportunity costs involved (i.e., every time a paper is rejected). It is seen as a poor predictor of the ultimate success (Wang et al., 2013). Among the IF's limitations, it should be considered as a measure of scientific use by other researchers rather than scientific quality (Callaway, 2016).

However, one of the limitations noticed was the content insensitivity. Disregarding the matter of which journals are made of, it biases the authors' decisions about submissions. Computer-aided screening and analysis might help to both overview and classify contents more efficiently. Already applied in multiple environments ranging from tweets and other personal opinions to sports news and movie reviews, machine learning algorithms has enabled efficient text classification encompassing subjective sentence contents, source identification and sentiment expression classification.

Machine learning in general allows for classifying data into specifically predefined classes based on manually annotated training data. The algorithm then can identify by itself key features specific of the defined classes. For text analysis, the words used, and their frequencies commonly represent the entry data. This method is called "bag of words". The current work was planned to assess the current potential of machine learning to extract content from articles published and compare it with journals blurb section. Machine learning encompasses several models that are implemented in code in different ways. For this purpose, we selected the Rain Forest model.

Innovation-oriented journals as the interest topic

More than half a century old, innovation studies as a research field emerged from different disciplines as Economics (Nelson, 1959), Management (Burns, 1961) and Sociology (Rogers, 1983) bringing such heterogeneity along (Fagerberg et al., 2012). This interdisciplinary was its nature as an eclectic borrowing of cognitive resources was used in its progress (Martin, 2012). Journals from multiple scientific fields are publishing articles related to innovation studies topic.

With the purpose of identify the outlets which accept and publish the most works on such an area of interest, Fagerberg et al. (2012) studied both the most productive as well as those using further innovation findings. Supporting the establishment of innovation studies as a field, we restricted our analyses to the twenty most influential journals Fagerberg et al. (2012) identified. Table 1 catalogues the principal set of outlets with their subject area, year of launch and quartile they occupy currently according to the IF achieved.

Although almost all journals are in the first quartile (the exception is *Technology Analysis & Strategic Management*) evidencing a prestigious position among their pairs, the subject categories where they are coming from vary greatly. The Business, Management and Accounting category attracts sixteen of our outlets and Economics, Econometrics and Finance are the common interest for three. Both *Administrative Science Quarterly* and *Human Relations* fit on Arts and Humanities and *Regional Studies* are set on Environmental Science and Social Sciences categories. For single journals, fields like Computer Science, Psychology and Engineering are also targets.

Believing such a set of outlets has sufficient in common to be addressed together but also varied interests to be distinguishable, we propose to use their both advertisement section, named *blurb*, and produced contents as objects for publication contents comparison. The current project aims to evaluate the potential of machine learning to assess the similarity between the contents published and the ones described in the blurb section designed to attract authors interest for submission.

Table 1. List of journals.

Short name	Journal	Subject area
AMJ	Academy of Management Journal	Business, Management and Accounting
AMR	Academy of Management Review	Business, Management and Accounting
ASQ	Administrative Science Quarterly	Arts and Humanities; Social Sciences
CJE	Cambridge Journal of Economics	Economics, Econometrics and Finance
HR	Human Relations	Arts and Humanities; Business, Management and Accounting; Social Sciences
ICC	Industrial and Corporate Change	Economics, Econometrics and Finance
IJTM	International Journal of Technology Management	Business, Management and Accounting; Computer Science; Engineering; Social Sciences
JIBS	Journal of International Business Studies	Business, Management and Accounting; Economics, Econometrics and Finance
JMS	Journal of Management Studies	Business, Management and Accounting
MS	Management Science	Business, Management and Accounting; Decision Sciences
OSc	Organization Science	Business, Management and Accounting
OSt	Organization Studies	Business, Management and Accounting
RDM	R&D Management	Business, Management and Accounting
RS	Regional Studies	Environmental Science; Social Sciences
RP	Research Policy	Business, Management and Accounting; Decision Sciences; Engineering
SBE	Small Business Economics	Business, Management and Accounting; Economics, Econometrics and Finance
SMJ	Strategic Management Journal	Business, Management and Accounting
TASM	Technology Analysis & Strategic Management	Business, Management and Accounting; Decision Sciences
TFSC	Technological Forecasting and Social Change	Business, Management and Accounting; Psychology
Tec	Technovation	Business, Management and Accounting; Engineering

Developing a model for blurbs classification

Model conception

This section presents the details of the proposed techniques for matching abstracts from articles published with blurbs sections. The rationales behind these techniques selected are also discussed. Since the accuracy of machine learning algorithms is known to improve with greater quantities of data to train on, articles' abstracts were used to train the model and test it for overall accuracy determination. Later, the algorithm will be applied to match journals blurbs to the related articles abstracts.

In this work, we propose to use a supervised text classification method as we can train the model with the articles' abstracts extracted associated to the outlets titles which published them. The algorithm will learn from the labelled training data to predict outcomes for unforeseen data.

The full process is illustrated in Figure 1 and encompasses five smaller steps which will be addressed in sequence.

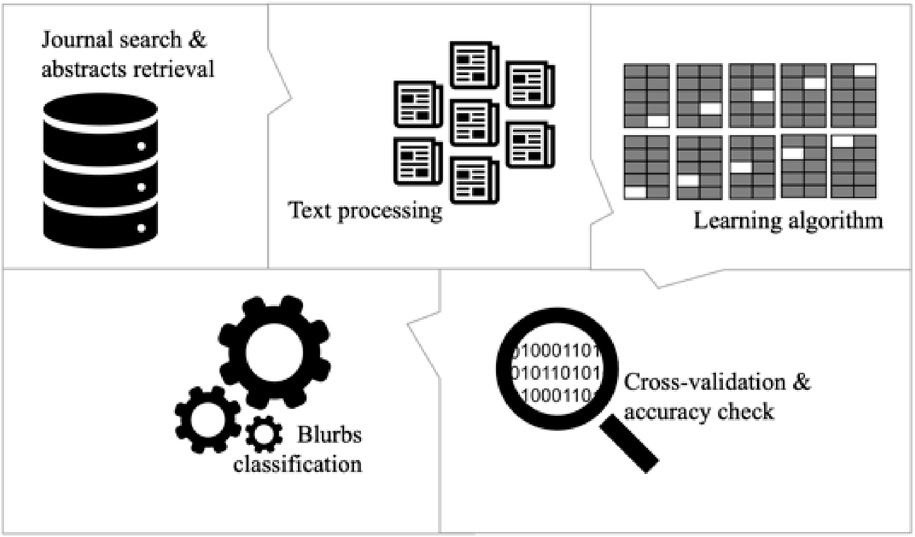

Figure 1. Supervised learning process applied.

With this approach, a training abstracts dataset (previously classified into journals) is used to identify unique patterns that represent each top-tier, and then use these identified patterns to correctly predict the outlet a future instance will belong to.

Journal's search & abstracts retrieval

We searched on Web of Science for the all the titles published in these twenty outlets from 2010 to 2019 (Norris & Oppenheim, 2007). For each one, we extracted the title, the list of authors, the abstract and year of publishing. Only articles with all these contents available were considered. At the end, we realised each journal published different numbers of articles per year and it changed over the years. The Figure 2 shows the number of articles published in each outlet during this ten-years period and the overall volume of articles published for all of them.

Outlets presented different number of published articles and an overall trend to increase over the years. Both TFSC and MS presented a significant increase in the number of accepted manuscripts for publication, publishing less than 150 articles in 2010 and publishing more than 300 in 2019. Some titles were also found with a more modest growth such as AMR and CJE which presented 28 and 64 articles published in 2010 and 34 and 70 in 2019, respectively.
Such increasing trend was anticipated by de Solla Price (1961) who first published quantitative data about the growth of science from 1650 to 1950 with a growth rate of 5.6% per year and forecasted an increasing in journals number reaching one million by 2000. Also interesting are outlets like IJTM which published more in 2010 than in 2019.

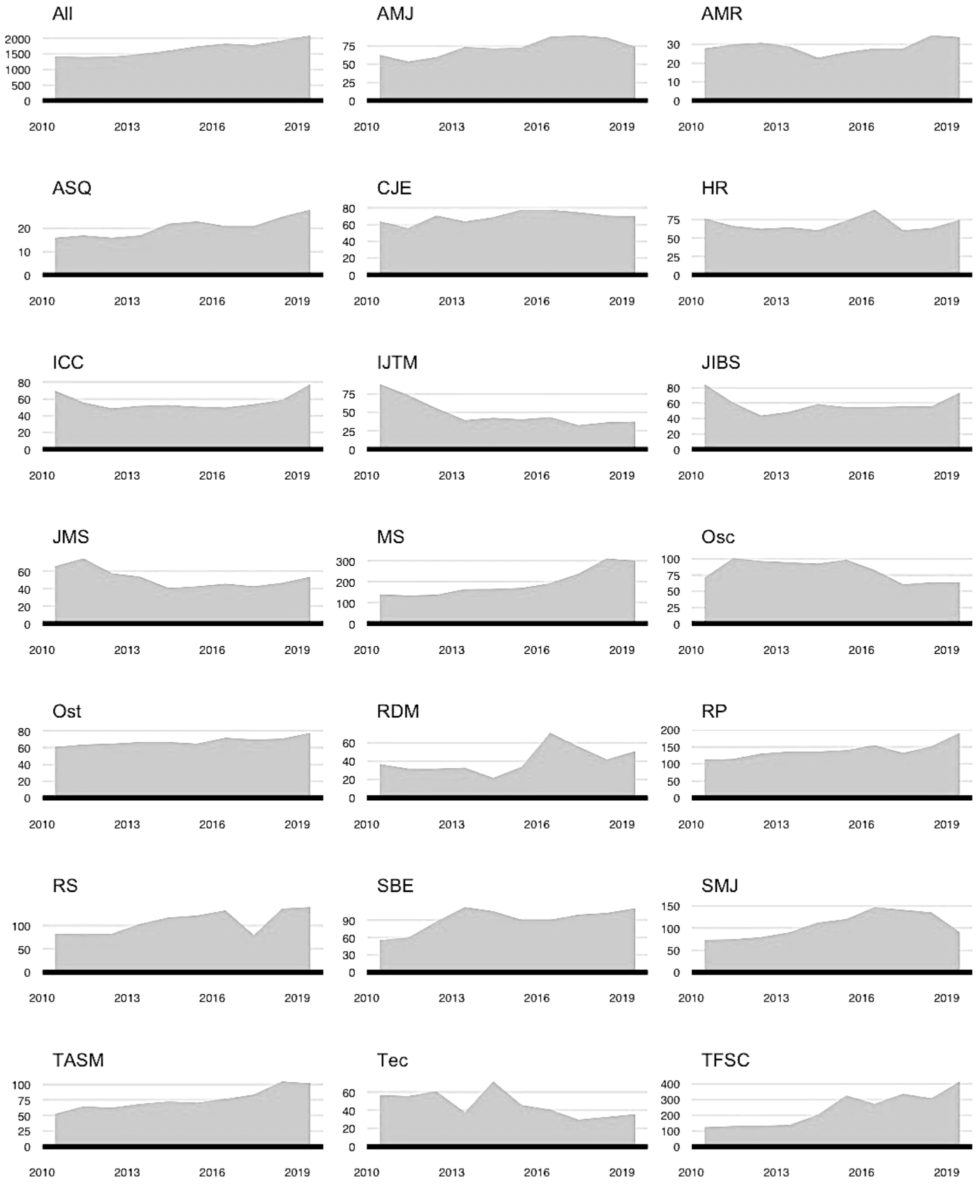

Figure 2. Number of articles published in each outlet from 2010 to 2019.

Text processing

As the classifiers and learning algorithms cannot directly process the text documents in their original form, we need to transform our raw text documents with variable length into numerical feature vectors with a fixed size. Therefore, abstracts collected were pre-processed and converted into a more manageable representation.

This first major step involved four smaller tasks: 1) word tokenization; 2) case transformation; 3) stop-word removal and 4) stemming. Word Tokenization aims to separate words as tokens.

In a simple way to perform tokenization is to assume [space] as separators between words or tokens. Case transformation involves changing all capitalized letters in a lower-case format. Stop-word removal aims to delete the most frequent words that occur in the English language like *the*, *and*, *a*, *is*... In addition, we also removed "paper" as it was quite frequent. These so common words do not bring any meaning to the text which allow us to exclude them without undesired impact. Finally, stemming reduces the inflected words to their root form or stem. In this study, we applied the Porter Stemmer algorithm, one of the most used stemming algorithms (Porter, 1980).

The pre-process step is considered a critical one as it affects the speed and accuracy of a learning algorithm. At the end, it is expected datasets no longer have high levels of noise or unmeaning stems which will be used as features. With this clean dataset, each feature (word) was mapped to the corresponding number of occurrences (term-frequency) within the whole text. This is called "word embedding" process and converts each abstract to a vector of the same length containing the frequency of the words. These vectors will be used to train the model and later, classify blurbs.

Learning algorithm

Among the supervised learning algorithms known, those combining multiple learning models using either boosting or bagging techniques have shown to achieve better results than simple learning models (Caruana & Niculescu-Mizil, 2006). For this work, Random Forests was the one which outperform other learning algorithms (Breiman, 2001). Although it does not consider the sequence of instances to be classified in sequential labelling tasks, it does not present a major problem for our project.

While correcting for decision trees' inherent problem of over-fitting of training examples, Random Forest was operated by constructing a multitude of decision trees during training, then outputting the class that was the mean prediction of the individual decision trees. Like any other supervised learning techniques, the goal of Random Forest model is to identify patterns in a training set and then use these identified patterns to predict future unseen cases.

The main assumption of machine learning is that the distribution of training data is identical to the distribution of test data and future examples. If the learning algorithm accurately classifies the set used for testing, then the machine learning assumption suggests that it will perform as well for future unseen cases. For the training purposes, our classification dataset made of abstracts was split into two disjoint sets and 70% of the observations were used for training and 30% for testing.

Cross-validation & accuracy check

Cross-validation is a technique to evaluate predictive models by partitioning the original sample into a training set to train the model, and a test set to evaluate it.

Training accuracy was determined by a ten-fold cross validation (Arlot & Celisse, 2010; Kohavi, 1995). In a ten-fold cross validation, the input data is divided into ten equal disjoint subsets. Each subset is used as the test set while all the others are used as the training set. For each validation, accuracy is measured by the ratio between the "number of correctly classified cases" and the "total number of cases". The final accuracy will be the average accuracy of the ten different subsets. Depending on the application the learning model is designed for, the minimum acceptable accuracy level may be different. The overall accuracy of our model was 80% which means our model can correctly predict four out of five abstracts. Previous articles have described and used accuracy measures that are widely recognized as the standard way to determine the test and training accuracies of prediction models (Mullen & Collier, 2004).

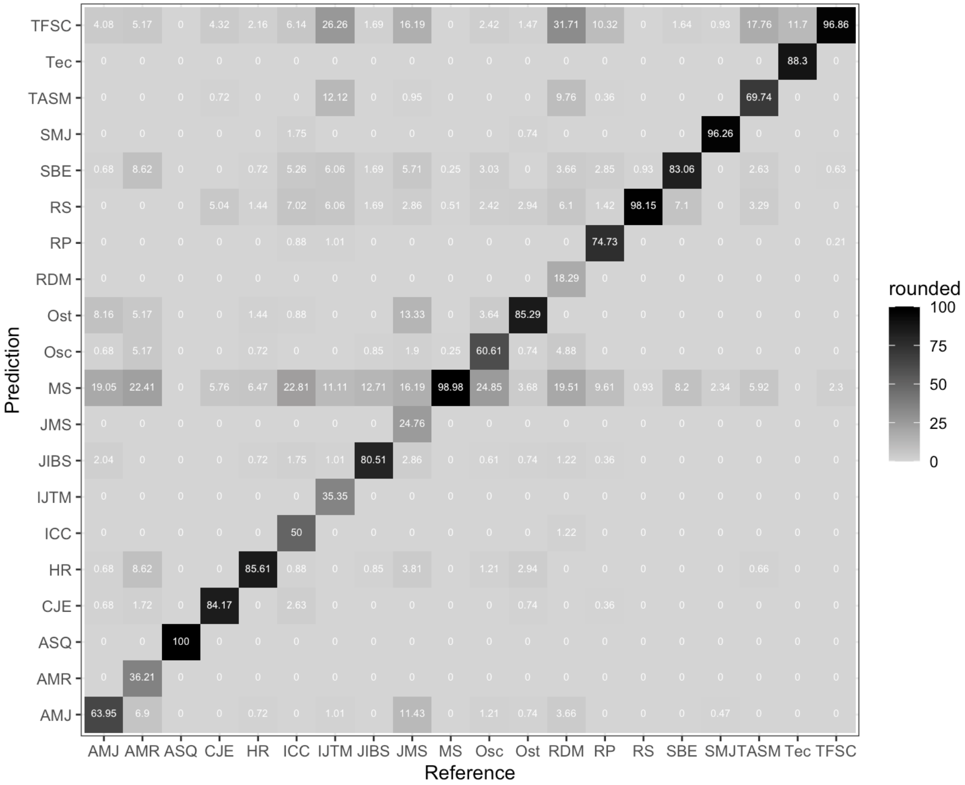

Figure 3. Abstracts' classification.

Although the overall accuracy was 80%, the accuracy achieved by model classifying the abstracts belonging to each specific journal varies greatly. Figure 3 shows all the *Administrative Science Quarterly*'s abstracts are correctly classified. Closer to this figure are the abstracts published on *Management Science* (98,98%), *Regional Studies* (98,15%) and *Technological Forecasting and Social Change* (96,86%). Nevertheless, the model performance was not so good predicting the abstracts published on *R&D Management*, *Journal of Management Studies*, *International Journal of Technology Management* and *Academy of Management Review*.
Such accuracy differences presented by the model are explained by the type of contents published. The more specialized journals are greater the predictable accuracy achieved by the model. Journals publishing a larger number of heterogeneous topics are classified as the publishers of abstracts from other outlets. This happens with *Management Science* and *Technological Forecasting and Social Change*. Both are predicted to have published great numbers of abstracts from other journals. Stating their eclectic and diverse interest, their editorial announcement is not only being defined as generalist but also as direct competitors of other journals.

Blurbs' classification

Our analysis showed that the current model can be efficiently used to match abstracts with the journals which published them. Abstracts previously collected were used to train and test the model, the algorithm was trained again considering this larger dataset. All pre-process steps were repeated before the training. This time the test dataset was the blurbs sections collected from the outlets. The model was asked to associate the blurbs according to the most semantically similar journal abstracts collection. Figure 4 presents the classifications suggested by the model.

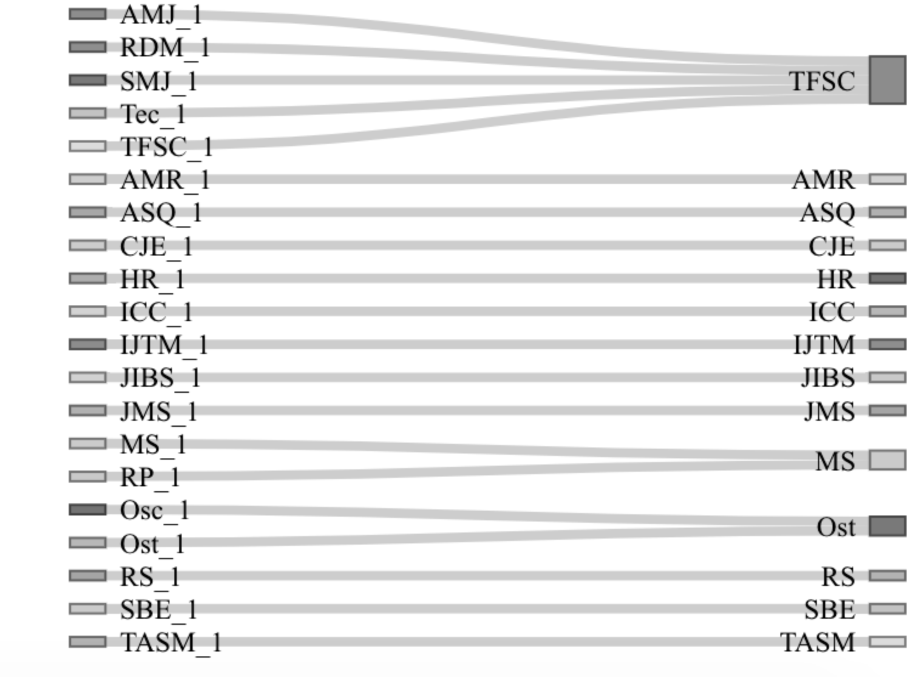

Figure 4. Blurbs' classification.

Within the twenty journals sample, fourteen blurbs were correctly linked to the journals they belong to. *Technological Forecasting and Social Change, Management Science* and *Organization Studies* were associated with blurbs from other journals besides their own's. The model recognized *Management Science* and *Research Policy* blurbs sections like *Management Science's* abstracts from ten years of published articles. The model also recognized blurbs from *Academy of Management Journal*, *R&D Management*, *Strategic Management Journal*, *Technovation* and *Technological Forecasting and Social Change* as being related to the last one. Blurbs from *Organization Science* and *Organization Studies* were also associated with *Organization Studies* published abstracts.

Following such results, an author may also wonder about submit a manuscript designed for *Research Policy* also to *Management Science*. It seems manuscripts from both top tiers are poorly differentiated and confusing to distinguish the outlets which published them. Thus, all manuscripts are classified as part of *Management Science* portfolio. As both are in Q1 according to the IF in their fields, a manuscript in the scientific area of *Research Policy* may be also interesting for *Management Science.* The same could be also true for the five journals which had their blurbs' section associated with the contents of *Technological Forecasting and Social Change.* Considering the contents previously published besides the journals' external metrics available may provide additional opportunities for researcher submissions.

Discussion

Given the constantly growing stream of scientific journals' data, automatic classification of unstructured text data into relevant researcher-defined content categories is likely to continue charming scientists. The results of our analysis both confirms it is possible to recognize journals contents by their blurbs and suggests blurbs are distinctive pieces of information able to judge journals interests.

In terms of the accuracy of determining the web page type using machine learning techniques, Random Forest achieved up to 80% accuracy. The automatic classifier, however, misclassifies articles from *Management Science* journal. The number of abstracts used to train the model cannot explain this behaviour as this journal was pointed out as one the journals with higher number of articles published over the years and with a significant increase. Our suggestion is that *Management Science* publishes a great variety of scientific topics misleading the algorithm when recognising the journals which published a manuscript.

Organization Studies showed to be also the outlet which could also publish the works a research may think about submit to *Organization Science. Technological Forecasting and Social Change* seems to be the outlet which could encompass choices from four different top-tiers: *Academy of Management Journal*, *R&D Management*, *Strategic Management Journal*, *Technovation* and *Technological Forecasting and Social Change*. The sematic similarity between these ones, make *Technological Forecasting and Social Change* an alternative option to the three others.

There are of course limitations to this research. First, we considered only the ten years of data from articles available on Web of Science from the Innovations Studies, a field which emerged a few decades ago. Considering other older scientific fields and larger data published may bring more accurate classifications. Second, for the algorithm training, we used only the abstracts of full articles which may differ from the usage of full articles contents. All these issues are also ideas for further studies to enlarge even more the scientometric approaches able to provide contents sensitive methods for journals comparison.

Concluding Remarks

Text classification, that is computer-aided analysis of textual data, offers a great opportunity to advance journal selection strategies. This motivated us to apply such technique to a real problem: compare published contents with the advertisement section designed to attract further submissions.

However, some limitations should be reported and overcome in the future works. First and foremost, the content period of this project is set as ten years (ranging between 2010 and 2019), which was mainly driven by the consideration of balancing the size of data and the computational capacity.

We applied a machine learning due to its great potential for efficient classification. However, a drawback was noticed for this method. It lacks transparency, which prevents identification of causal factors (Liu et al., 2019).

For future exploration of the potential of machine learning algorithms to compare journal contents, a larger set of annotated training abstracts, blurbs and journals would be necessary. For the current proof of concept, the "Abstracts" and Blurbs sections were manually taken from journals' websites. Automatic extraction will efficiently generate a larger data sets and may bring such methodology to other areas of science knowledge, benefiting researchers from areas beyond innovation studies.

Abstract

The second quantum technological revolution started around 1980 with the control of single quantum particles and their interaction on an individual basis. These experimental achievements enabled physicists and engineers to utilize long-known quantum features - especially superposition and entanglement of single quantum states - for a whole range of practical applications. We use a publication set of 54,598 papers from the Web of Science published between 1980 and 2018 to investigate the time development of four main subfields of quantum technology in terms of numbers and shares of publication as well as the occurrence of topics and their relation to the 25 top contributing countries. Three successive time periods are distinguished in the analyses by their short doubling times in relation to the whole Web of Science. The periods can be characterized by the publication of pioneering works, the exploration of research topics, and the maturing of quantum technology, respectively. Compared to the US, China has a far over proportional contribution to the worldwide publication output, but not in the segment of highly-cited papers.

Introduction

In the beginning of the 20th century Planck's quantum hypothesis to derive the correct black body radiation (Planck, 1901) and Einstein's explanation of the photoelectric effect (Einstein, 1905) led to a full-grown quantum theory in the mathematical formulations of the matrix mechanics of Heisenberg, Born, and Jordan (Born, Heisenberg, & Jordan, 1926) as well as of Schrödinger's wave mechanics. Quantum theory turned out to be highly consistent with experiment. The theory formed the basis for the development of solid state physics and for a first quantum technological revolution. This development led to applications such as lasers, transistors, nuclear power plants, solar cells, and superconducting magnets in NMR devices or particle accelerators. These applications have in common the exploitation of quantum behavior of great ensembles of particles.

In the late 1970s and early 1980s, scientists learned to prepare and to control systems of single quantum particles such as atoms, electrons, and photons, and to let the particles interact on an individual basis. This ability sparked a second quantum revolution, where physicists and engineers worked together to utilize the long-known quantum features - especially superposition and entanglement of single quantum states - for a whole range of practical "next generation" applications. These applications may be summarized as "quantum engineering" or "quantum technology 2.0" (QT 2.0).

The present study provides a bibliometric analysis of QT 2.0 methodologically following previous studies which have dealt with research fields such as climate change in general (Haunschild, Bornmann, & Marx, 2016), specific aspects thereof (Marx, Haunschild, & Bornmann, 2017a; Marx, Haunschild, & Bornmann, 2017b, 2018), and density functional theory (Haunschild, Barth, & Marx, 2016). This study analyzes QT 2.0 over the time period 1980-2018 with a focus on the following four topical fields:

(i) *Quantum information science* (Q INFO): The proposition by Einstein, Podolsky, and Rosen (1935) that quantum systems can exhibit non-local, entangled correlations unknown in the classical world could be experimentally proven after 45 years (Aspect, Grangier, & Roger, 1982; Clauser & Shimony, 1978). Since then it is the basis of quantum information processing, e.g., by the use of non-local photon correlations to make an unbreakable quantum cryptographic key distribution over a long optical fibre (Tapster, Rarity, & Owens, 1994). The concept of a quantum bit or qubit (the quantum mechanical generalization of a classical bit) can be physically realized as a two-state device, exploiting the coherent superposition of both states. The engineering challenge is the layout of hardware systems that are able to handle many qubits in quantum gates, registers and circuits. In particular, the qubits must be stored and kept stable enough to perform several computation cycles in order to realize a quantum computer.

(ii) Quantum metrology and sensing (Q METR): New measurement techniques provide higher precision than the same measurement performed in a classical framework. One example is a new generation of quantum logic clocks achieving a previously unknown accuracy by exploiting the sensitivity of quantum entanglement against disturbances. Other examples are atom interferometry-based gravimeters (Snadden, McGuirk, Bouyer, Haritos, & Kasevich, 1998) and magnetic field sensors based on quantum defects in diamonds (Barry et al., 2016). Control of quantum systems is achieved via manipulating quantum interferences of the wave functions in coherent laser beams. The control is guided by the so-called quantum optimal control theory (Brif, Chakrabarti, & Rabitz, 2010).

(iii) Quantum communication and cryptography (Q COMM): The field started by the publication of the BB84 protocol for quantum key exchange by Bennett and Brassard (1984). BB84's main component is the quantum key distribution via entangled qubits which would render under cover eavesdropping impossible. Quantum networks consist of quantum processors which exchange qubits over quantum communication channels. Secure communication in quantum networks is essential for the long-range transmission of quantum information usually by quantum teleportation.

(iv) Quantum computing (Q COMP): This field promises a quantum leap in computational power, since previous speed-ups as described by Moore's law (Moore, 1995) appear to come to an end on the basis of semiconductor technology (Bilal, Ahmed, & Kakkar, 2018). The original idea of quantum computing had been expressed by Feynman (1982): quantum systems as, e.g., molecules should be simulated by letting a model quantum system evolve and calculate the system in question. That was a new approach – rather different from implementing the classical algorithms of, e.g., quantum chemistry, which consume a high amount of computational resources. The first implementation of quantum simulation had been the quantum variant of simulated annealing, a widely used Monte Carlo optimization. In 2011, the Canadian enterprise D-Wave announced to have built the first commercial quantum annealer (Johnson et al., 2011). Others try to implement a universal model of quantum computation using quantum logic gates in superconducting electronic circuits. They tried to reach "quantum supremacy" by means of demonstrating that a programmable quantum device can solve a problem that no classical computer can feasibly solve. In 2019, Google has claimed to have reached this goal (Arute et al., 2019) with its quantum processor for a very special problem, for which the world's largest supercomputer would take thousands of years. New algorithms and software are necessary to exploit the advantages of quantum computing.

Tolcheev (2018) published a bibliometric study on quantum technology including a very broad set of papers (by comprising all papers that use "quantum" in their title, abstract, or keywords). In contrast, this study has a more focused view by including papers from specific technology-relevant subfields. This study does not consider many foundational quantum mechanics/physics applications, quantum chemistry applications, and other quantum related concepts that are too unspecific. These applications and concepts would decrease the precision of the search.

Methods and Data set

Data set

The bibliometric data used in this study are from three sources: (1) the online version of the Web of Science (WoS) database provided by Clarivate Analytics (Philadelphia, Pennsylvania, USA), (2) the bibliometric in-house database of the Max Planck Society (MPG), developed and maintained in cooperation with the Max Planck Digital Library (MPDL, Munich), and (3) the bibliometric in-house database of the Competence Centre for Bibliometrics (CCB, see: http://www.bibliometrie.info/). Both in-house databases were derived from the Science Citation Index Expanded (SCI-E), Social Sciences Citation Index (SSCI), Arts and Humanities Citation Index (AHCI) , Conference Proceedings Citation Index-Science (CPCI-S), and Conference Proceedings Citation Index-Social Science & Humanities (CPCI-SSH) prepared by Clarivate Analytics. The analyses considered publications of the document types "Article", "Conference Proceeding“, and "Review". The results are based on 54,598 papers published between 1980 and 2018. The papers had been searched in the online version of the WoS on 25 May 2020 by using 14 subqueries related to QT 2.0. The subqueries have been carefully constructed for sufficient recall and high precision (Bornmann, Haunschild, Scheidsteger, & Ettl, 2019).

Publication output, citations indicators, and mapping of research topics

We analyzed the number of papers (full counting) broken down by year, field of QT 2.0, and country. Citation impact analyses are based on time- and field-normalized indicators. We focused on the share of papers belonging to the 10% most frequently cited papers in the corresponding publication year, document type, and subject area. In case of more than one paper with a citation count at the required threshold of 10%, these papers are assigned fractionally to the top 10% publication set. This procedure ensures that there are exactly 10% top 10% papers in each subject area (Waltman & Schreiber, 2013). The top-10% indicator is a standard field-normalized indicator in bibliometrics (Hicks, Wouters, Waltman, de Rijcke, & Rafols, 2015). The citation window relates to the period from publication until the end of 2018.

Besides indicators such as publication and citation counts as measures of scientific activity and impact, techniques of text mining are also used in bibliometric studies. The analysis of keywords in a corpus of publications can identify important research topics and reveal their development over time. This analysis can be managed with the software package VOSviewer (van Eck & Waltman, 2010) which produces networks based on bibliographic coupling. The nodes in these networks are keywords, their size signifies the number of corresponding publications, and the distance between nodes is proportional to their relatedness regarding cited references. Keywords of papers citing similar literature are located closer to each other. The nodes are divided into classes of similarity, displayed by clusters of different colors. The network can be controlled by some adjustable parameters such as minimal cluster size or resolution.

Results

Respective share and overall growth of fields

We retrieved 54.598 publications using the search queries. Table 1 shows the number of papers in the four fields, their percentages of the total number of publications (which add up to more than 100% because of overlaps between the fields), and the percentage of papers belonging to only one field.

Table 1. Number and percentage of papers in four fields of QT 2.

Field of QT 2.0	*Number of papers*	*Percentage of the number of distinct papers*	*Number and percentage of one-field-only papers*
i) Q INFO	16,300	29.85%	9,706 (59.55%)
ii) Q METR	12,531	22.95%	9,766 (77.93%)
iii) Q COMM	13,985	25.61%	9,809 (70.14%)
iv) Q COMP	21,786	39.90%	16,545 (75.94%)
Sum of all fields		118.77%	45,826 (83.93%)

Figure 1 shows the annual publication counts for QT 2.0 and its four fields for the period from 1990 to 2018. The annual numbers of publications on QT 2.0 before 1990 never exceeded a dozen per year. Especially papers about Q METR were published before 1990, which can be explained by the efforts and achievements in manipulation, controlling and measuring of single quantum systems. An exponential growth until about 2000 can be seen in Figure 1, mainly caused by Q METR and Q COMP. From 2000 to 2011, Q COMP is the most strongly represented field, with about twice as many papers as Q INFO and Q COMM.

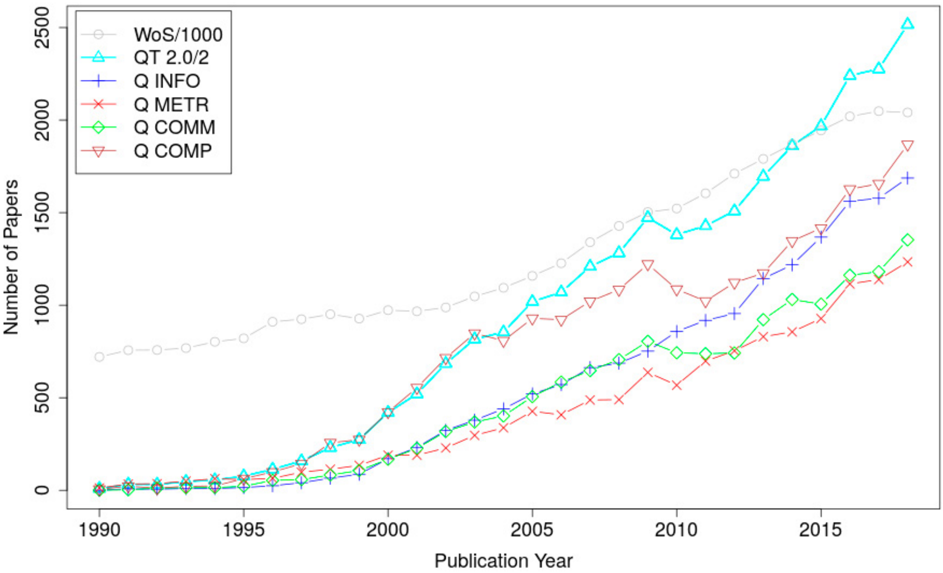

Figure 1: Annual numbers of publications of QT 2.0 and its four fields between 1990 and 2018 (in earlier years the annual numbers of all fields together never exceed 12) compared to the number of articles, reviews, and conference proceedings in the whole WoS. The numbers for QT 2.0 and the whole WoS are scaled by factors of 2 and 1000, respectively, for better comparison.

To study the time evolution, we divide the period in three phases: (1) from 1980 to 1999, (2) from 2000 to 2011, and (3) from 2012 to 2018. The numbers of papers in the last two periods are on the same order of magnitude with 24,322 and 28,132. With 2,144 papers, the first pioneering phase has only less than a 10th of the paper numbers in the other periods. A measure of the growth of the research fields during the three time periods is the doubling time (see Table 2). The four fields have very similar values as the total QT 2.0. The very short doubling time of two years is characteristic for the first period until 1999, slowing down to four years in the second period and to seven years in the most recent period. The last doubling time is comparable to the 5-6 years which Haunschild, Bornmann, et al. (2016) found for the climate change literature until 2014. However, this time is significantly shorter than the 12-13 years for the overall growth of the WoS records. Bornmann and Mutz (2015) calculated an even higher doubling time of nearly 24 years for the WoS in the time period from 1980 to 2012 by applying a non-linear segmented regression analysis. During the 20 years from 1991 to 2010 the annual number of publications grew by a factor of 42, compared to a factor of ten for the climate change corpus and to a factor of about two for the whole WoS.

Table 2: Doubling times in years of the three time periods for all QT 2.0 papers and the four fields compared to the whole WoS publication records.

Time period	*All QT papers*	*Q INFO*	*Q METR*	*Q COMM*	*Q COMP*	*WoS*
1980-1999	2-3	1-2	3-4	1-2	1-2	7-8
1980-2011	4-5	4-5	4-5	4-5	5-6	11-12
1980-2018	6-7	5-6	6-7	6-7	7-8	12-13

Contributing Countries

Many countries are contributing research on QT 2.0 by collaborating with each other. The 25 top publishing countries (with at least 500 papers published between 2000 and 2018 in QT 2.0) give a similar picture in the four subfields and in QT 2.0 as a whole – with nearly the same countries dominating. The same 22 countries are among the top 25 countries in QT 2.0 and *all four* fields, even when we focus on the 10% most cited papers in QT 2.0 and its fields. For both cases (either all papers or only the top 10% papers), we calculated two numbers: the first number is the difference (%QT - %WoS); positive and negative signs mean more or less publication activity than expected. The second number is the corresponding quotient (%QT / %WoS). The quotient is identical to the so-called Activity Index (AI) which was introduced by Frame (1977). AI is a variant of the Revealed Comparative Advantage (RCA) used in economics (Mittermaier et al., 2017). AIs greater than 1.0 indicate national publication outputs higher than expected (from the whole WoS). Both indicators are presented as radar charts in Figure 2 each containing a plot including all papers and the top 10% papers. In each radar chart, the 22 common countries are denoted by their respective two-letter country codes. The codes start at the top with the country having the most publications in QT 2.0 (US) and descend clockwise. In each radar chart, the dividing values between under and over achievement are marked by a grey dashed line at the value 0 for the difference and 1 for the AI.

The most striking insight from these figure is the very different assessment of the two leading countries with very similar output, the US and China, in comparison with the whole WoS: while the US is less active in QT 2.0 than in other WoS-covered research fields (QT 2.0: Difference = -5.7%, AI = 0.77), China is much more active in QT 2.0 (QT 2.0: Difference = +6.9%, AI = 1.71). The difference is most pronounced in Q COMM (Difference = +15.2%, AI = 2.5). With respect to top 10% papers, the strong research focus of China on QT 2.0 is dampened considerably (QT 2.0: Difference = +1.9%, AI = 1.26; Q COMM: Difference = +7.4%, AI = 2.0).

Figure 2 shows that Austria, Singapore, and Switzerland contribute rather high shares of QT 2.0 research in comparison with their research activities as a whole. Austria has an overall AI of above 2 in QT 2.0 and Q COMP, and of nearly 3 in Q COMM and Q INFO. The AIs even exceeded by focusing on the top 10% papers, leading to values of more than 4. These high AIs are explainable by high activities of research groups in Vienna and Innsbruck concerning quantum teleportation. Singapore has AI values of nearly 3 in Q INFO, Q COMM, and Q COMP. Switzerland's AI value of about 1.6 is mainly caused by a high value of 2.4 in Q COMM.

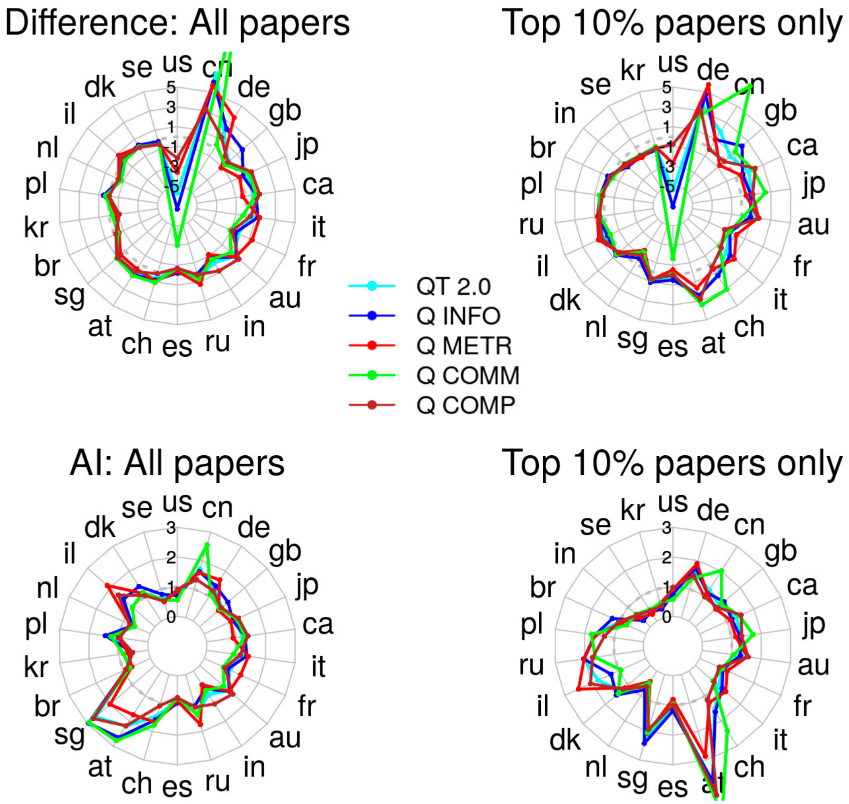

Figure 2: Radar charts of the differences (upper graphs) and quotients (activity indices, lower graphs) of the national shares of papers in QT 2.0 and its four fields (for the period 2000-2018). On the left side, all papers are included; on the right side, only the top 10% most cited papers in the time period 2000-2016 are included. The 22 countries, which are among the top 25 in all fields and the whole QT 2.0, are denoted by their country codes, and ordered clockwise in descending order of the number of publications. The grey dashed lines at 0 and 1 indicate the expected output of the country. An online version can be viewed at https://tinyurl.com/yy75v77a.

We investigated to what extent the growth of QT 2.0 research in specific countries was transferred into the area of applications. This can be measured by the share of publications with commercial co-authorships. Since the databases that we used for this study only provide this information for German affiliations, we focused on the subset of publications with authors only from Germany. Because of the very small number of QT 2.0 publications in the first (pioneering) period until 1999, we only consider the second and third period starting from 2000. The share of publications with German commercial co-authorships is between about 4.5 and 5.5% in the whole WoS with German authorship alone from 2000 to 2018. The QT 2.0 share of these publications during the exploration period from 2000 to 2011 is about 2.3%, but during the maturing period from 2012 to 2018 it is nearly twice as high with 4.3%.

Visualization of research topics and their time evolution

For the various time periods, we have created keyword maps based on author keywords and keywords plus assigned by Clarivate Analytics. A common thesaurus file (https://tinyurl.com/y35eqaax) was used to unify singular/plural forms of words and synonyms. The minimal number of keyword occurrences is chosen such that about 100 keywords are displayed for each time period. The VOSviewer parameters for the clustering have been chosen to be default values. However, for the minimal cluster size, we used a value of 5 to receive a well interpretable network. All VOSviewer maps are provided as Java-based web-startable versions (Oracle, 2020) via URLs for an interactive inspection by the readers, e.g. by zooming into the clusters.

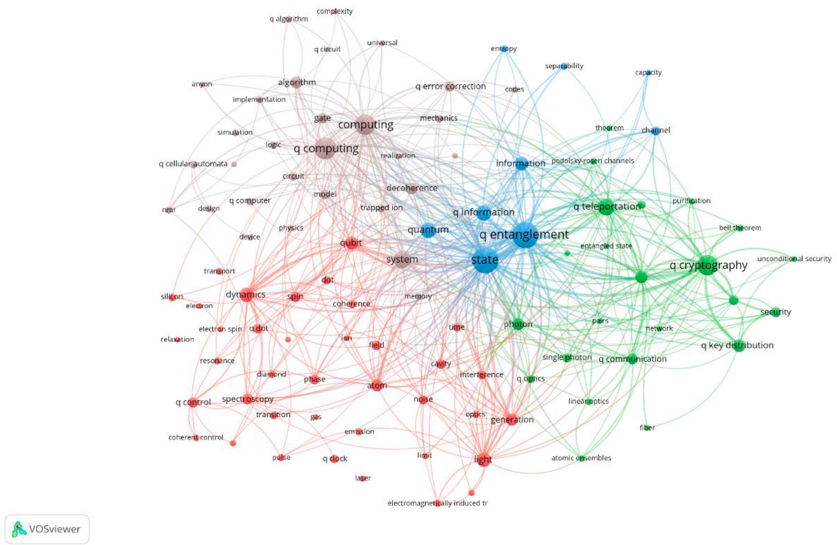

Figure 3: Co-occurrence map of the top 100 keywords (author keywords and keywords plus) in the period 1980 to 2018 with four topical clusters, using the VOSviewer parameters resolution=1.0 and minimal cluster size=5. (The two biggest unnamed green nodes belong to the keywords communication and key distribution.) For better readability of compound keywords, quantum is abbreviated to q (web-startable version at https://tinyurl.com/y8lvjnyt).

Figure 3 shows the overall co-occurrence map of 100 keywords occurring at least 298 times for the period from 1980 to 2018. Maps with about 100 keywords usually are a good compromise between keeping readability of the map and displaying most of the content. In the figure, the four fields of QT 2.0 are nicely discernible by the *keywords* in four clusters, whose colors are kept consistent in all networks: (1) Red (Q METR) with the *manipulation* of single *atoms*, *molecules*, and even (*electron*) *spins* as in *quantum dots*, and the *quantum control* using *light fields* of *coherence* (*lasers*) that lead to the *realization* of single *qubits* and of very high precision *quantum clocks*. (2) Brown (Q COMP) with q*uantum computing* and *computers* that build on *quantum circuits* with *logic gates* realized as *trapped ions, anyons* or in *NMR* devices. On this hardware, *quantum algorithms* have been implemented that are much in need of *quantum error correction*. (3) Blue (Q INFO) with *quantum entanglement* of *states* that is a major subject of *quantum information science*, also investigating *entropy* and *channel capacity* in a generalization of Shannon's information theory. (4) Green (Q COMM) with q*uantum communication* that is built upon the *quantum teleportation* of *pairs* of *entangled states*, often realized by *single photons*, as a basis for *quantum cryptography* and *quantum key distribution*.

When we inspect the topic maps for the three partial time periods, we see continuity and persistence of clusters as well as change of focus and occurrence of keywords: from the first to the second time period only 60 out of 99 keywords in the maps are identical. From 1980 to 1999 (https://tinyurl.com/y7c2nxcc) the focus had been on the preparation, manipulation, and control of single quantum systems at the atomic scale and the pioneering work on building materials, devices, and sensors for quantum metrology. From 2000 to 2011 (https://tinyurl.com/ycwqehyu) the focus had, on the one hand, switched to the advanced design of hardware components for real quantum computers and the development of algorithms utilizing quantum properties. On the other hand, the exploitation of quantum effects like entanglement for secure communication using quantum key distribution had become prominent (favorably utilizing quantum optics of single photons). From the second to the third time period, i.e. 2012 to 2018 (https://tinyurl.com/y7c2nxcc), nearly 80% of the keywords remain the same (78 out of 99 and 101 keywords, respectively). There are only slight changes in the main direction of research, but some keywords moved into the new clusters of Q INFO and quantum optics. For example, memory and storage are located in the clusters Q COMP and Q METR in the second period, and are connected with quantum optics in the third period. This connection is probably because of their importance for optical quantum communication networks. The keyword quantum simulation appears only on the third map in the Q COMP cluster. This coincides with the enlarged efforts to build a quantum simulator as the fulfilment of Feynman's vision of a quantum computer (Harris et al., 2018; Johnson et al., 2011).

Visualization of the geographical distribution of research topics

Figure 4 shows a combination of the approaches taken in the previous two sections. For the period from 1980 to 2018, we have produced a co-occurrence map of countries (denoted by their two-letter country code with a prefixed "@") with at least 400 occurrences (multiple co-authorships of the same country on one paper are counted only once) as well as a map of keywords (author keywords and keywords plus assigned by Clarivate Analytics) with at least 300 occurrences. These thresholds lead to the above mentioned top 25 countries and to 104 keywords, sorted into five topical clusters (by using the VOSviewer parameters resolution=1.1 and minimal cluster size=5). Four clusters in the figure can be assigned to the four fields of QT 2.0. About ten countries are assigned to the clusters Q METR and Q INFO, respectively. Three countries are assigned each to Q COMP and Q COMM. In case of Q COMP, India and Iran are mainly connected to the *design* of *logic gates* and *circuits*.

We compare now the assessment of the countries in the radar charts for all QT 2.0 papers in Figure 2 with their placement and connection in Figure 4: the large node of China in the green cluster (Q COMM) mirrors the dominance of China in this field with respect to the total number of papers and its high AI of nearly 3. Germany with the third highest publication output and the highest values in Q METR in the radar charts is located consequently prominently in the red cluster. Germany has significant contributions to quantum optics, and is connected to some other countries in the blue cluster (Q INFO). Q INFO is the field of Germany's second highest AI.

We would like to emphasize two other countries. These countries have with 2.5% a small share of all QT 2.0 papers, but a high AI of about 3 in Q INFO and Q COMM: Singapore has a high AI of about 3 in Q INFO and Q COMM. In the map, consequently, it can be found in the blue cluster of Q INFO connected with *quantum entanglement* and *information* (and with the UK).

The country is additionally connected with the green cluster of Q COMM and its major player China. Austria's activities, especially in Innsbruck and Vienna, are mirrored by its placement in the blue cluster Q INFO. This cluster is strongly connected to *quantum entanglement.* It is also connected to the green Q COMM keywords *communication* and *pairs* of *photons* (quantum optics, orange cluster).

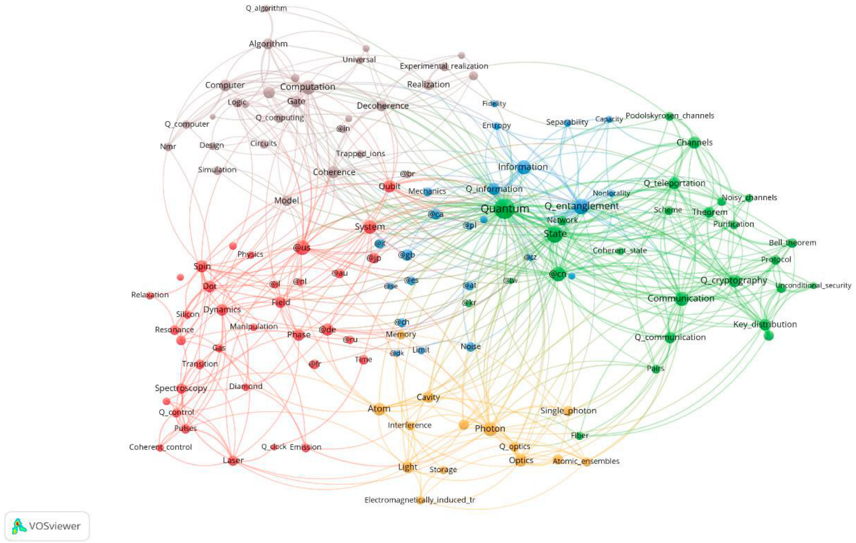

Figure 4: Co-occurrence map of the top 25 countries (denoted by their two-letter country code with a prefixed "@") with at least 400 occurrences and the top 104 keywords (author keywords and keywords plus) with at least 300 occurrences in the total publication set (from 1980 to 2018) with five topical clusters, using the VOSviewer parameters resolution=1.1 and minimal cluster size=5. For better readability of compound keywords, the term Quantum is abbreviated to Q (web-startable version at https://tinyurl.com/y978bpzm).

Discussion and Conclusions

This bibliometric study on QT 2.0 identified four main subject fields, namely Q INFO, Q METR, Q COMM, and Q COMP. For these four fields, we analyzed their respective share and growth. Of the 54.598 publications in our dataset, the four fields have shares from about one fifth (Q METR) to two fifth (Q COMP) (see Table 1). In the first decade considered here, less than 100 publications have appeared dominated by Q METR with its pioneering works on preparing and controlling single quantum systems. During the second decade (the 1990s) Q COMP joined Q METR in driving the exponential growth, leading to the ongoing dominance of Q COMP in the new millennium (see Figure 1). Between 1980 and 1999, the doubling time of QT 2.0 was between 2 and 3 years; the doubling time of the whole WoS is 7 to 8 years. During the time periods until 2011 and until 2018, respectively, the doubling times were about half as long as in the whole WoS, with 4 to 5 years and 6 to 7 years, respectively (see Table 2). In the most recent decade, therefore, QT 2.0 is a very active research area with a steady exponential development, which is common for mature research fields. We also analyzed the main contributing countries to QT 2.0. We focused on a time period with a substantial annual number of papers from 1990 until 2018. We looked at the top 25 contributing countries in more detail and compared their publication output in QT 2.0 and its four fields to the one expected from the whole WoS (see Figure 2). We visualized the geographical distribution of research topics with a co-occurrence map of countries and keywords in Figure 4. The main result is the sharp contrast of the US and China which are the greatest contributors to QT 2.0. The US shows a much smaller contribution to QT 2.0 than could be expected from their otherwise leading role in science. China has a far over proportional contribution, especially in the field of Q COMM – corroborated by its hub-like function in the topical map. By focussing on highly cited publications, China's share and AI are significantly diminished.

In future studies, the transfer of QT 2.0 research into the area of (commercial) applications might be an interesting research question. In this study, we could only investigate this topic for publications with authors exclusively from Germany.

Acknowledgments

The bibliometric data used in this study are from the bibliometric in-house databases of the Max Planck Society (MPG) and the Competence Centre for Bibliometrics (CCB, see: http://www.bibliometrie.info/). The MPG's database is developed and maintained in cooperation with the Max Planck Digital Library (MPDL, Munich); the CCB's database is developed and maintained by the cooperation of various German research organizations. Both databases are derived from the Science Citation Index Expanded (SCI-E), Social Sciences Citation Index (SSCI), Arts and Humanities Citation Index (AHCI) prepared by Clarivate Analytics (Philadelphia, Pennsylvania, USA). We thank one of the reviewers for pointing out the interesting research question concerning commercial applications of QT 2.0.

Abstract

This *research-in-progress* paper analyzes Wikipedia's representation of the Nobel Prize winning CRISPR/Cas9 technology to explore to what extent and with what temporal dynamics Wikipedia cites the most relevant and visible scientific literature on this topic. We use both verbatim and fuzzy matching heuristics to match publications cited from a selection of secondary formats—like reviews—as well as field-delineated highly cited publications with the central Wikipedia article on CRISPR. Our methodical results confirm that a combination of verbatim searches by title, DOI, and PMID is sufficient. Initial evidence also shows that the Wikipedia article references a substantial amount of articles that are well acknowledged by experts and highly cited, as well as literature that is not strictly scientific or less visible. Delays in coverage on Wikipedia compared to the publication years show a dependence on the dynamics of both the field and the Wikipedia article itself.

Introduction

The Nobel Prize winning development of the CRISPR/Cas9 mechanism and technique, the first steps of which date back more than twenty years, has left a long paper trail of scientific publications and its citation network. To understand outstanding innovation processes such as CRISPR/Cas9 and for science policy to act upon it, the identification of the most relevant publications is of key importance. One way this can be done is by measuring certain properties of the citation network and taking them as proxies for relevance. Another option is to turn to the secondary literature (like reviews) which tries to answer the question of relevance with its specific methodologies, depending on the systematic or narrative format. A problem with the latter is time: Even if a review accurately reflects the relevant literature at the time of its publication, the review may soon become outdated—a problem even more pronounced in the recent development of so-called Living Reviews (Elliot et al., 2014).

In this paper we introduce and explore a third approach to determining the relevant literature of innovation processes like CRISPR/Cas9: the analysis of Wikipedia. The online encyclopedia is a tertiary literature format whose extensive network of articles on scientific subjects is comparable to the concept of a Living Review and hence may be utilized as such for specific domains. Wikipedia is characterized by the fact that it addresses the general public, that articles are constantly revised and updated; thus reflecting dynamics to a greater or lesser extent, as well as by its unique reviewing process. The evolution of references to academic literature on Wikipedia has increased significantly over the years, suggesting that Wikipedia could even be harnessed for altmetrics (Zagovora et al., 2020). Giles (2005), Reavley et al. (2012), Estevez & Cukierman (2012) and Garcia del Valle et al. (2018) suggest that Wikipedia's reflection of scientific knowledge is accurate, while Teplitskiy et al. (2015) as well as Jemielniak et al. (2019) show that top impact journals are most referenced in Wikipedia (medical) articles. For these top biomedical journal papers, it takes (on average) only about three months to be referenced in Wikipedia. Seeing as innovation processes are characterized by transferring scientific knowledge into application contexts with implications on commercial, political, ethical, and legal aspects or questions, connecting wider societal spheres and public perception, these characteristics suggest Wikipedia as an interesting format for representing and mapping innovation processes.

In our paper we use the CRISPR/Cas9 innovation as an in-depth case study to shed light on Wikipedia's referencing patterns. Based on reference corpora matched to the central Wikipedia article on CRISPR we assess when references to scientific articles are picked up. We analyze to which extent the reference structure in Wikipedia articles can be explained by two field perspectives, namely focusing on secondary accounts and on citation impact. This paper is part of a larger pilot study on Wikipedia as a lens into innovation-in-the-making (Simons et al. 2021).

Materials and Methodology

We provide two corpora of publications on CRISPR, the CRISPR Accounts Corpus and the CRISPR WoS Corpus, each representing a different perspective on the CRISPR innovation, and we compare them with the revision history of the central Wikipedia article on CRISPR.[i,ii] Both corpora are exploratory, and, to a certain extent, pragmatically defined, as patterns for literature referencing in Wikipedia in the specific case of innovations are as of yet unknown.

The CRISPR Accounts Corpus comprises publications referenced in predominantly secondary literature formats, such as reviews and short communications. These accounts present and discuss the development of CRISPR, thus conveying experts' and stakeholders' perspectives on which publications have been relevant for the innovation process—collectively called 'accounts'. To create this corpus, we searched for the phrases "crispr history", "crispr development", and "crispr discovery" on Google Scholar, and, based on Google's relevance ranking, reviewed the paginated search result pages until no more relevant publications were identified in a row of consecutive pages. 12 publications, despite containing history sections, were discarded for not focusing on the history of CRISPR, one for not being listed in WoS. The resulting 29 sources have been complemented by three web resources presenting CRISPR timelines, which were obtained by searching for "crispr timeline" on Google, and reviewing the search results pages accordingly. We extracted all references from the 29 sources through WoS and extracted references manually in case of the timeline documents.

The CRISPR WoS Corpus is based on a bibliometric field delineation of CRISPR in the Web of Science (WoS). Publications containing "crispr"—as a highly distinctive term—in the title are defined as the core field. As a second layer, we add publications containing "crispr" in their abstracts. For a third layer, representing influences and effects, we delineate publications for which the proportion of references or citations to the core field to total references or citations is higher than 30 percent, thus representing a substantial connection. The number of publications in this corpus amounts to 20,532.[iii] In order to represent an impact perspective in contrast to that of the history-oriented accounts, we sort this corpus by the absolute citation counts and cut off at 500 publications. This number is roughly in line with the magnitude of the references in the article (see below). The reason for not using citation windows here is rooted in the specific dynamics of an innovation, where early publications typically accumulate significant citation numbers over time[iv].

For both corpora we downloaded the metadata from WoS, resulting in **1,186** and **500** unique publications, respectively, to be matched against all revisions of the English CRISPR article. All revisions of the CRISPR article were downloaded using the MediaWiki API, collecting the HTML versions of each revision's page (2,072 revisions as of February 28, 2021). Each revision has a unique revision timestamp, text sections, such as headings, paragraphs, captions, tables, and lists, the reference sections *References* and *Further Reading*, as well as other metadata. While more recent revisions of articles usually apply Vancouver style to format references, Wikipedia does not have a single house style but expects the editors to adopt a consistent style within articles, potentially causing shifts of citation styles over the course of an article's history. This ambiguity together with the fact that editors easily introduce typos when manually adding a reference to an article necessitates the development of a fuzzy reference matching approach—at least we thought so at the outset.

Our reference matching approach implements heuristics with various degrees of precision, which can be divided into verbatim heuristics and fuzzy heuristics. As verbatim heuristics, we match titles, DOIs, and PMIDs of the publications against the entire article text including all references. All strings are converted to lowercase ASCII, with title matching additionally utilizing alpha-numerical normalization. As fuzzy matching heuristics, we match titles against extracted references and allow for a normalized edit distances of 0.2, 0.3, and 0.4, and combine the latter with three author matching strategies. We use the publication-to-reference-author ratio, the Jaccard Index of publication and reference authors, and an author order score: Each author of the publication is assigned a gain equal to its position in the inverted list of authors divided by its actual position, with the sum of all values being the ideal score. The authors of a given reference are then evaluated in turn, winning the same value if matching the author of the publication in the respective position and losing that value if not. The author order score is calculated by dividing the sum of these values by the ideal score.

Verbatim match for "**CRISPR provides acquired resistance against viruses in prokaryotes**", "**10.1126/science.1138140**", or "**17379808**".

Correctly matching "**CRISPR elements in Yersinia pestis acquire new repeats by preferential uptake of bacteriophage DNA, and provide additional tools for evolutionary studies**" by **Pourcel**, **Salvignol**, and **Vergnaud** with a normalized edit distance ≤ 0.2 (0.072).

Incorrectly matching "**Efficient genome editing in plants using a CRISPR/Cas system**" by **Feng**, **Zhang**, **Ding**, **Liu**, **Yang**, **Wei**, **Cao**, **Zhu**, **Zhang**, **Mao**, and **Zhu** with a normalized edit distance ≤ 0.2 (0.110).

Looking for "**A programmable dual-RNA-guided DNA endonuclease in adaptive bacterial immunity**" by **Jinek**, **Chylinski**, **Fonfara**, **Hauer**, **Doudna**, and **Charpentier**. Author ratio score (1.0) and Jaccard index (1.0) ignore inversion of first and second author, whereas author order score penalizes it heavily (-0.479).

Looking for "**Clustered regularly interspaced short palindrome repeats (CRISPRs) have spacers of extrachromosomal origin**" by **Bolotin**, **Quinquis**, **Sorokin**, and **Ehrlich**. Author ratio score (1.0) misses incorrect author list, Jaccard index (0.667) and author order score (-0.413) penalize surplus authors and incorrect order respectively.

Looking for "**Multiplex genome engineering using CRISPR/Cas systems**" by **Cong**, **Ran**, **Cox**, **Lin**, **Barretto**, **Habib**, **Hsu**, **Wu**, **Jiang**, **Marraffini**, and **Zhang**. Author ratio score (1.0) and Jaccard index (1.0) are oblivious to change in order, author order score tolerates inversion of sixth and seventh author (0.865).

Figure 1: Examples showing verbatim and fuzzy heuristics; divergent data underlined.

For the time being we refrain from calculating exact recall values, since it requires manually reviewing all 2,072 revisions for possible matches. However, for an estimate of what might have been missed, we manually checked and deduplicated all titles, DOIs and PMIDs that had been extracted from all references throughout the article's entire revision history, resulting in 324 DOIs, 302 PMIDs, and 465 titles. The latter boil down to around 370 titles, which result in 331 unique WoS items. When mapped to our corpora, only two publications were missed by the reverse procedure, thus being almost completely in line with our matching. Around 40 items not indexed in WoS are mainly articles in popular scientific or technological journals and blogs, as well as clinical trials and patents.

Results

Table 1 shows for both publication corpora the absolute numbers of matched publications, the relative numbers in relation to the sample corpora, and the precision of each method, calculated by manually checking the respective publications and matched references. The fuzzy matching heuristics D, E, and F generally identify more publications than the verbatim ones; at the cost of precision. The comparably smaller number of matches of the fuzzy heuristics G, H, and I may be a result of the fact that author lists in the Wikipedia article are somewhat less well-maintained than identifiers and titles.

A revision cites a publication if any of the matching heuristics correctly flags the publication in the revision. The number of uniquely matched publications resulting from both corpora is 201. Table 2 (left) shows the mean and median delays for each method relative to the timestamp of the earliest correctly matched revision for both corpora. In 184 out of 1,186 and 138 out of 500 cases, respectively, the earliest match can successfully be identified using the three verbatim heuristics alone. Only in one case a publication is identified earlier using a fuzzy heuristic.

Table 1: Evaluation of the reference matching heuristics applied to the revision history of the CRISPR article, dependent on the two corpora of relevant CRISPR-related publications.

Reference Matching Heuristic	**CRISPR Accounts Corpus**			**CRISPR WoS Corpus**

While there is very little discrepancy in the number of matches between the verbatim methods, the delays in Table 2 indicate that the methods sometimes match at different times, e.g. PMIDs earlier than titles and DOIs. For the majority of entries, however, this does not matter, as can be seen from the median. The matrix on the right side of Table 2 indicates for each matching heuristic (rows) how often another heuristic (columns) correctly identifies a publication in an earlier revision. The matrix depicts the results based only on the CRISPR Accounts Corpus and only takes correct matches into account. Since all matching is aimed at eliciting the earliest revision, a relaxed method might incorrectly select a revision to be the first one for a specific publication, which leads to a lower overall recall if cleaned for correctness. The title edit distance heuristic with the most relaxed threshold of 0.4 therefore seems more sensible than the more stringent methods using thresholds of 0.2 and 0.3, being superseded by the PMID methods in only 47 rather than 49 cases. This, however, is an expected consequence of the former's overall weaker precision of 172 correctly identified publications, as compared to 179 and 177 for the latter methods. Overall, the results of the combination of verbatim methods can hardly be improved by the relaxed methods, even with regard to delays.

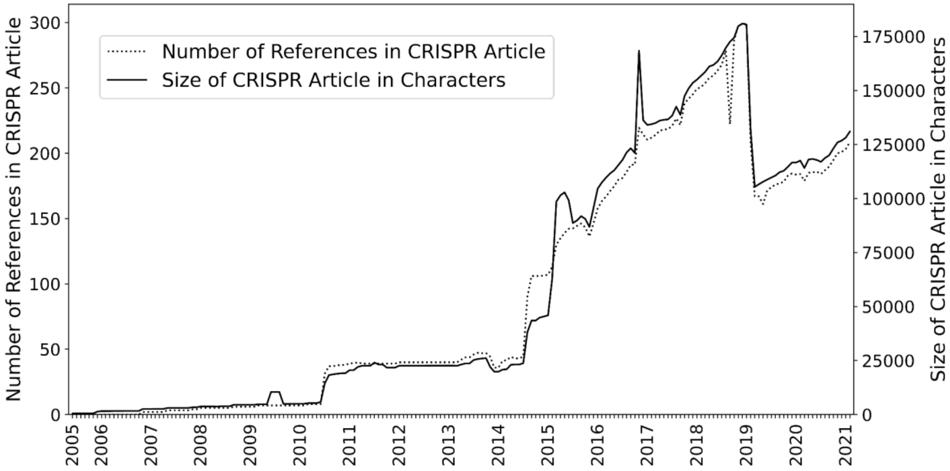

Figure 2: Smoothed dynamics of text growth of CRISPR article to growth of references.

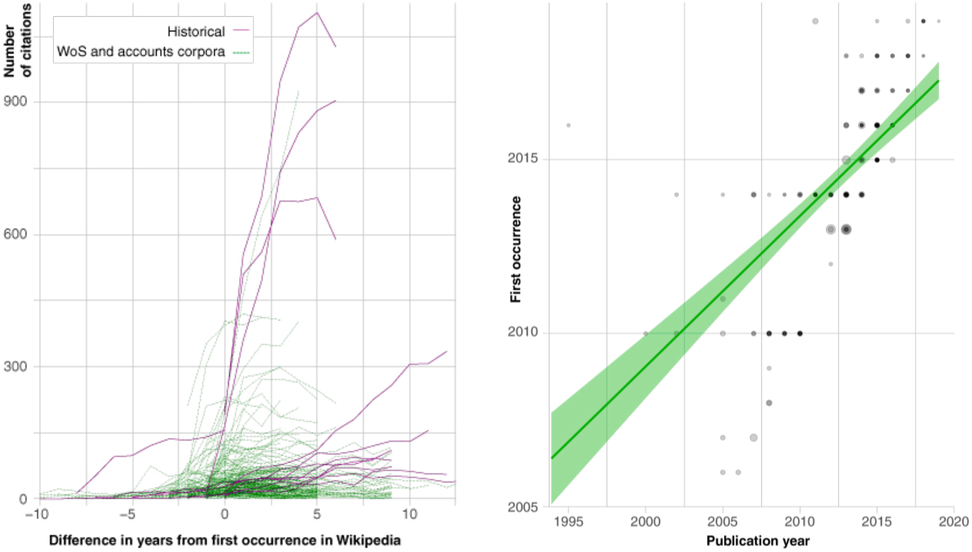

Figure 3: Citation distributions in relation to occurrence in Wikipedia. *Left:* Matched publications (201) in yearly citation counts, with date of first occurrence in CRISPR article as baseline (so that citations before date appear with negative numbers). Some prominent cases—on basis of

citations by secondary accounts and references' occurrence in current version of History section—marked by solid lines. *Right:* Publication years over years of first occurrence. Point sizes correspond to number of citations in absolute numbers, overlapping points displayed darker.

Both graphs in Figure 2 show a step in 2010 coinciding with the introduction of a 'History' section in the article. Key publications result from the years 2011 to 2013, which is reflected in the growth of text and references from 2014 onwards. In 2019, a section is moved to a new article on CRISPR gene editing. Similarly, Figure 3 on the right side shows that a number of publications dating from 2000 to 2010 were added in 2010 and a similar phenomenon can be observed in 2014, corresponding to the dynamics in Figure 2. These patterns suggest that the delays with which publications are referenced on the CRISPR page correspond to general dynamics of Wikipedia's edits on this topic. The graph on the right side of Figure 3 shows the first occurrence happens before the peak of the respective citation distribution in many cases.

Conclusion

We explored Wikipedia's usage of scientific literature in Wikipedia's article on CRISPR and the timeliness of its referencing patterns in order to gauge its relevance and adequacy as a medium for the representation and tracing of scientific innovations. More specifically, we proposed matching procedures to map from WoS publication corpora to all revisions of Wikipedia's central article on CRISPR. The results are promising: initial evidence suggests that substantial portions of the CRISPR/Cas9 literature referenced in Wikipedia are highly cited or have been acknowledged by experts in the field. We observe that the currency of referencing improves over time, and that article editing dynamics is captured as well. For the CRISPR/Cas9 case we can give evidence that a combination of verbatim matching heuristics yields sufficient accuracy, thus making Wikipedia an interesting object for analyses of science communication in addition to standard bibliometric sources.

Abstract

The use of citations as indicators of topical relatedness of publications is common in the algorithmic mapping of the structure of science. References to source documents, however, may serve a variety of epistemic functions, and hence represent rather different dimensions of topical relatedness. They may pertain to the research methods used, the empirical objects studied, the theoretical resources build on, the research questions pursued, or the external motivation for and relevance of the work. In this case study, we explore the diversity in topical dimensions along which publications are linked in citation networks, by coding the epistemic function of in-text citations. To construct an informative sample of publications, we first made a quality assessment of an existing field delineation of invasion biology and identified the core and the boundary of the field. We then sampled 9 publications from each layer to analyze the epistemic functions of citations. Our preliminary results for the core layer show the diversity of epistemic functions that underlie in-text citations and suggest substantial variation between studies. While current approaches to science mapping use citation links as generic indicators of relatedness, future algorithmic extractions that distinguish between epistemic functions of citations might greatly enrich science mapping.

Introduction

The use of citation links as indicators of topical relatedness is common in the algorithmic mapping of the structure of science (see e.g. Sjögårde & Ahlgren 2018). The resulting structures, consisting of interrelated groupings of publications are commonly interpreted as scientific fields (in global mappings), and topics or subfields (in field mappings). However, very few validation studies are done that inspect such algorithmically generated structures in order to explore their interpretation and relate them to a sociological understanding of the social and cognitive structures of science (Gläser et al. 2017). There is a tacit understanding that topics structures overlap and publications may reference each other along different topical dimensions (e.g. with regard to the methods used versus the empirical objects studied). However, current mapping approaches use citations as generic indicators of topical relatedness and apply algorithms that produce disjoint, non-overlapping clusters of publications, without systematically validating how these pragmatic choices affect the representation of fields and topics by these maps.

To improve our understanding of how such methodological choices may influence the topic structures represented by algorithmically generated science maps, we take a closer look at citations as the input data of the algorithmic mapping process, and investigate the diversity of dimensions of topical relatedness that citations may incorporate. We proceed in two steps that both involve an intellectual assessment, first of publications, then of citation links: In a first step, we investigate how the publications in a lexically delineated field data set relate to the cognitive structure of the targeted field, distinguishing four ordinal classes of degree of 'field focus.' This is to deepen our understanding of how the publications that we select for citation analysis in the next step relate to the targeted research specialty. We then construct a purposive sample of publications to represent different types of studies in the targeted research specialty and investigate the variation in topical dimensions of relatedness that citations entail by zooming in on their epistemic function. Early work in citation classification has primarily examined the informative value of citations for assessing the impact of a cited publication (e.g. Moravcsik and P. Murugesan 1975, and Chubin & Moitra 1975). More recent work in citation classification has taken on further objectives, such as improving literature retrieval systems and automatic article summarization (Jha et al. 2017, Teufel et al. 2006). Our interest here is to consider the epistemic function of a citation in the citing text. Our coding scheme is inspired by recent work in the sociology of science that distinguishes different forms of epistemically mediated interdependencies in the collective knowledge production in the sciences (Gläser et al. 2018).

We present preliminary results, since the second half of the citation classification is ongoing. Our results about the degree of field focus for a random sample of 100 publications from the field data set are not only relevant for the construction of the purposive sample for this study, but also provide insights into the quality of the field delineation of invasion biology conducted by Held & Velden (*in preparation)*. We further report proportions of epistemic functions of in-text citations across different types of studies in invasion biology, and show how the proportion of cited sources that are located inside or outside the field differ by epistemic function.

Data and Methods

This is a case study, focused on publications in the field of invasion biology. Invasion biology is a research specialty that we are also studying through ethnographic observations and expert interviews to better understand research and sharing practices in this field. This background informs the sampling approach that we adopt in this study, and the decisions it entails, namely to distinguish publications by their degree of focus on the target field (invasion biology), and by study type, in order to stratify the sample by types of studies that are common in the field.

Field Data Set

To sample publications from the field of invasion biology we start from a bibliometric field data set that was generated using a lexical query to retrieve relevant articles and reviews from the Web of Science SCI and SSCI databases (Held & Velden, *in preparation*). The lexical query is an extension of the original query by Vaz et al. (2017) that was used in a previous citation-based mapping of the field of invasion biology (Held & Velden 2019). After constructing the direct citation network of the publications retrieved using the UTs of references, the final field data set is defined as the giant component of the network[i]. It consists of 53,524 publications published between 2000 and 2019.

Field Focus Coding

Since the manual coding of in-text citations is time consuming, we had to restrict ourselves to coding a small number of publications. To ensure the sample would represent studies in invasion biology well, we randomly sampled 100 publications from the field data set that were published in 2018, and classified them by the degree of their research focus on invasion biology ('field focus'). We defined a coding scheme that distinguishes four degrees of field focus, described in table 1. Coding decisions were taken in a step-wise process: first by determining whether a link to invasion biology existed or not[ii]. Then, if a link existed, by determining whether the link was strong or not. And finally, if the link was strong, by deciding whether the focus was singularly on invasion biology, or not. Following this decision tree, the 100 publications were coded independently by two coders. Basis for the assessment was the way that authors frame the contribution of their publication by composing title and abstract, choosing author keywords and selecting a journal to publish in. The inter-coder reliability, measured using a linearly weighted Cohen's Kappa, was 0.72[iii], a value which is commonly regarded as indicative of substantial agreement.

Table 1. Coding Scheme for Field Focus

Code	*Definition*
Core	Singular focus on invasion biology.
Boundary	Additional research focus, outside invasion biology.
Periphery	Explicit contribution to invasion biology is marginal.
Outside	No discernible connection to invasion biology.

Purposive Sample Construction for Citation Coding

We include in our sample core and boundary publications. Combined, we would argue, these types of publications define the field of invasion biology. We further take into account the type of study, distinguishing 'empirical' (observational, experimental), 'modeling'[iv], 'theoretical', and 'application-oriented' studies, in order to reflect the great variation in research approaches in invasion biology. We found the large majority of core and boundary publications to be empirical studies. Because theoretical studies were rare and occurred only among core publications, we omitted them from our sample for citation coding, and stratified the final sample of 9 core and 9 boundary publications by three study types: application-oriented, empirical, and modeling.

Citation Coding

Our classification scheme for capturing the epistemic function of in-text citations distinguishes between five epistemic functions that in-text citations may serve when referring to a source: clarifying the methodological approach (*method*), explicating properties of the empirical object (*empirical object*), drawing on or disputing theoretical insights (*theory*), defining and discussing the research problem (*research problem*), and referring to the external motivation or practical application of the work (*ext. interest*). If the context was ambiguous, we coded an in-text citation with up to two functions. We tried to use this option sparingly. The coding was conducted by two coders, one coding the core set of publications (see Seitz 2020), the other coding the boundary set, which is ongoing work. For resource reasons we could not afford double coding the entire sample. To ensure coding consistency, we performed selective double coding and review.

First Results

Field Membership

Our assessment of the field focus of randomly selected publications in the field data set finds that 71% (± 9%)[v] directly pertain to the field of invasion biology, either as core publications (49% ± 10%), or as boundary publications (22% ± 8%). Twenty-three percent (± 8%) are only peripherally related (e.g. simply mention the problem of invasive species as an ecological concern among other concerns). The remaining 6% (±5%) of publications are erroneously included, with no obvious relationship to the field.

Epistemic Functions of Citations

We observe considerable variation between the 9 core invasion biological studies in our sample. As figure 1 shows, the epistemic functions of in-text citations vary between studies, showing strong variation even among studies of the same study type. The most suggestive difference between study types seems to be that application-oriented studies tend to have more in-text citations that relate to external interest than empirical or modeling studies. Overall, in the aggregate, external interest and theory related in-text citations are fewer than empirical object, method or research problem related citations.

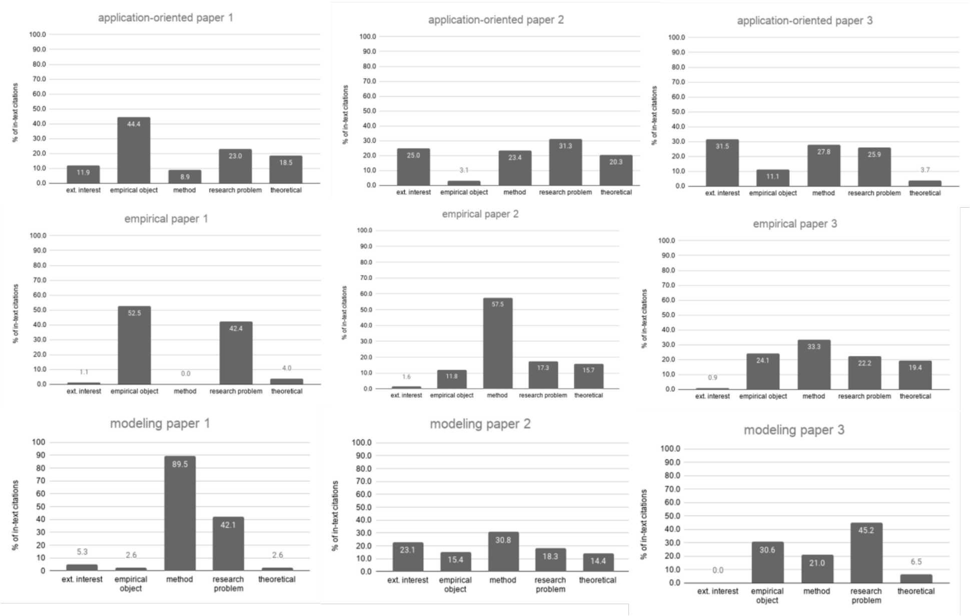

Figure 1. Epistemic function of in-text citations for each of the 9 publications in the core invasion biology sample.

Figure 2 shows the extent to which in-text citations in the 9 core invasion biology publications refer to publications inside versus outside the field data set. Only cited publications carrying a WoS UT and published within the time window of the field data set (2000-2019) are considered. Of the 568 references, 354 references in the 9 sample articles fulfill this criterion, corresponding to 571 in-text citations. Sources outside the field data set dominate among method related citations, whereas citations related to research problem, theory, or application aspects predominantly refer to publications within the field data set. For empirical object related citations the proportion of internal versus outside sources is almost even.

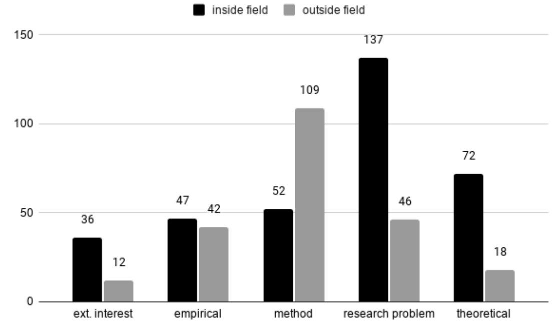

Figure 2. Proportion of in-text citations to publications inside versus outside the field data set by epistemic function (for subset of publications indexed by WoS and published in 2000-2019)

Discussion

How to get field delineation right is a critical issue in the bibliometric study of scientific fields (Zitt et al. 2019). Our coding of field focus is one possible approach to validate results and reveals that an estimated 71% of the lexically delineated field data set consists of publications that can be considered to represent research in invasion biology. Since this kind of validation exercise is rare, there is limited data to compare our result to. Haunschild et al. (2018) probed the purity of an algorithmically generated field classification by intellectual inspection of a random sample of 123 publications. They found roughly 50% of publications in the sample to belong to the target research specialty of 'common water splitting'. The decision criteria for whether a publication is considered to belong to the target field are not made explicit in their publication. Our approach differs in that we define a more fine-grained classification along with coding guidelines that help distinguish between those classes.

The process of developing the coding guidelines forced us to make explicit and agree on what, for us, defines field membership of a publication. By distinguishing between core and boundary publications, we found that a little more than 2/3rd of the field to consist of publications with a singular focus on invasion biology, and a little less than 1/3rd of the field to consist of publications that share a research focus on invasion biology with a research focus on a neighboring field. Importantly, some of the publications that were classified as singularly focused on invasion biology, simultaneously contribute to a field that can be interpreted as 'pervasively' overlapping. For example, invasion biological studies that examine the interaction of an invasive species with a potential biological control agent to be used in invasion control can be simultaneously regarded as studies in the field of pest control. This observation underlines the poly-hierarchical structure of scientific fields (Havemann et al. 2017).

The results of coding the epistemic functions of in-text citation in the 9 core invasion biology papers are intriguing. That application-oriented studies would refer more strongly to an external interest such as the motivation for the study and the application relevance of its result, seems plausible. The strong within group variation in the epistemic function of in-text citations is striking. It points to shortcomings of the high-level study classification that we define and points to a diversity of subtypes. Take e.g. the variation in the proportion of method related in-text citations among empirical studies. Empirical paper 1 constitutes a classical field study reporting a small-scale observational survey of species occurrences. It has no method related in-text citations. By contrast, empirical paper 2 uses genetic analysis to determine invasion success factors and proposes a methodological innovation, criticizing previous analyses for a methodological deficiency. In this paper more than 50% of in-text citations relate to methods.

If we look at the epistemic function of citations to the concurrent literature inside versus outside the field, this case study further provides a window into the epistemic interdependencies between fields. Our (small sample of) data suggests that invasion biology is highly reliant on method-related knowledge published in other fields, followed by knowledge about empirical objects. Knowledge pertaining to the research problem, external interest, and theoretical assumptions, on the other hand, is primarily referenced by citing publications from inside the field. Whether this pattern holds for other fields is an open question.

Conclusions

We provide empirical evidence for the diversity in topical dimensions of relatedness that are represented by in-text citations. We find great variation in the epistemic functions that drive citations to other publications within the field versus outside the field. The current practice in science mapping of using citations generically as signals of topical relatedness conflates these different dimensions that could be highly informative for science mapping, if only these different dimensions were algorithmically accessible for automated extraction.

[i] Held &Velden (2019, in preparation) disregard publications outside the giant component in order to increase the precision of the field delineation.

[ii] At times, publications picked up by the lexical query do not relate to invasion biology. This happened when a publication uses a term in the abstract that is part of the lexical query in order to signal invasiveness (such as 'introduced'). To be relevant, the lexical query requires such terms to be combined with another relevant term (such as 'species'), however it does not restrict the order of terms and permits a two word distance between terms, which can lead to irrelevant matches.

[iii] After the inter-coder assessment, one item in the coding guidelines was tweaked one last time in order to increase the internal consistency of the guidelines. The change meant to categorize studies that have an invasive species as empirical object, but do not articulate a link to an invasion biological research question, as peripheral – in agreement with the weight given in our qualitative classification approach to the framing of studies. This resulted in the reassignment of three studies that focus on invasive species from boundary to peripheral. We did not re-assess inter-coder reliability after this change.

[iv] Studies that use computational or statistical modelling approaches to predict the distribution of invasive species or factors that influence mechanisms of invasive processes.

[v] Based on a 95% confidence interval for the estimate of a population proportion.

Geographic Differences in the Uptake of Open Access

Abstract

Open Access (OA) is a process that aims to make research output freely available on the internet. The OA movement originated from the growing demand to make research more accessible worldwide. It has been gaining a lot of momentum, with the implementation of several OA policies by funding institutions and the development of several new platforms that facilitate the publication of OA content at low cost. Studies have shown that nearly half of the scientific literature could be available online for free, but only a few have compared the use of OA literature at the country level and from a worldwide perspective. Along these lines, this study aims to provide a global picture of the current state of OA adoption by countries, using two indicators: publications in OA and references to articles in OA. We find that, on average, low-income countries are publishing and citing OA at the highest rate, while upper middle-income countries and higher-income countries publish and cite OA articles at below world-average rates. These results highlight national differences in OA uptake and suggest that more OA initiatives at the institutional, national and international levels are needed to support a wider adoption of open scholarship.

Introduction

Open Access (OA) is a process that aims to make research output freely available on the public internet, allowing the users to read, download, copy, distribute, print, search or link to the full text without any financial, legal or technical barrier, in accordance with an open copyright license. The OA movement originated from the increasingly growing demand to make research more available worldwide. One of its milestones was 2001's Budapest Open Access Initiative, which established the first clear distinction between the two main types of OA: self-archiving (green OA) and a brand-new generation of journals that would allow scholarly material to be distributed in its full form, freely on the publisher's website (gold OA). Gold open access journals may be associated with charge article processing charges, originally intended to cover publication costs. The movement has recently been gaining momentum, with the implementation of several OA policies by funding institutions worldwide and the development of several OA new platforms such as including Open Journal System (OJS), SciELO, and Érudit. These platforms facilitate the publication of OA content at low cost. According to different studies, nearly half of research articles could be available online at no cost (Archambault et al., 2014; Piwowar et al., 2018; European Commission, 2019). Previous studies have addressed different aspects of the OA phenomenon, such as the availability of articles (Archambault et al., 2014; European Commission, 2019; Piwowar et al. 2018), the so-called "citation advantage" of OA articles (Antelman, 2004; Swan, 2010; Piwowar et al., 2018), and OA mandates (Larivière & Sugimoto, 2018). However, very few articles (Evans & Reimer, 2009; Iyandemye & Thomas, 2019) have compared the use of OA literature at the country level. In this paper, we provide an up-to-date portrait of the adoption of OA across the world, distinguishing between publishing in OA and citing OA publications, between two types of OA (green and gold).

Research Objectives

The purpose of this paper is to provide a global picture of the current state of OA adoption by countries, using two indicators: publications in OA and references to articles in OA. Our research questions are as follows:

1. What proportion of the scientific output of countries is Open Access?
2. To what extent are different countries citing literature in open access?
3. Does OA publications correlate with OA references at the country level?
4. How does OA usage relate to the level of income of countries?

Methods

We collected all articles and reviews in the Web of Science (WoS) published between 2015 and 2019. Science being increasingly collaborative, publications are generally authored by multiple individuals, often from different institutions and countries, among whom the work has typically been unevenly distributed (Larivière et al. 2015). We argue that choices in terms of cited literature and publication venues are predominantly made by authors who played a leading role in the research. Thus, when assigning a publication to a country, we only use the institutional affiliations of the first and corresponding authors. We further classified countries based on the World Bank's country classifications by income level (2018–2019).

To determine the OA availability and OA type of a paper or reference, we searched for its DOI in the Unpaywall (http://unpaywall.org) database, which identifies OA content from open indexes (e.g., Crossref, DOAJ), journals and repositories. This data indicates whether the paper is published in an OA journal (gold OA) and if a publication is found in a repository (Green OA). These two categories are not mutually exclusive since a paper can be deposited in a repository even if it is published in an OA journal. Because we use the DOI to link the WoS and Unpaywall data, WoS publications that do not include a DOI are excluded from our study. The distribution of publications by fields may differ between countries. We weight this field-normalized indicator based on the proportion of publications in each field by that country. The resulting indicator is a weighted and field-normalized measure of OA usage, which we apply to the analysis of OA publications and references. The main purpose of our analyzes being to identify differences in OA uptake between countries, we add another layer of normalization comparing the weighted and field-normalized indicator to the world average (which is represented by a value of 1 in the results).

Results

Tables 1 and 2 presents an overview of our dataset by discipline and type of OA in terms of publications and references, respectively. In table 1, we see that the proportion of publications in OA varies by fields, with 40.5% of papers being OA in biomedical research (BM; 40.5%) and 20.2% and 20% in natural sciences and engineering (NSE) and in social sciences and the humanities (SSH) respectively. The very small proportion of papers that are in gold OA only (1.3 - 3.9%) shows the large overlap between green and gold OA.

In table 2, we see that the share of references to OA papers also varies by fields with Biomedical Research citing more OA papers. However, we can observe that the proportion of references to gold OA articles is generally lower than the proportion of gold OA publications, with social sciences and humanities being the only exception. But overall, the proportion of OA references is higher than the proportion of OA publications. Again, the small proportion references to articles that are available only via gold OA shows the large overlap between green and gold.

Table 1. Proportion of OA publications by type and by fields.

Field	*Number of publications*	*% OA*	*% Gold OA*	*% Green OA*	*% Gold Only*	*% Green Only*
BM	2,529,405	40.5%	18.9%	39.3%	1.3%	21.7%
NSE	3,371,682	20.2%	7.2%	16.2%	3.9%	13.0%
SSH	757,466	20.0%	6.8%	18.5%	1.5%	14.1%
All	6,658,553	27.9%	11.4%	25.2%	2.7%	16.4%

Table 2. Proportion references to OA by type and by fields.

Field	*Number of references*	*% OA*	*% Gold OA*	*% Green OA*	*% Gold Only*	*% Green Only*
BM	14,913,746	48.2%	13.8%	47.5%	0.6%	34.4%
NSE	18,471,269	24.9%	6.0%	23.5%	1.5%	19.0%
SSH	2,055,463	32.2%	7.7%	31.6%	0.6%	24.4%
All	35,440,478	35.1%	9.3%	34.1%	1.1%	25.8%

Figures 1 and 2 reveal that countries mostly cite OA more often than they publish in OA. Sub-Saharan African countries publish and use OA more often. In North America, the United States publishes and cites OA more than the world average, however, Canada publishes in OA less often but cite OA more often. South American countries also cite OA more often, however, Brazil publishes more in OA rather than citing it. In Europe, Western European countries mostly publish and cite OA, while the trend is opposite for the Eastern European countries. In Asia, North Africa and the Middle East, most countries publish or cite OA less often.

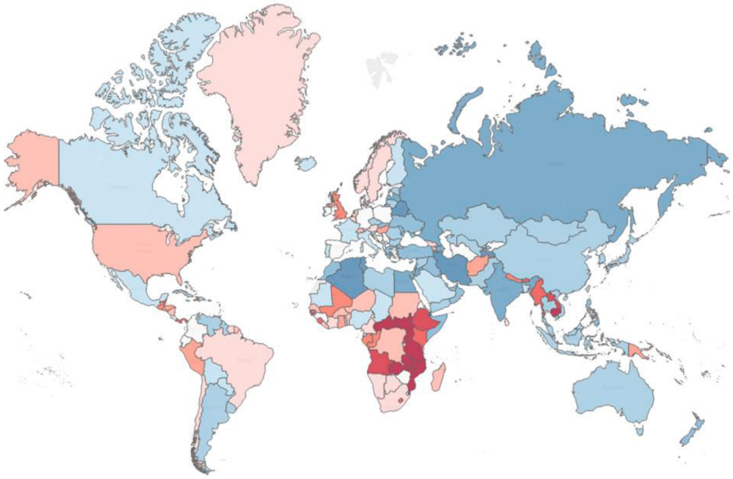

Figure 1. Weighted and normalized map of number of OA publications by country. Red indicates that a country is above the world average, blue indicates it is below the world average. White represents the world average.

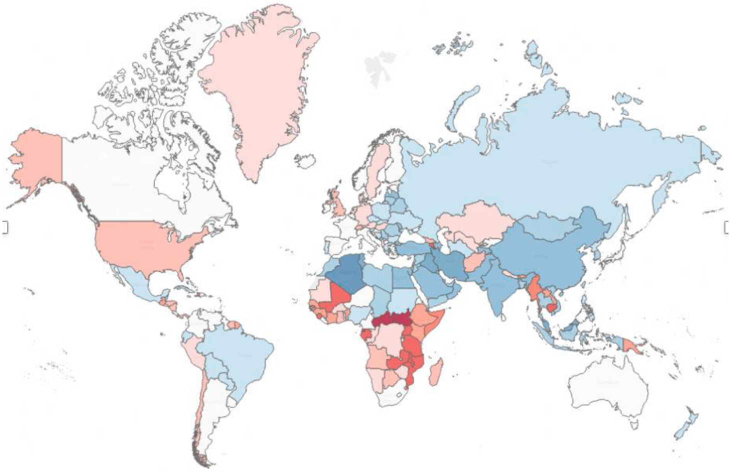

Figure 2. Weighted and normalized map of references made to OA publications by country. Red indicates that a country above the world average, blue indicates it is below the world average. White represents the world average.

Figure 3 illustrates the relationship between the weighted and normalized OA publication indicator of countries with the weighted and normalized reference indicator. A Pearson correlation shows a very strong relationship between the two indicators (r = 0,870; p < 0,001), which indicates that the more a country publishes in OA, the more it is likely to make references to OA papers.

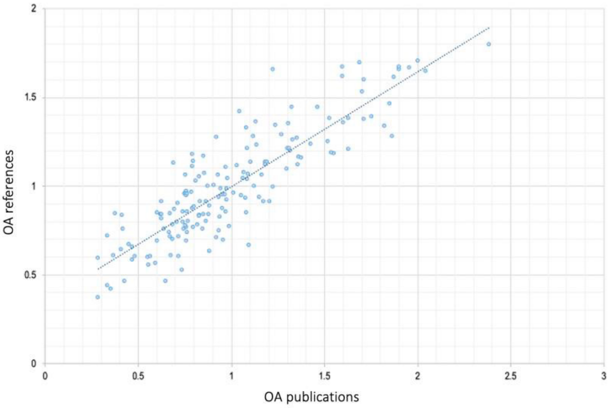

Figure 3. Scatter graph indication the relation between the weighted and normalized OA publication indicator of countries with the weighted and normalized reference score.

Figure 4 shows plots of countries according to their OA publications and references compared to the field-normalized world average. We observe that overall, as figure 1 suggested, the two indicators correlate. The correlation is, however, 1.3 times stronger for lower middle-income and low-income countries and upper-middle-income countries. On average, the different groups are positioned in different quadrants: the higher and upper-middle-income countries are on average in the third quadrants while low income and lower middle-income countries are situated in the first quadrant. This shows that overall, countries with higher income have a lower tendency to both publish and cite OA papers than lower income countries.

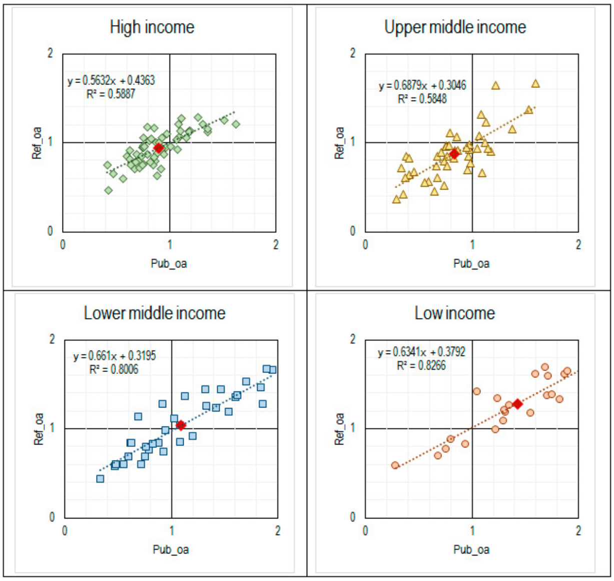

Figure 4. OA publication vs. references per country income (red dots; average for all the countries of the same income category).

Conclusion

Our findings show that Sub-Saharan Africa is publishing and citing OA at a higher rate than the rest of the world, while we found that the Middle East and Asia are the areas where the proportion of publications available in OA is lower, as their use of OA. This could be explained by the fact that APCs are mostly waived for Sub-Saharan countries (e.g., research4life countries) but is not or only partially waived for most Middle Eastern and Asian countries. One other possible explanation is that the national and transnational OA initiatives such as plan S for the European Union and PubMed Central in the United States are almost non-existent in these countries, and institutional repositories are not well developed. Looking at income levels, our findings also reveal that lower middle-income and low-income countries are those who publish and cite the most OA. Again, this may be partly explained by the fact that APCs are generally waived for these countries, making publishing in gold OA more accessible for them. Moreover, some commercially owned gold OA journals may have less strict publication criteria and given the lack of research infrastructure in these countries, they may be more likely to publish in these journals (Butler, 2013). We also found that the upper-middle-income countries behave similarly to the higher-income countries. However, the underlying mechanisms behind the use of OA potential may be different. For instance, upper middle-income countries may lack the resources to pay for APCs on top of high subscription prices for closed journals (both of which they don't qualify for waivers), and which is not necessarily the case for high-income countries. There may also be other factors, such as a lower reputation of OA journals in certain parts of the world. Ultimately, while high-income countries have mandates and repositories, and low-income countries have waivers, our results highlight national differences in OA uptake and suggest that more OA initiatives at the institutional, national and international levels are needed to support a wider adoption of open scholarship.

From Citing Sentences to Causal Networks: The Causality Index

Henry Small

hsmall@mapofscience.com
SciTech Strategies, Inc., Bala-Cynwyd, Pa. (USA)

Abstract

Citing sentences for highly cited papers are examined to ascertain the presence of causal assertions. The incidence of causal statements varies by field of science, and the type of causality depends on the nature of the cited paper. Analysis focuses on papers in the biomedical category. Samples of citing sentences are analyzed to extract causes and their related effects. Aggregation of cause-effect patterns, following the unification of terminology, allows the construction of causal networks. These networks can be compared with the content of the cited paper to highlight new findings and points of consensus. Machine learning sheds light on the words associated with causal and non-causal assertions, and a grammatical analysis of causal sentences provides a way to partially automate the identification of statements of cause and effect by combining noun or noun phrase positions in sentences with the presence of causal words, leading to the formulation of a "causality index".

Introduction

According to Pearl (2018) we are all causal thinkers. It is natural for humans to try to make sense of our experiences by positing causes whether these explanations are scientific or conspiratorial. Philosophers from Aristotle to David Hume have developed philosophies of nature based on various types of causes (Bunge, 1959). While notions of causality may break down at the subatomic level, they remain a pervasive way of thinking about macroscopic phenomena in all branches of science from physical to social.

This paper came out of an investigation of the role of theory in citing sentences. Citing sentences were examined for samples of highly cited papers, and each paper was classified as dealing in some way with theoretical issues. On closer examination it was seen that discussions of theory were often embedded in statements of a causal nature where theories were cast as causes and their effects as empirical outcomes. This led to an attempt to extract causes and effects from the citing sentences and representing them as networks. As an example of how theories and causes are intertwined, consider how Newton's theory of gravitation "causes" the planets to travel in elliptical orbits around the sun. Here the theoretical construct of "gravity" is at least in part the cause of the observed phenomenon.

It turns out "causal networks", or "causal maps", have had a long history particularly in fields such as management, operations research, and political science (Narayanan & Armstrong, 2005; Axelrod, 1976). These efforts have also been described as "cognitive maps", "fuzzy causal maps" and "Bayesian causal networks." Data sources are commonly questionnaires, surveys or texts, but rarely scientific or technical texts (Sobrino, Olivas & Puente, 2010). Methods for extracting causal content are mostly qualitative and subjective, although increasingly algorithms utilizing deep learning are being developed (Li, et al. 2021; Trieu et al. 2020).

The advantage of performing this analysis on citing sentences is that we can tap into the multiple perspectives of citing authors on the unique causal aspects of a single cited paper, not only the viewpoint of the cited author. Linking a cited paper to its citing sentences also reveals the degree of agreement among citing authors on what causes what, and these diverse views can be aggregated to form a directed network of assertions where each arrow points from a cause to an effect. The resulting network can be interpreted as a collective model of the theory including, in some cases, its empirical outcomes.

Of course, not all cited papers and not all citing sentences are causal in nature. Sentences can also be descriptive, procedural or programmatic. Method papers, for example, often contain procedural sentences as do sentences citing such papers. While methods appear at first glance not to be causal, their real causal basis may be hidden in earlier generations of papers. Interestingly, this situation is analogous to technologies that have predictable outcomes and a deterministic basis which is hidden as in a "black box."

Various types of causation can be seen in these data ranging from hypothetical, to deductive in mathematics, to deterministic in chemistry, to statistical in medicine or the social sciences. There is also a range of certainties associated with these mechanisms, and their degree of empirical confirmation can, at least in principle, be modelled by Bayes's theorem using conditional probabilities (Small, 2019; Zeevat & Schmitz, 2015).

Data and Methods

The data for this study are drawn from the full text of papers published by Elsevier as described by Boyack, et al. (2018). The cited papers comprise the 2,500 most cited papers published between 2000 and 2004 which are separated into five broad fields of science. Citing sentences are taken from the same Elsevier full texts covering the years 2000 to 2016. The 500 papers for each field are divided into centiles.

The number of highly cited papers dealing with theoretical issues can be used as an approximate indicator of the fraction of causal citing sentences in each of the five fields. Fields with the highest fractions of causal citing sentences are biomedical sciences and social/behavioral sciences, followed by mathematics/computer science. Life science/geosciences and physics/engineering had the lowest fractions.

Table 1 shows examples of causal sentences drawn from various fields. In three of the five examples, the cause is identified with the subject of the sentence and the effect with the predicate. In the examples from biology and physical science this role is reversed due to the use of the passive voice signaled by verb - preposition combinations "caused by" and "due to".

Table 1. Examples of causal citing sentences from different fields.

Health
Smoking is the leading preventable **cause** of death in the United States.
Biology
Harmful heavy metal action in plants is **due to** the generation of reactive oxygen species and induction of oxidative stress.
Physical Science
The improved heat transfer by nanofluids is **caused by** the increased thermal dispersion due to the chaotic movement of nanoparticles.
Social Science
It has been shown that oil price changes **affect** economic growth asymmetrically.
Statistics
Maximum likelihood approaches have been shown to substantially reduce bias **arising** from missing data.

For the present study, causal analysis is performed only on the fifth centile of papers in the biomedical field. Focusing on the 5th rather than the 1st centile avoids the overrepresentation of method papers. The second most cited paper in the 5th biomedical centile (Caterina, et al., 2000), which is the test case below, has 764 citing sentences and deals with nociception.

Highly cited papers were classified as causal or non-causal based on the examination of a sample of about 20 citing sentences. On this basis roughly one-half of the papers in the 5th biomedical centile were deemed predominantly causal in nature. For these 50 papers, the samples of citing sentences were manually scanned to extract text strings representing causes and effects. The text strings were then joined together in directed networks as in Figure 1 representing each cited paper, where causes point to effects. The same node can be both a cause and an effect, as in the case of chaining, and causes can have multiple effects, and effects multiple causes.

Because citing authors often use different technical terms to refer to the same concepts or entities, it is necessary to unify the terminology in constructing these networks. The causal network for the Caterina paper is shown in Figure 1. The node labelled "TRPV1 knockout mice" is unified with "TRPV1 -/- mice", "TRPV1-deficient mice", and other variants. Each link in the network is labelled by the relative frequency of citing sentences linking the cause and effect and the links are labelled as having a "promoting" (+) or "inhibiting" (-) influence as is customary in the causal network literature. The network is also annotated to indicate effects having empirical evidence (italics), "new" relationships absent in the original cited paper (underlined text), and future possibilities (dashed outlines).

Caterina, et al, Science, 2000.

Figure 1. Causal network of citing sentences for the Caterina, et al. (2000) paper.

The following citing sentence illustrates the procedure used to construct the network: "The most salient phenotype of TRPV1 null mice is a profound loss of the thermal hypersensitivity normally associated with inflammation." The cause in this sentence corresponds to the node labelled "TRPV1 knockout mice" at the left of the Figure, while the effect corresponds to the node labelled "heat hypersensitivity." Clearly the challenge is to automate the construction of the causal network as far as possible.

To this end a machine learning exercise was undertaken using the Caterina paper as a test case. A sample of 327 sentences were selected from papers citing the Caterina paper, and manually classified as causal or non-causal. The Scikit-learn package was used for machine learning (Pedregosa et al., 2011). The median of the ten classifiers was 73% (F1 = .74). It is instructive to look at the coefficients of the individual words that define the optimal surface for a given classifier. For example, high coefficient words for the Bernoulli classifier included cause or effect words like "induced", "activation", "stimuli" and "responses" while low coefficient words were more action oriented like "performed" or "examined" but in general were more diverse. This suggests that, despite the modest accuracy, individual words can, to some extent, differentiate causal from non-causal sentences. Thus, a vocabulary of 77 words signalling causes or effects was compiled and used to code the sentences.

However, further evidence is required to make the distinction of causal from non-causal. This is provided by information on the relative positions of nouns and noun phrases within the sentence. It was observed that in some cases frequently occurring noun phrase pairs, such as "TRPV1 knockout mice" and "heat hyperalgesia", correspond to links on the map. Further, the nouns or noun phrases representing causes were most often associated with the subject of the sentence while effects were associated with the predicate (Findler & Bickmore, 1996). For example, based on the sample of sentences used to create Figure 1, "causes" appeared in the subject of the sentence 73% of the time and "effects" appeared in the predicate 87% of the time. This suggested the simple rule of parsing each sentence into segments defined by the position of the verbs. A rough division of subjects and predicates is thus obtained by applying a part-of-speech analysis to the citing sentence. An example is shown in Table 2 based on the simple citing sentence quoted above. Here the verb "is" separates the causal noun "TRPV1" in the subject of the sentence from the effect phrase "thermal hypersensitivity" in the predicate. For more complex sentences with multiple verbs, additional segments are defined and numbered sequentially. Part-of-speech analysis was implemented using the standard NLTK tagger with customizations for biomedical terminology (Bird et al. 2009), followed by separation of the sentence into numbered segments.

Table 2. Parts of speech (POS) for a citing sentence indicating cause (C) and effect (E).

Seq	*Word*	*POS*	*Cause/Effect*
1	The	DT	C
2	most	RBS	C
3	salient	JJ	C
4	phenotype	NN	C
5	of	IN	C
6	TRPV1	NNP	C
7	null	NN	C
8	mice	NN	C
9	is	VZB	E
10	a	DT	E
11	profound	JJ	E
12	loss	NN	E
13	of	IN	E
14	thermal	JJ	E
15	hypersensitivity	NN	E

Results and Conclusions

Combining information on the relative positions of noun phrases with one or more of the 77 cause/effect signal words noted above, it was possible to create a causality index for a given pair of nouns or noun phrases purported to be a cause-effect pair. First, we count the number of times the candidate noun-cause appears in a sentence segment that precedes the candidate effect-noun and divide this by the total number of times the two nouns appear jointly in sentences. Then we compute the percentage of sentences that contain signal words. For example, referring to Figure 1, a stem search is carried out across all citing sentences for the link representing "*TRPV1*" and "*heat*" where the first term appears in a segment prior to the appearance of the second term. This gives 157 sentences where the cause precedes the effect out of a total of 238 sentences where both terms are present, or 66%. Signal words appear in 142 of the 157 sentences (90%) and in 208 of the 238 sentences (87%). Since we want the causal word combinations to have a high causal signal as well as a high positional precedence, a suitable causality metric is the product of 66% and 90%, that is, the product of the proportion of sentences where the cause precedes the effect and the proportion of those same sentences containing causal signal words. A causality index of 100% would mean that the cause word precedes the effect word in all sentences, and all the sentences contain causal signal words.

Table 3 shows the analysis of a number of the links on Figure 1 where TRPV1 is the primary causal noun and the effect words correspond to specific links. Other non-causal effect words such as "studies" and "evidence" are included for comparison. The top six effect words with the highest causality indexes are represented on the map. Two effect words "antagonist" and "neuron" are on the map but have lower scores. The three words with the lowest scores are not on the map as effects. While the index looks promising as a means of distinguishing causal from non-causal word combinations, a comprehensive assessment would involve computing the index for all possible noun or noun phrase combinations in the citing sentences.

Table 3. Causality indexes for the cause word "TRPV1" combined with selected effect words.

Causality Index %	*Cause word*	*Effect word*	*On map*
63	TRPV1	hyperalgesia	Yes
60	TRPV1	heat	Yes
59	TRPV1	acid/proton	Yes
57	TRPV1	chemical	Yes
50	TRPV1	mechanical	Yes
38	TRPV1	capsaicin	Yes
29	TRPV1	evidence	No
24	TRPV1	antagonist	Yes
19	TRPV1	neuron	Yes
11	TRPV1	mice	No
11	TRPV1	studies	No
10	TRPV1	gene	No

One aspect of causal relationships not yet addressed is whether there are indications of empirical confirmations and how we would go about finding them. While the citing sentences generally do not detail theory-evidence connections, we can learn more about these by looking at neighboring text in the citing papers. For example, looking at the paragraphs containing the citing sentences for the Caterina paper, the word stem "*observ*" ("observe", "observation", etc.) is found an average of four sentences following the citing sentence, suggesting that the observational details are given at a later point in the text. This finding may be important for quantifying the degree of confirmation of theory (or its causal assertion) by evidence, but the nature and strength of this coupling remains to be investigated.

From a broader perspective, I think quantitative science studies can benefit from research into causal networks because it brings us closer to the content and substance of science, scientific theories, theory confirmation, and ultimately the credibility of science.

Acknowledgments

I would like to thank Nees van Eck of CWTS for providing data, Mike Patek for programming, Kevin Boyack and Richard Klavans of SciTech Strategies, and Caleb Smith at the University of Michigan for valuable discussions.

Abstract

This paper aims to measure the internationalization of Brazilian research within the common beans research topic. To achieve this goal, we employed bibliometric techniques using Scopus's bibliographic database. For the analysis, we use diffusion, collaboration and research impact indicators. The results show the predominance of national collaborations and the role of the United States and Brazil in the mainstream of scientific production on common beans. Although there is a strong national appeal on the subject, the analysis of the Field-Weighted Citation Impact indicates that Brazilian publications in international collaboration are more cited than the global average, thus showing the positive impact collaborations have on the global dissemination of science. Furthermore, by offering inputs on the international projection of research, we design a methodological path to assess the internationalization of scientific production by countries and institutions. From this point of view, this paper can support the improvement of research internationalization policies and the strategic planning of science.

Introduction

One of the most relevant criteria to evaluate scientific production is the degree of internationalization (Fiorin, 2007), as it demonstrates the capacity of countries and institutions to produce knowledge for the world scientific community (Santin; Vanz & Stumpf, 2015). In this context, bibliometric studies are gaining ground, which allow visualizing the scientific activity of a given object or field of knowledge, taking into consideration aspects such as collaboration, impact of citations and co-authorship networks (Araújo, 2006; Guedes & Borschiver, 2005).

In this perspective, this article applies bibliometric indicators to measure the internationalization of Brazilian research regarding beans, one of the most produced and consumed legumes in the world, as the object of study (Miyamoto et al., 2017).

Bean is a seed of a leguminous plant of the *Phaseolus* genus (Singh et al., 1991). The species with the greatest representativeness in cultivation and consumption is *Phaseolus vulgaris L.*, also known as "common bean" (Miyamoto et al. 2017, Chiorato et al. 2018). Such legume is an important food and contribute to the food security of several world populations due to the low cost of production, less impact on the family budget and its recognized nutritional quality (Hayat et al. 2014; Messina, 2014; Hartmann & Siegrist 2017).

Methodology

This study applied bibliometric indicators (of scientific diffusion, research collaboration and impact) of papers retrieved from the Scopus platform, due to its scope and volume (Archambault et al., 2009). Scopus is a database of abstracts and citations from scientific literature and academic-level information sources that indexes more than 22,000 journals, 5,000 international editors, in addition to other documents (CAPES, 2016).

From exploratory readings on the theme and support from experts, descriptive terms about the common bean were selected (Table 1):

Table 1. Boolean search equation for common bean

TITLE("Phaseolus vulgaris" OR "common bean" OR "carioca tegument" OR "black tegument" OR "alubia tegument" OR "navy tegument" OR "red tegument" OR "cranberry tegument" OR "pinto tegument" OR "Dark Red Kidney tegument" OR "white tegument" OR "rajado tegument" OR "mulatinho tegument" OR "roxinho tegument" OR "jalo tegument" OR "bolinha tegument" OR "rosinha tegument" OR "bico de ouro tegument")

Note: Search date on November 4, 2020.

Source: Research data.

The search process was carried out using the Boolean formula indicated in Scopus in November 2020, using filtering publications whose terms were present in the "title" field. For capturing the most recent dynamics of scientific production on the subject, we established the 2010-2019 timeframe.

To organize and process data, we used the Scival and VOSviewer tools. Scival is an Elsevier solution based on Scopus' publication records and features metrics on productivity, citation impact and collaboration. VOSViewer, by its turn, is a software to create and explore maps based on network data and bibliometric information.

Findings and Discussion

The application of the search equation in the Scopus database resulted in 3,327 publications (91% of which were articles and the remaining chapters of books, books, reviews and conference articles). Of the total publications, 29% (979) have at least one Brazilian affiliation. Regarding the historical trajectory of publication in the world and Brazil (Figure 1), it is clear that 2018 was the year with the largest number of research products on the theme. In general, there is a global tendency for growth within this research topic, which is also true for Brazil but at a rate almost four times lower.

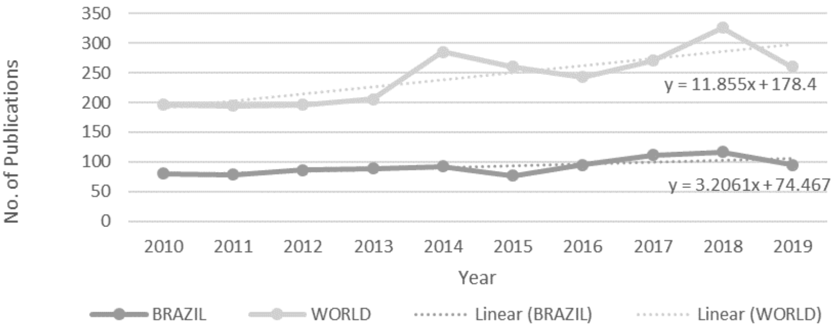

Figure 1. Evolution of publications on common beans over the years (2010-2019)

Source: Research data.

Figure 2 represents the co-authorship network established by the researchers' institutions' home countries. In the figure, the size of the sphere is relative to the number of publications in the country, so that the larger the sphere, the more scientific productions were published by that nation. The connecting lines, by their turn, represent co-authoring relationships. The more intense the connection, measured by the thickness of the line, the greater the number of joint works among researchers from these countries.

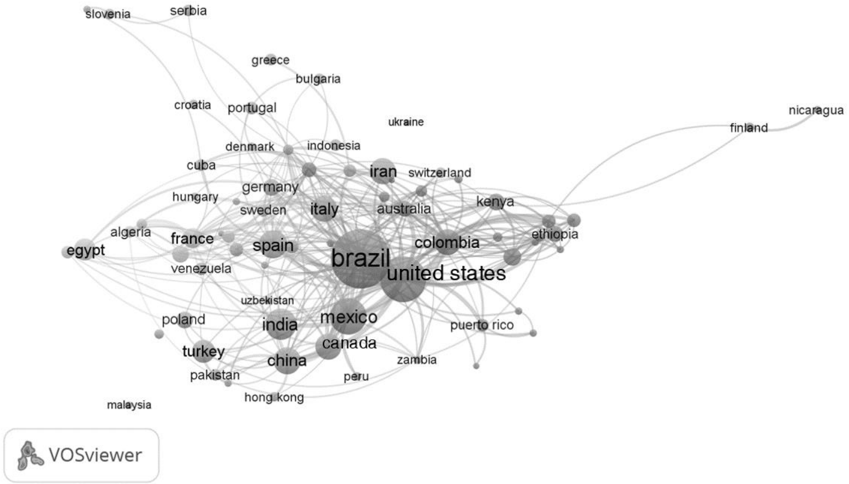

Figure 2. Co-authorship network between countries based on publications on common beans (2010-2019)

Source: Research data.

The network reveals the representativeness, in terms of the number of publications, of Brazil, the United States, Mexico and Colombia and the strong co-authoring relationship between them. Besides, there is the formation of 5 clusters. The first, formed by Brazil, the United States, Mexico, Chile, Colombia and Peru, stands out both for the number of publications and the intensity of the established co-authored relationships. The second (composed of China, India, Turkey, Canada etc.) and third clusters (Italy, Spain, Germany, Indonesia, United Kingdom, Portugal, Japan, etc.) have weaker relationships, but an important number of publications. Egypt, France, Sweden, South Korea, Finland, among others, have moderate indicators of publications and co-authorship.

In Figure 3, the collaboration metrics of the papers are described according to the affiliation to which the authors belong, categorizing them in terms of individual authorship (single), intra-institutional, national collaboration and international collaboration. The data reveal the predominance of national collaborations in publications on common beans, both for the world and Brazil. Such occurrence can be justified by the nature of the research with beans, which can be characterized as applied research and, in general, in line with edapho-climatic conditions and local demands for consumption preference. An example is the case of Brazil where there is a preference for the type of "Carioca" tegument, which is not consumed in other countries.

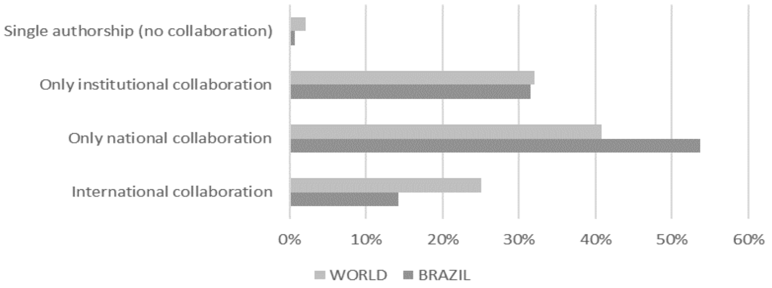

Figure 3. Global collaboration metrics for common beans publications (2010-2019)
Source: Research data.

Regarding the number of countries that cite publications on beans (that is, the countries where the referencing authors' affiliation institutions are located), according to Figure 4, Brazil presents a lower performance than the world. However, within the analyzed period, its publications were referenced, on average, by 80 countries, which indicates considerable global dissemination of Brazil's scientific production on common beans.

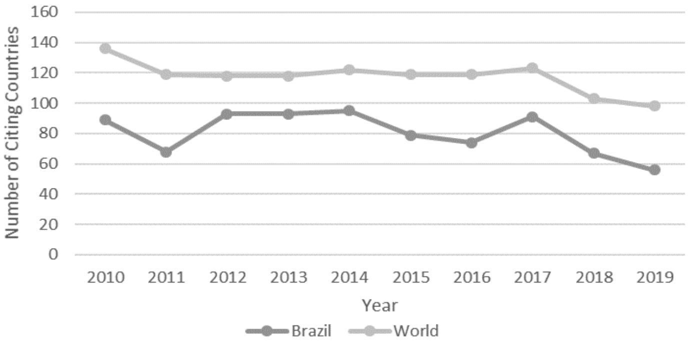

Figure 4. Number of citing countries (2010-2019)
Source: Research data.

Figure 5 presents the collaboration metrics associated with the Field-Weighted Citation Impact (FWCI). This indicator reveals how the number of citations received by a set of publications compares to the average number of citations received by all other similar publications in the data universe. That is, the FWCI reveals how the citations received by publications in Brazil are compared to the world average. An FWCI of 1.00 indicates that Brazilian publications were cited exactly as expected based on the global average of similar publications (with the same period, type and field of knowledge). A FWCI greater than 1.00, in turn, indicates that national publications were cited more than expected based on the global average (ELSEVIER, 2021).

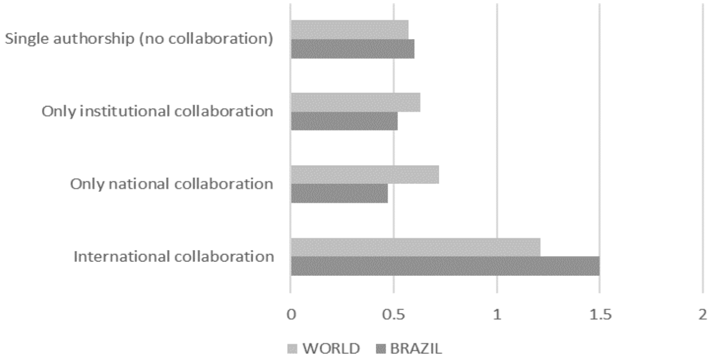

Figure 5. Global collaboration metrics for common bean publications *versus* Field-Weighted Citation Impact (2010-2019)
Source: Research data.

As Figure 5 illustrates, scientific production on common beans is an area of research with relatively low impact, as measured by the FWCI. Only publications resulting from international collaboration reached values greater than 1.00 (which means a positive impact). However, if we analyze the others categories of collaboration (national, institutional and single authorship), the indicator reflects a similar impact behavior in terms of citation of Brazil concerning the world.

Conclusions

The contributions of this paper are twofold. The first refers to the field of Information Science and Science and Technology Management and Planning. By offering inputs on the international projection of research, through indicators of science diffusion, collaboration and impact, we trace a methodological path to assess the internationalization of scientific production by countries and institutions. From this point of view, our paper can aid the improvement of research internationalization policies and the strategic planning of science.

The second contribution is specifically related to studies regarding common beans or studies of similar scope in the context of the Agricultural and Biological Sciences fields. Results show the predominance of national collaborations and the role of countries such as the United States in the mainstream of scientific production on common beans, to which there is a strong national appeal. Moreover, the analysis of the Field-Weighted Citation Impact indicates that Brazilian publications born of international collaboration are more referenced than the global average.

We emphasize that the research topic on common beans can be directly related to the context/environment of ST&I, leading to results of a regional character, which are also influenced by the agricultural technology maturity stage, edaphoclimatic conditions, availability of genetic resources and food security aspects. Thus, it is necessary to take into account the production of social, economic and environmental impacts beyond the scientific dimension. In this sense, we understand that scientific performance indicators based on citations and collaboration networks may underestimate or neglect regional specificities that influence the characteristics of the scientific publication on common beans. Therefore, complementary studies using bibliometric indicators (such as keyword network, institutional link, corresponding author), and other research approaches, can enrich the results presented in this paper.

Abstract

In 2018 Dimensions was introduced as an alternative bibliometric database to the well-established Web of Science (WoS) and Scopus, however all three databases have fundamental differences in coverage and content, resultant from their owners' philosophies. Considering these differences, we use a citation network analysis and assessment of normalised citation impact of "duplicate" publications to explore whether the three databases offer structurally different perspectives of the bibliometric landscape or if they are essentially homogenous substitutes. Our citation network analysis of core and exclusive 2016-2018 publications revealed a large set of core publications indexed in all three databases that are highly self-referential. In comparison, each database selected a set of exclusive publications that appeared to hold similarly low levels of relevance to the core set and to one another, with slightly more internal communication between exclusive publications in Scopus and Dimensions than WoS. Our comparison of normalised citations for 69,044 publications in all three databases found that German sectors were valuated as more impactful in Scopus and Dimensions compared to WoS, particularly for sectors with an applied focus. We conclude that the databases do present structurally different perspectives, although Scopus and Dimensions vary more from WoS than they do from one another.

Introduction

Just as the introduction of Scopus in 2004 challenged the Web of Science's (WoS) primary position on bibliometric databases, the recent launch of Digital Science's Dimensions may change the bibliometric landscape once more. Like WoS and Scopus, Dimensions has amassed a huge index of scientific documents, however Dimensions has important fundamental differences to its predecessors which may offer a different bibliometric perspective. Further, Digital Science's position as part of the Holtzbrinck Publishing Group, owner of the SpringerNature publishing house, has embedded Dimensions in a content-rich environment that, combined with its relatively open approach, means Dimensions is likely to establish itself in the market as an enduring product. Given the potential uptake of Dimensions for bibliometric studies, it is important we understand how the diverging coverage of Dimensions, WoS, and Scopus might influence the results of bibliometric analyses.

Bibliometric analyses reflect their underlying databases' characteristics in that the databases' coverage fundamentally defines what is included in the analysis and bibliometric evaluation further contextualises the analysed content against the database, again emphasizing its coverage. As such, divergences between databases can have implications for bibliometric assessments. The primary differences between WoS, Scopus, and Dimensions lay in the scope of documents indexed, the content selection processes, the accuracy of internal matching of citing items, and how items are classified to disciplines.

Dimensions indexes content across the full research spectrum, including grants and datasets, beyond the typical content of publications and conference papers prioritized in Scopus and WoS, and as such, it is a much larger database. These differences result from the database owners' varying philosophies: WoS and Scopus use selection panels to curate their content to that of a certain quality – with WoS enacting a higher threshold than Scopus – whereas Digital Science applies no editorial judgement to what is indexed in Dimensions. Within the databases, there are differing levels of accuracy in matching documents that cite one another. Visser, van Eck, and Waltman (2020) found issues with missing reference lists and subsequent incomplete citation links in Dimensions, while missing references, incorrect reference metadata, and incorrect item matching are a problem in WoS and Scopus (van Eck and Waltman, 2017), although less extensively so than in Dimensions. Also, WoS and Scopus classify items to disciplines based on the subject orientation of the publishing journal, while Dimensions classifies individual items based on their content. These differences all have important implications for the set of documents against which a publication is normalized and compared in the context of each database.

As Dimensions was only recently launched, so far only a small number of studies have examined the differences between it, WoS, and Scopus that result from these differing practices and philosophies. Orduña-Malea & Delgado-López-Cózar (2018) compared samples of Library and Information Science documents, authors, and journals in Scopus and Dimensions and found that coverage in Dimensions exceeded that of Scopus, but Dimensions recorded fewer citations. Thelwall (2018) tested Dimensions' retrieval of nearly 90,000 food science articles with DOIs in Scopus, alongside a random sample of 10,000 articles from 2012. Over 90% of the food science articles were captured in Dimensions, and the citation counts in both databases were highly correlated (0.9-1.0), leading Thelwall to conclude that Scopus and Dimensions were interchangeable on coverage and citations. Harzing (2019) compared Dimensions, Scopus, and WoS on retrieval of her own publication corpus and six key Business and Economics journals. She found Dimensions and Scopus were approximately equal in both their coverage and citation counts, and both produced higher measures than in WoS.

Visser et al. (2020) compared WoS and Dimensions to Scopus, identifying Dimensions as the largest database, although there was substantial overlap in content between Scopus and both WoS (overlap of 17.7 million documents) and Dimensions (21.3 million). However, the share of Dimensions' content not in Scopus was nearly double (40.9%, 14.8 million) that of WoS (22.7%, 5.2 million). Martín-Martín, et al. (2020) also noted that, while Scopus and Dimensions offered twice as much exclusive content as WoS, the databases contained a high degree of overlapping content; 75-78% of their sample overlapped in pair-wise comparisons and 66% was present in all three databases. The largest content convergence occurred in the hard sciences, where 73-78% was in all three databases, with more divergent content in the medical sciences and engineering (65% in all three databases), social sciences (54%), and humanities (41%).

Coverage differences between WoS and Scopus have already been shown to influence the outcome of bibliometric analyses (Stahlschmidt & Stephen, 2019; Huang et al., 2020), however seemingly no study has yet examined such differences between WoS, Scopus, and Dimensions. As such, here we use a quantitative comparison to determine the extent to which bibliometric indicators are influenced by the characteristics of the three databases. We do this by first analysing the databases' citation networks. Previous studies show that the divergent coverage between the databases results in different subsets of publications indexed in only one, two or all three databases (Visser et al., 2020; Martín-Martín, et al., 2020). The power set of these subsets consists of the set of publications and citation links between them that are contained in all three databases, partial intersections of publications and related citations in two databases, and the residual sets of exclusive publications and related citations indexed in only one database. We investigate the role of these subsets for themselves and other subsets. With respect to citation analyses, role is understood as relevance and impact, which can be measured by reducing citations to their Mertonian ideal ("give credit, where credit is due"), by citations between and within these subsets. Citations between subsets represent how information flows and how the publications indexed exclusively in a database are embedded in this information flow. The role of these publications in the overarching citation network, which is unknown in its population, can be identified and the added value of each database as a reflection of previously unobserved scientific communication can be approximated.

Using the context provided by the citation network, we then assess the differences in normalized citation impact of duplicate publications between the three databases. In bibliometrics, priority is given to normalised indicators that evaluate a publication in relation to its environment. Due to the different coverage of the databases, environment-specific differences arise in the evaluation of the same publication. We therefore analyse the same publications in the different databases and determine how each publication's valuation changes given the environment of the databases against which it is normalised. This varying evaluation of the same content can be used to illustrate the structural differences in the databases, which is informative for interpreting bibliometric analyses (Stahlschmidt & Stephen, 2019). Through these two analyses, we examine whether the databases offer a slightly varying but essentially homogeneous representation of the general citation network and are therefore substitutes, or whether the databases show structurally different perspectives.

Methods

We sourced the data for our analyses from the German Competence Centre of Bibliometrics' (KB) in-house versions of WoS and Scopus databases. For WoS, this version includes the Science Citation Index Expanded, Social Science Citation Index, and Arts and Humanities Citation Index. Scopus and Dimensions databases are not organised into indices and as such, we used the relevant documents from the entire databases. Dimensions data are a snapshot of the database as of September 2019 and WoS and Scopus data are snapshots as of April 2019.

Citation network analysis

We analysed articles and reviews published in 2016-2018 and citations in a three year window between 2016 and 2018. We restricted our analysis to articles and reviews, however a known issue in Dimensions is that all documents in journals are assigned document type “article” (Visser et al., 2020). For instance, Dimensions holds more documents of type “article” in 2016-2018 than the intersection of core publications jointly indexed by WOS, Scopus and Dimensions does. However, most of these documents do not include any references. In comparison, only 1% of WOS and 4% of Scopus articles and reviews in 2016-2018 had no source references, and no WoS and only 9 Scopus articles had no references at all. To address this issue, we selected articles and reviews indexed in WoS and Scopus, and articles in Dimensions with at least one reference. Thus for Dimensions we separated the substantial scientific contributions that build on and highlight former contributions via references from other journal content to improve the validity of the database comparison. Still this requirement of at least one reference for Dimensions articles constitutes a lower bound rather than a solution to the insufficient document type classification in Dimensions, but WOS and Scopus also disagree sometimes upon the document type.

We joined the three databases via an exact string matching procedure based on DOI identifiers. DOIs uniquely identify publications and are therefore suitable for matching purposes. DOIs recorded in bibliometric databases have partially been observed to include errors (Akbaritabar & Stahlschmidt, 2019), e.g. non-unique DOIs or misread string characters in optical character recognition processes, however these issues might arise randomly and might not adversely affect any structural differences between databases. Instead DOI matching has been observed to produce highly valid matching results (Fraser & Hobert, 2019) and less than 7%, 10%, respectively 1% of articles and reviews in 2016-2018 indexed in WoS, Scopus or Dimensions were missing a DOI.

The citation network analysis is implemented by the indicators (1) out/in-degree, as a network analytical perspective on the micro level of publications, which is translated to the level of the subsets previously described by representing the respective distributions, and (2), as far as possible the indicator internal coverage, as an aggregated value on the database level. With this approach, in addition to the expected increased coverage in Dimensions due to its larger size, i.e. the pure "more" of communication, communicative characteristics of the databases can also be partially quantified, which provides useful context for the normalised citation analysis.

Normalised citation analysis

We selected German sectors as the level at which we would assess the effect of database choice on normalised citation impact. We first identified all articles published in 2016 affiliated with German institutions that were indexed in all three databases, which we refer to as "duplicate" publications. We retrieved the WoS-Scopus duplicates, which were identified by comparing hash values on a subset of metadata strings between the two databases. We then extracted all German articles published in 2016 from Dimensions and matched their DOIs to the DOIs from Scopus of the WoS-Scopus duplicates to identify the documents in all three databases. We then validated the DOI-based matches by calculating the Jaro-Winkler distance on the title strings between the three versions using *stringdist* in R (van der Loo, 2014).

To assess the effect of the database's environment on the normalised citations, we calculated for every German duplicate the number of citations the article received between 2016 and 2018 from each database (observed citations), and the average number of citations received in these three years by all articles published in 2016 that were allocated to the same discipline (expected citations). We then calculated the difference Δ in normalised citations between databases as:

$$\Delta\, norm.cit. = \frac{obtained\ citations_i^{(s1)}}{expected\ citations_i^{(s1)}} - \frac{obtained\ citations_i^{(s2)}}{expected\ citations_i^{(s2)}}$$

where *i* is each German duplicate, and *s* is the source database. We normalised each duplicate's citations against documents of the same type and discipline as they were defined in each database. This necessitated that we exclude unclassified documents. As we wanted to examine the effect of using each data source in its "natural" state as much as possible, we did not control for the differences between databases in the disciplines to which publications are assigned. Further, as each database allows documents to be assigned to multiple disciplines, there were often multiple contrasts made for a single duplicate between databases for each combination of disciplines. To account for this, we calculated the difference in normalised citations for each combination of disciplines for each duplicate, then averaged the differences to obtain one summary observation of the differences in normalised citations of the duplicate per database combination. We then aggregated the duplicates to sectors on a whole-counting basis.

In normalising the observed citations in each database against the expected citations in the same database, we achieved a database-specific valuation of each article. The content of the database is influential here as the inclusion or exclusion of particular articles in the corpus may influence both the citations received by the article and the average citations received by all articles in the discipline, affecting the ratio between the two observations. In examining the difference in normalised citation impact between databases, we can examine how the same publication can be valuated differently between databases due to the database's environment.

Results

Citation network analysis

We show in Figure 1 the number of articles and reviews published in 2016-2018 in each database, and the intersection and exclusive content in each combination of databases as identified through the matching process. Dimensions indexed the largest number of publications (>6.3 million), followed closely by Scopus (5.9 million), while WoS indexed substantially fewer documents (4.8 million). The difference between Dimensions and Scopus may actually be smaller than reported here as the aforementioned imperfect lower bound that Dimensions articles contained at least one reference might still allow other non-article documents to be included. The majority of publications (4.3 million) were indexed in all three databases and this set of core publications is by far the largest intersection (67%, 71%, 88% of the entire Dimensions, Scopus, and WoS corpuses, respectively). Dimensions indexed 1.3 million exclusive publications, or about 20% of its entire corpus, and Scopus exclusively indexed 0.6 million publications or ~10% of its corpus, while WoS' exclusive publications constituted less than 1% of its corpus. Hence WoS differentiated itself from other databases not by exclusively indexed publications, but seemingly by foregoing the indexation of more publications. Notably, contrary to its inclusive indexing policy, Dimensions apparently does not index some 1.05 million documents indexed in either or both WoS and Scopus.

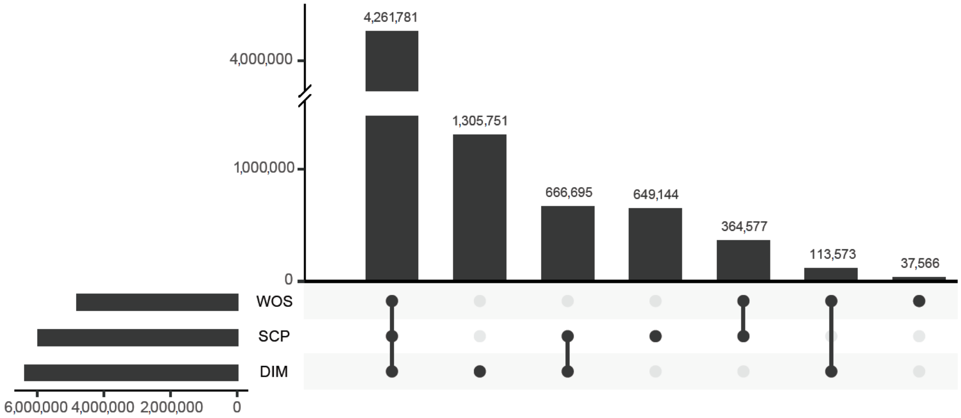

Figure 1. Number of publications with a DOI in 2016-2018 (left panel), magnitude of intersections (upper panel) and relation between total databases and intersections (lower panel).

Given the sizable differences between the databases, we analysed how the internal coverage of core publications varied due to the different indexation practices. By observing if a reference in an indexed publication is or is not itself indexed in the same database we compared the relevance attributed to the work by the author with the relevance attributed by the database provider. A pronounced difference in assumed relevance, manifesting as low coverage, indicates that a database only partially captures the communication flow perceived relevant by authors and hence a bibliometric analysis might be biased on any such out-of-sync dataset.

As documents in the core set of jointly indexed publications have unanimously been deemed relevant by the three database providers and hence allow for a comparison, we used their reference lists to observe potential differences in database-specific coverage. References to non-core publications in particular differentiate the databases in their coverage. Figure 2 shows the database-specific percentage of indexed, or so-called source references, via a density plot across the 4.2 million core publications. The upper panel shows the internal coverage of all 2016-2018 publications, while the lower panel depicts the share of indexed references published in 2016.

The overall internal coverage shows large variability with values from zero to one hundred percent. All three distributions are skewed to the left indicating that although a large share of references in core publications were indexed, some indexed core publications had few of their references indexed in the respective database. In particular, the social sciences and humanities, with their reduced focus on journal articles as the primary communication device, have been observed to lack internal coverage (Stephen, Stahlschmidt & Hinze, 2020). Apart from this discipline-specific effect affecting all databases, we observed notable differences in the overall internal coverage between databases. Whereas Dimensions and WoS demonstrated relatively high internal coverage, with over 90% of references from many core publications also indexed, Scopus had lower agreement with the authors' relevance attribution.

The lower panel shows the three-year citation window perspective as we restricted the analysis to references from 2016-2018 publications to 2016 publications. We observed no pronounced visual difference between the databases here, however on average only approximately 5% of all references are considered and most other signals of relevance attribution via references are discarded. As the scale of the x axis might conceal actual differences between the databases, in the following analyses we focused especially on this lower end of 2016 publications. In doing so we adopted a maximum contrast approach comparing core publications indexed in all three databases with exclusive publications indexed solely in one of the three databases.

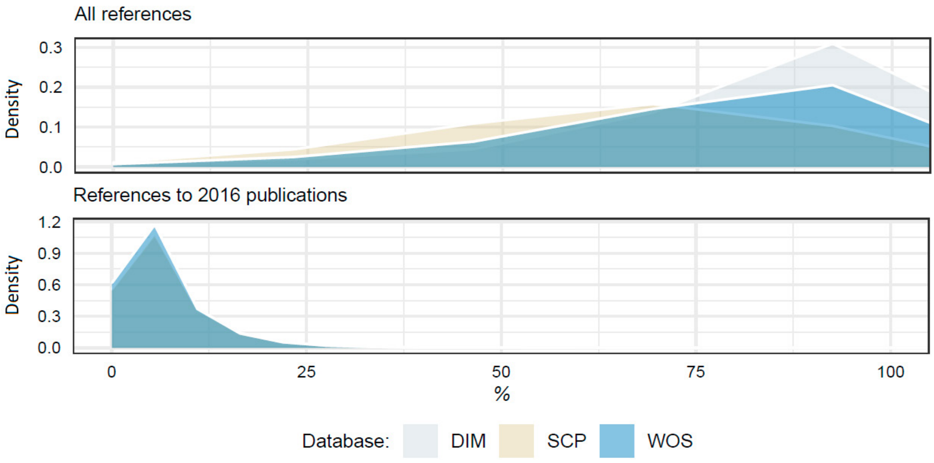

Figure 2. Internal coverage of references in jointly indexed publications published 2016-2018.

We commenced the analysis of references to 2016 publications by examining the internal communication patterns of core publications. Figure 3 shows the share of 2016-2018 core publications that cited a core 2016 publication. As to be expected by the overall low share of references to 2016 publications depicted in the lower panel of Figure 2, the share of internal communication is rather small and the majority of 2016-2018 publications did not reference a 2016 publication. This observation holds for all databases and hence they can only be compared in the following analyses on the residual share of publications that did reference a 2016 publication. We observed that core publications possessed a high degree of internal communication with a sizeable number of core publications referencing other core publications. Hence these publications define a highly self-referential, interlinked network component. This component was identified and indexed by all three databases and constituted between 67% (Dimensions) and 88% (WoS) of the databases.

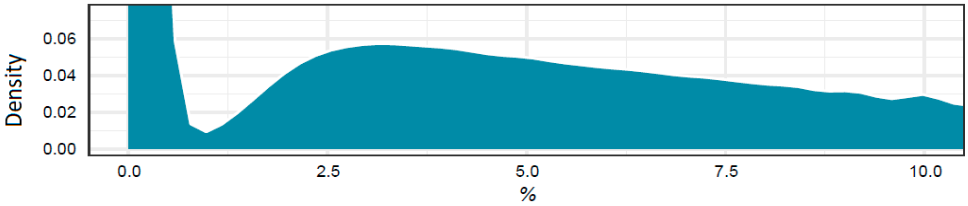

Figure 3. The share of internal references from core 2016-2018 publications to core 2016 publications.

We then examined how core and exclusive publications are interlinked. In Figure 4 we show the share of references in exclusive 2016-2018 publications in each database to core 2016 publications. As Digital Science currently only provides source references for publications indexed in Dimensions, the total number of references in Dimensions-exclusive publications is unknown and for comparability we report instead the share of 2016 publications among all source references of 2016-2018 publications. Comparing the three databases, especially publications exclusive to WoS exhibited a strong dependence on core publications, resulting in a denser overall database than Scopus and Dimensions. But exclusive publications in these two larger databases also rely to a large and similar extent on core publications. Considering the different number of exclusive publications (Figure 1), WoS seemingly foregoes indexing more publications, but offsets this with a more dense citation graph.

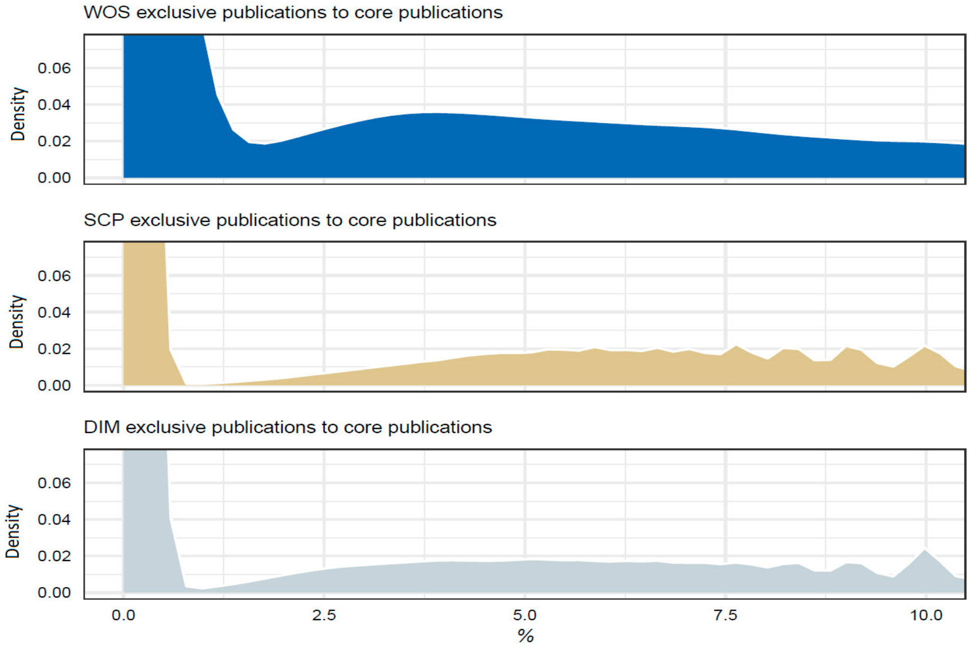

Figure 4. The share of references in exclusive 2016-2018 publications to core 2016 publications.

To complete the interlinkage between core and exclusive publications, we depict in Figure 5 the share of references in core 2016-2018 publications citing exclusive 2016 publications. As we could observe the total number of references of these core publications via WoS and Scopus, we normalised by the total reference count and not the source reference count used before when the total number of references in the Dimensions-exclusive publications was unknown.

A notable share of core references linked out to exclusive publications across all databases. However, considering the actual percentage is often less than 2.5%, it appears that the exclusive publications are of low relevance to core publications. In comparison, the range for internal references among core publications in Figure 3 and the share of core publications referenced in exclusive publications in Figure 4 is much higher, often above 5%. Hence, the content of core publications seemed to carry more relevance than the content of exclusive publications. Exclusive publications might then be understood as an outer, consecutive circle building upon the content provided in core publications. The lower density in WoS compared to Scopus and Dimensions may reflect that its 38,000 exclusive publications may not appear in the 4.2 million core publications as often as Dimensions' 1.3 million exclusive publications.

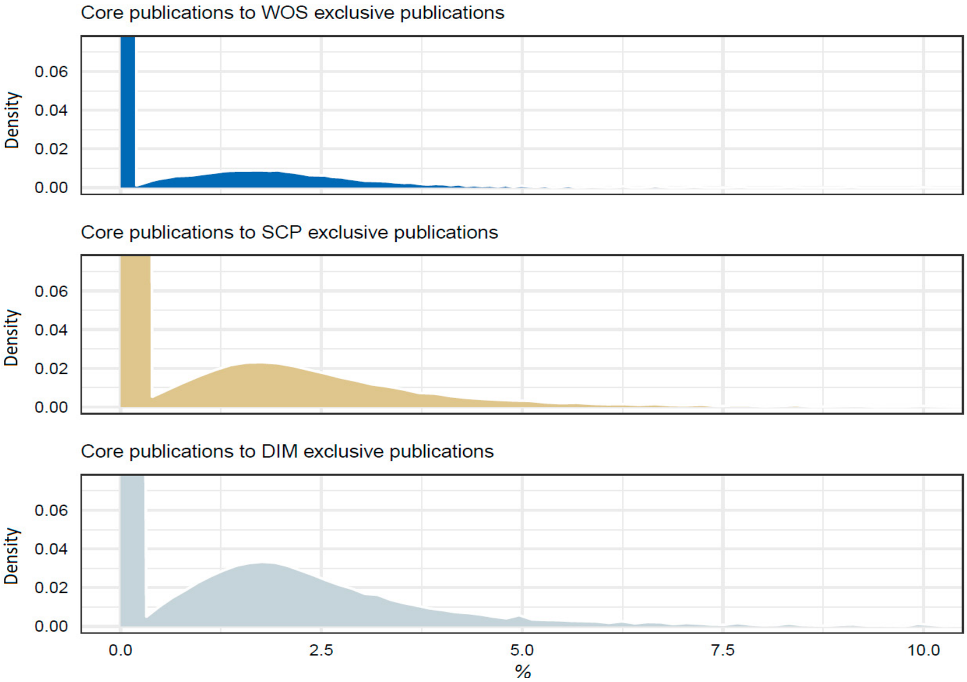

Figure 5. The share of references in core 2016-2018 publications to exclusive 2016 publications.

Normalised citation analysis

For the citation analysis, we matched 2016 publications affiliated with a German institution across databases. The KB WoS-Scopus matching process identified 107,800 of the 113,227 WoS publications (95.2%) and 127,542 Scopus publications (84.5%) as duplicates. We identified 118,688 German publications in Dimensions, however this is an under-estimate as up to 43% of Dimensions records were missing information about the publishing country in the applied Dimensions 2019 snapshot. Via DOI matching we identified 84,332 publications that were in all 3 databases, which was 74.5% of the total 2016 German publications in WoS, 71.1% in Dimensions, and 66.1% in Scopus. After removing review documents, and records missing discipline or sector data, we had a final sample size of 69,044 duplicates. We calculated the Jaro-Winkler distance on the combinations of the duplicates' titles to validate the DOI matching. The average distance was 0.02 and we manually confirmed cases above 0.25, concluding that the DOI-based matching was accurate.

As a preliminary examination of the differences in citations between the databases, we present in Figure 6 pair-wise comparisons of the citations observed for each duplicate article between databases. The diagonal lines represent a perfection correlation. Positive correlations were evident between each database, suggesting all three databases present a comparable picture of the bibliometric landscape, however there appeared to be a slight trend toward higher citations in Scopus and Dimensions compared to WoS. The greatest variation was between WoS and Scopus (mean difference = 1.2), with slightly less between Dimensions and WoS (1.0), and least between Dimensions and Scopus (0.2). These variations from a linear trend due to the databases' exclusive content generate changes in the ratio of observed to expected citations, which translates to variations in publications' normalised citation impact between databases.

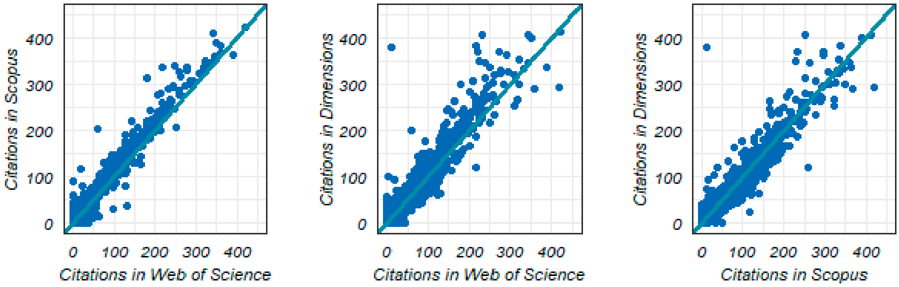

Figure 6. Pair-wise comparisons of duplicate articles' observed citations in each database

We see in Figure 7 the macro effect of the databases' structural differences via the differences in normalised citation impact of the six German sectors. Data are presented as the density in the distribution of differences in each sector's 2016 duplicate publications, and divided into quintiles. The sectors are the Leibniz Association (WGL), the Max Planck Society (MPG), the Helmholtz Association (HGF), the Fraunhofer Society (FhG), universities and colleges of applied science constitute the higher education institutions (HEI), and the business sector (Economy). Each sector has a particular research profile. The universities undertake both teaching and research in all disciplines, while the colleges focus on technical application in specific areas. The HGF has a health, energy, earth and physical sciences orientation focusing on research infrastructure. The WGL conducts basic and applied research in engineering and social, health, and natural sciences, the MPG conducts primarily basic research, and the FhG focuses on applied research.

We see in the bottom panel of Figure 7 that the majority of publications in each sector had higher normalised impact valuations in Scopus compared to WoS. The FhG and Economy sectors benefitted most strongly from Scopus's exclusive content, with around 80% of these sectors' publications improving in impact, compared to around 70% in the other sectors.

Dimensions' content and characteristics also improved the impact of all sectors compared to WoS, as shown in the middle panel, although the effect is not as strong as between WoS and Scopus. The increased impact is nearly uniform across sectors, with the 40% of publications constituting the central and middle-high quintiles in each sector increasing in impact by up to 25%. The MPG lost slightly more impact in Dimensions than the other sectors, particularly when compared to the FhG. Finally, the differences in impact between Scopus and Dimensions in the top panel are more normally distributed, however there is a slight skew toward improved impact in Dimensions, particularly for the FhG where nearly 60% of publications improved.

Overall then, the larger content and specific characteristics of Scopus and Dimensions appears to produce higher normalised citation scores than in WoS, particularly for the sectors with a focus on applied sciences, such as the FhG and Economy sectors. However, the differences in content between Dimensions and Scopus produced less notable differences in normalised impact at this macro level.

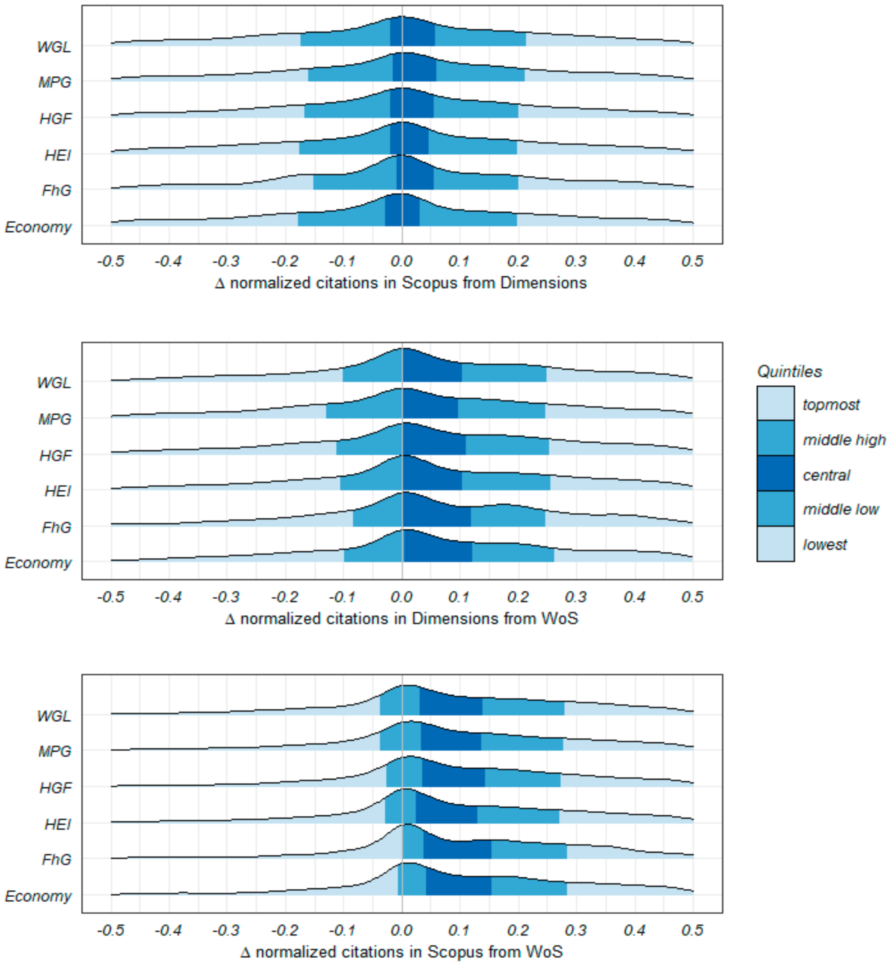

Figure 7. Distribution and quintile of differences in duplicates' normalized citations between databases by German sector.

Discussion

WoS, Scopus, and Dimensions databases differ in particular fundamental characteristics, such as the number and type of documents indexed, the completeness of citation links between documents, the inclusion criteria applied to content, and how items are classified to disciplines. Previous studies have found these differences resulted in variation in database size and coverage, although there was substantial overlap in the databases' content, and that the databases produced similar citation counts (Martín-Martín et al., 2020; Visser et al., 2020; Orduña-Malea & Delgado-López-Cózar, 2018; Thelwall, 2018; Harzing, 2019). However, no study had yet compared the three databases on normalised bibliometric indicators. In this study, we analysed the citation networks and differences in normalised citation impact between the databases to investigate whether the exclusive content of the databases meant they offered structurally different perspectives of the bibliometric landscape.

In our citation network analysis, we identified core publications jointly indexed in all three databases and exclusive publications solely indexed in each of the three databases. In a maximum contrast approach we compared the communication flows via references across these sets to observe the analytical value each database revealed by its particular indexation practices. Not unexpectedly, the indexation of more publications was accompanied by an offset in the density of communication flows in the resulting citation graph, particularly in Dimensions. In all databases, the group of core publications might be characterised by its relatively high degree of self-reference, where former core publications constitute the base or frame for new core publications. Exclusive publications appeared to mark an outer ring drawing substantially upon core publications, hence knowledge is transferred from the core to the outer circle, and this transfer was especially visible in Scopus and Dimensions. However, exclusive publications in all databases exhibited low relevance to the core, denoted by low citation of exclusive publications by the core. The emerging model of knowledge transfer within databases appears to be that of a star, wherein an interconnected core produces knowledge in a self-referential mode, which is then disseminated to the outer circle. Notably, this model persisted across databases because the particular choice of exclusive publications by a database resulted in no visual difference in the citation of these publications by the core, signaling that no database apparently managed to identify particularly relevant publications for the core publications. Instead, all three databases found different exclusive publications of the same low relevance to the core. As a seeming paradox, exclusive publications in this sense do not distinguish databases from one another, but constitute different samples with the same characteristics. As a consequence, core publications might not be enhanced by any of the three perspectives offered by the databases.

The combined effect of larger exclusive content, similar reliance on core publications, but more internal communication between exclusive content in Scopus and Dimensions than WoS (unreported) appears to increase the normalised citation impact of all German sectors in Scopus and Dimensions compared to WoS, in particular for those sectors with an applied focus. The applied science sectors, such as the Economy sector, likely especially benefit due to the better coverage of the social sciences in Scopus than WoS (Stephen et al., 2020). Scopus and Dimensions' similar levels of communication between and within the core and their choice of exclusive publications means there was little difference in impact between the databases.

We caution that, given the relatively small difference between Scopus and Dimensions in absolute article counts, the imperfect document type resolution in Dimensions, the likelihood that the article document type in Dimensions has not been perfectly singled out by our reference requirement but is actually over-reported, the additional 6 months of content in the Dimensions data, and the reliance on only a small portion of references as the relevance attribution, a sizeable amount of incertitude accompanies the current study.

In summary, we conclude that the databases' structural differences mean they provide different bibliometric perspectives, and that Scopus and Dimensions vary more from WoS than they do from one another. WoS with its restrictive indexation policy and Scopus with its selective indexation policy might constitute two separate self-imposed stances with a distinct message: WoS largely represents the well-interconnected core citation network component, while Scopus allows us to observe some transfer from the core to the periphery, resulting in increased normalised impact for most core publications. Dimensions with its laissez-faire indexation policy conveys more coverage but a less decisive, although similar, message to Scopus.

Acknowledgments

Data in this study were obtained from the German Competence Centre for Bibliometrics, funded by the Federal Ministry for Education and Research (BMBF) with grant number 01PQ17001.

Abstract

The last few decades have witnessed the rapid growth of scientific publications and scholar data, and citation context is one of the most frequently used data in scientometrics and natural language processing. However, current citation context datasets have limitations in several regards. Therefore, we propose a large citation context dataset based on the open accessed PubMed Central papers. In total, we generated about 97.5 million citing-cited document pairs, 34.7 million paragraphs of citation context based on 2,658,541 PubMed Central papers of biomedical and life sciences. The dataset can not only be applied for citation analysis, but also can be used for biomedical text mining and other natural language processing tasks.

Introduction

Citation context is the text around the citation marker in the body text of a citing document. Even though the citation context is embedded in the citing document, it is also a short description about the citing document from the citing authors' point of view. Some previous studies treated citation contexts as an alternative representation of the cited document (Bradshaw, 2002, 2003; Ritchie, 2008). The applications of citation context include summarization, synonym identification and disambiguation, entity recognition and relation extraction, curation and information retrieval, and citation context can also be a source of unannotated comparable corpora (Nakov, Schwartz, & Hearst, 2004). Though early studies of citation context were conducted in the late 1970s (Small, 1978) and early 1980s (O'Connor, 1982, 1983), there are not many studies in this area until the late 1990s mainly due to availability of digital scientific documents. After the upcoming of the Internet era, more and more machine-readable scientific literatures are available online (Lawrence, Giles, & Bollacker, 1999), and studies on citation context have gained much interest among the scientific community in the last two decades. A few reviews about the studies of citation context can be found in the last few years (Bornmann & Daniel, 2008; Ding et al., 2014; Jha, Jbara, Qazvinian, & Radev, 2017; Zhang, Ding, & Milojević, 2013).

However, there are only a few publicly available large citation context datasets for research community, and existing datasets have limitations in different regards. A recent study (Saier & Färber, 2020) compared several scholarly dataset, which include CiteSeerX (Huang, Wu, Liang, Mitra, & Giles, 2015), Scholarly Dataset 2 (Sugiyama & Kan, 2015), arXiv CS (Färber, Thiemann, & Jatowt, 2018), ACL-ARC (Bird et al., 2008), ACL-AAN (Radev, Muthukrishnan, Qazvinian, & Abu-Jbara, 2013), and PubMed Central Open Access Subset. These datasets might contain noisy, inaccurate information, and some datasets are in PDF format, which is hard to process for computers even with the modern artificial intelligence technology.

In this paper, we aim to give a description of a large citation context dataset (Sun, 2020), specifically, the citation context dataset extracted from PubMed Central articles. PubMed Central (PMC) is the online repository for free full text of biomedical and life sciences published journal papers (Roberts, 2002). It is operated by the National Center for Biotechnology Information, a division of the National Library of Medicine at the U.S. National Institutes of Health. Until March of 2021, there are about 6.9 million articles in the PMC archive. However, even though the full text of the PMC papers is freely accessible online, some of the articles cannot be downloaded in bulk due to the operator's policy, and only a few collections of the PMC files are permitted for bulk retrieval. Theses collections are provided for the task of text mining for researchers, which are Open Access Subset, Author Manuscript Collection, and Historical OCR Collection. Among the three collections, the Open Access Subset (OA Subset) we used in this paper is the largest collection available for text mining via PMC and the subset has been used in several recent studies (Boyack, van Eck, Colavizza, & Waltman, 2018; He & Chen, 2018; Small, 2018; Small, Tseng, & Patek, 2017). Articles in this subset are still protected by copyright laws, however, they are made available for bulk download under license such as Creative Commons, which give users the liberty for redistribution and reuse about the data. The files of the articles in the collection are in three formats (PDF, XML, TXT), and we chose to process the XML files, because XML format is designed to be both human- and machine-readable and has tags to locate specific elements in the file, thus simplifying our later processing of the full text of the PMC paper.

Even though, the full text of PubMed Central articles can be a great resource for citation-based tasks with clean, heterogeneous annotation of citations, however, as the study (Gipp, Meuschke, & Lipinski, 2015) pointed out, the collection of full texts don't provide relationship between documents, and the mixed usage of identifiers is not convenient for users to gain accurate citing-cited relationships between documents. On the one hand, we might utilize the XML annotations of document identifiers to reveal the explicit citing-cited relationships between documents. On the other hand, the full text mixed with XML tags itself provides noise for information tasks such as natural language processing. Thus, we need to eliminate the XML tags, leaving clean and pure text of citation context to be processed for future users.

Methods

As our data is based on the PMC text mining open dataset, we first downloaded the dataset in late December of 2019 using the official FTP service. The downloaded PMC XML files are in eight compressed files with the file extension "tar.gz", in which four of compressed files can be used commercially and the other four compressed files can only be used non-commercially. First, we uncompressed all 8 compressed files and saved the PMC files in one directory. There are 2,658,541 PMC papers in total for this dataset. Each PMC file is in the XML format with the file extension "nxml".

The source code of the program to generate the citation context dataset from the original PMC XML files can be found on github: < https://github.com/ku69vOZ8/PubMed-Central-Citation-Context>. To build the PMC citation context database, we need to process each of the PMC paper and get the necessary information within the PMC paper's XML file, including PubMed ID (or PMID, if available), local path, cited documents, citation context of each of the cited documents. The program to process the PMC files includes the following steps (see Figure 1):

(1) extract the PMC paper's metadata.
(2) extract the citation relationships.
(3) extract the citation contexts.

As it is shown in Figure 1, we can obtain the PMC paper's metadata from the full text for step 1, citation relationship from reference list for step 2, and citation contexts based on both full text and reference list for step 3. We use 4 entities in our program and database, which are Literature, Cite, CitationContext and CitationContextText.

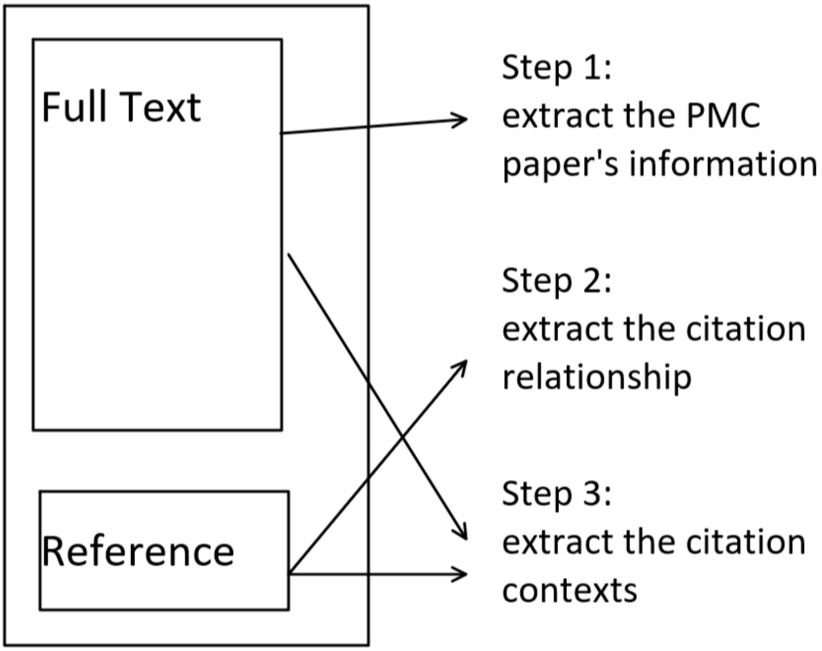

Figure 1. The steps to generate the dataset.

Literature represents a research paper or a scientific document. The PMC paper and its cited documents can all be described using the entity "Literature". To simplify our study, besides the ID of the entity, we chose to save only 4 attributes in our Literature entity. The 4 attributes are: pmc_uid, pmid, local_path (path of the PMC file in the local disk), and fully_updated (a Boolean value, true if a PMC paper is processed). The pmc_uid is used to store the PMC ID or the paper ID for PMC articles, whereas pmid is applied for saving the PubMed ID or the paper ID in the PubMed database. The local_path is the attribute to keep the path of the PMC paper file in the local disk drive, and the attribute fully_updated is a Boolean value used to tag whether a PMC paper is processed or not. Note the fact that only PMC papers have the pmc_uid, local_path and fully_updated, and other documents do not. Also, the documents in the dataset are either PMC citing papers or PMC citing papers' cited documents.

Cite is the entity for storing the relations that one document cites another document. For Cite, there are 4 attributes: citer (the citing document), cited (the cited document), local_reference_id (reference ID for the cited document in the PMC file), and reference_sequence (the sequence for the cited document). Note the fact that both citer and cited are Literature objects, and all the citers are PMC papers in our dataset. But the cited documents include both PubMed documents and non-PubMed documents. The relationship is revealed in Figure 2.

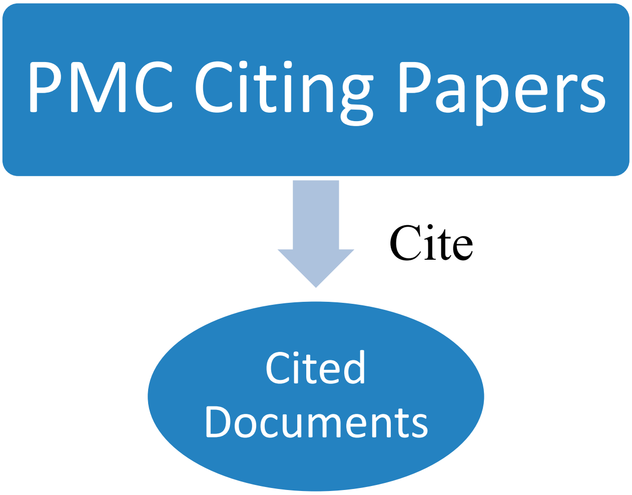

Figure 2. The PMC papers cite cited documents.

CitationContextText is used to save the text of the citation context. As one cited document can be cited multiple times from one citing document and one citation context might have multiple citation markers, we use the CitationContext to link the Cite and CitationContextText. In CitationContext, there are one Cite attribute cite and one CitationContextText attribute citation_context_text. For a citing-cited pair, there can be multiple CitationContext with the same Cite object but different CitationContextText objects. Besides, there is also an attribute called "position" in CitationContext, and we use it to record the exact index of the citation marker in the text of the citation context. All these 4 entities (Literature, Cite, CitationContext and CitationContextText), are represented by class in the object-oriented programming language. Since cite-paragraph is one special case of citation context, we also set two subclasses, CiteParagraph as the subclass for CitationContext and CiteParagraphText as the subclass for CitationContextText.

Some might wonder why we did not use text as an attribute of CitationContext and chose to create a separate CitationContextText to save the text of CitationContext. This is because one paragraph might have multiple CitationContext, and different CitationContext might have the same text of a cite-paragraph. If we use the attribute "text" in CitationContext to save the text, we might have a lot of duplicate data in the database. By using a separate CitationContextText, the same text can be shared by different CitationContext, thus minimizing the size of the database.

PMC paper's metadata

The program first iterates every PMC file in the uncompressed working directory. For each PMC paper, we created a corresponding Literature record in the database. We add the three features extracted from the PMC XML file to the literature object in our database, namely the pmc_uid, pmid and the local_path. The name for each PMC file is in the format of "PMC[PMC ID].nxml" (e.g. PMC100320.nxml). PMC ID (or pmc_uid) is the unique identifier for each PMC paper, and we simply extract the PMC ID from the file name. We search the database if there are any Literature objects with the PMC ID, if there is and fully_updated attribute of the Literature object is also true, then the program will continue to process the next PMC file. If there is none, the PMC file will be processed. Similarly, the local path of the file in our disk can also be extracted for each PMC file in this step.

As the files of PMC papers are in the format of XML (Extensible Markup Language), we can locate the specific attributes with the corresponding XML tag in the PMC file. For a PMC paper, it may have three unique identifiers, namely the PMC ID (or pmc_uid), the PubMed ID (or pmid), and the Digital Object Identifier (DOI). With the help of the XML tag, we can find the pmid for the PMC paper if it is available in the full text. In the dataset, we only focus the pmid and the pmc_uid. We search the database to find out if there is a Literature object with the pmid. If there is, that means it has already been added to the database. This happens when the paper is the cited document for a citing PMC paper that has been processed already. Instead of creating a new object, we update the Literature object with the information in the PMC file; if there is none in the database, we will create a new Literature object and add the information extracted from the PMC file to the newly created object.

Citation relationships

After the elements have been added to the Literature object, our program then extracts the cited documents for the PMC paper, revealing its citation relationships. The cited documents reside in the reference list of the PMC paper. We locate each cited document in reference list and iterate each of the cited documents to obtain the information. Each cited document has a sequence number and a reference ID (such as B12). The sequence number range from 1 to n, where n equals to the number of the cited documents for the paper. As the reference ID not only shows in the reference list, but also appears in the full text where the citation marker is, we can use it to link the cited document and the corresponding citation marker for later citation context extraction. Besides the sequence number and the reference ID, some of the cited documents also have pmid, which also means they are PubMed documents. For these PubMed cited documents, again, we search the database to find if there is a Literature object with the pmid. If there is, we retrieve the Literature object with the pmid as the cited document; if not, we create a new Literature object with the pmid. After the information of the cited document has been gathered, we create a new cite object, where the attribute citer is the PMC paper, and the attribute cited is the cited document. Besides, one Cite object also contains the sequence number and the reference id of the cited document.

Citation context

When the cited documents are added to the database, the next step is to obtain the citation context using the full text of the PMC paper. As we noted before, the reference ID appears both in the cited document in the reference list, and in the full text where the citation marker resides. This feature provides convenient way to help us locate where the citation marker is or where the citation context starts. For each citation marker in the full text, we replace the tag which contains the reference ID (and also the text between the tag) with a new citation marker "~~[sequence number]~~" (e.g. ~~B12~~), where the sequence number equals to the sequence number of the cited document in the reference list. After that, we extract the citation context corresponding to each of the cited document and save the index of the citation marker in the paragraph.

Even though the cited text span is around the citation marker, however, to determine the right window size of the citation context can be a tricky problem (Jha et al., 2017), and the cited text span might vary for different tasks. To simplify the task, some studies use the sentence where the citation marker is in, or the citance (Nakov et al., 2004), as the cited text span (Bornmann, Haunschild, & Hug, 2018; Small, 2018; Small et al., 2017). In our dataset, we assume the window size of the citation context would not exceed the paragraph (or the cite-paragraph) in which the citation marker is in. As a paragraph contains one or more sentences usually dealing with one specific idea, the cite-paragraph is more likely to cover the entire citation context compared with a single sentence. However, in most cases, the cite-paragraph might be much larger than the accurate citation context of one citation marker.

We chose to keep the cite-paragraph as citation context in our dataset, because we want to leave the decisions to be made by future users for further processing. They can choose to implement their technical plan to have a better cited text span for their own use cases. As the citation context does not exceed the cite-paragraph based on our assumption, we view the cite-paragraph as the largest citation context we could possibly have. Besides, we also save the position of the citation marker in the cite-paragraph, which is a number describing how many characters between the starting character of the paragraph and citation marker. We assume the citation markers separated by "and/or" and comma have same position in the cite-paragraph. In the result of the cite-paragraph, to have a clean text for information processing, the citation markers, the "and/or" and commas between the citation markers are all deleted. Therefore, the text in the cite-paragraph might be a little bit different with the original text.

Data records

Our data is saved using MongoDB, which is the database based on distributed file storage. It is designed to provide scalable, high-performance data storage solutions for web applications. Besides, MongoDB is also a database product between the traditional relational database and the non-relational database. It is one of the most feature-rich among non-relational databases and most like a relational database, and suitable for our task. In MongoDB, a table in relational database is called a "collection" and a record in relational database is called a "document". In order not to get confused with the scientific document for our readers, we call each record in MongoDB database as "MongoDB document". In total, there are 37,782,343 Literature objects, 97,526,947 Cite objects, 148,151,328 CitationContext objects, 34,728,502 CitationContextText objects in our database.

Table 1. Literature collection example.

_id ObjectId	*pmc_uid String*	*pmid String*	*local_path String*	*fully_updated Boolean*
5daac89e98fcf8f911522e7a	"2572131"	"18973706"	"/comm_use.A-B.xml/Asia_Pac_Fam_Med/PMC2572131.nxml"	true
5daac89f98fcf8f911522f3e	"2572132"	"18973707"	"/comm_use.A-B.xml/Asia_Pac_Fam_Med/PMC2572132.nxml"	true
5daac89e98fcf8f911522e7b	No field	No field	No field	No field
5daac89e98fcf8f911522e81	No field	"9381230"	No field	No field

In the database, one Literature object have 4 attributes, namely pmc_uid, pmid, local_path and fully_updated. Among the Literature objects in our database, there are 2,658,541 with pmc_uid and local_path, 12,886,421 with pmid, and 24,735,791 without pmc_uid nor pmid. Note the fact that, the Literature objects with pmc_uid and local_path represent our original PMC papers. And as we noted before, only Literature objects for PMC papers have the attributes: pmc_uid, local_path and fully_updated. If one cited document has the PubMed ID, there is a 'pmid' attribute for that document. If there is no pmid for the cited document, all the 4 attributes of the corresponding Literature object will show "No field". In the following example in Table 1, the first two Literature objects represent the citing PMC papers with pmid, the third Literature object represents a non-PMC cited document, and the fourth Literature object represents a cited document with pmid.

A Cite object has 4 attributes, namely citer, cited, local_reference and reference_sequence. The citer stands for the object ID for the citing document and cited represent the object ID for cited document. Besides, the reference sequence and local reference string are also saved. In our example below (see Table 2), there are three Cite objects, and they have the same citing document with the Object ID "5daac89e98fcf8f911522e7a". This citing document cites three different cited documents. Each cited document has different Object ID, reference id ("B1", "B2" and "B3") and sequence ranging from 1 to 3.

Table 2. Cite collection example.

_id ObjectId	*citer ObjectId*	*cited ObjectId*	*local_reference_id String*	*reference_sequence Int32*
5daac89e98fcf8f911522e7c	5daac89e98fcf8f911522e7a	5daac89e98fcf8f911522e7b	"B1"	1
5daac89e98fcf8f911522e7e	5daac89e98fcf8f911522e7a	5daac89e98fcf8f911522e7d	"B2"	2
5daac89e98fcf8f911522e80	5daac89e98fcf8f911522e7a	5daac89e98fcf8f911522e7f	"B3"	3

Each CitationContextText (or CiteParagraphText in our case) has the attribute "text" for its corresponding CitationContext (or CiteParagraph). The text is for the paragraph where the citation context belongs to. Note the fact CiteParagraphText is one special case (or subclass) for CitationContextText. MongoDB use the field _cls to identify which subclass the object belongs to. In the example below (see Table 3), there are two CitationContextText objects.

Table 3. CitationContextText collection example.

_id ObjectId	*_cls String*	*text String*
5e0dc026f40c0c510c201d03	CitationContextText.CiteParagraphText	The placement of a partially … shorter stent patency.
5e0dc026f40c0c510c201d18	CitationContextText.CiteParagraphText	Two types of SEMS were … been previously reported.

As CitationContext is used to link a Cite object and a CitationContextText object, it has one cite field and one citation_context_text field in it representing a Cite object and a CitationContextText object. Besides, the object also has a field called "position" to save the index of the citation marker of the Cite object in the text string of the corresponding CitationContextText. Since CiteParagraph is the subclass of CitationContext, so each object for CitationContext also has the _cls attribute which equals to "CitationContext. CiteParagraph". In the example below (see Table 4), the three CitationContext objects share the same CitationContextText object but have different Cite objects.

Table 4. CitationContext collection example.

_id ObjectId	_cls String	position Int32	cite ObjectId	citation_context_text ObjectId
5e0dc026f40c0c510c201d04	CitationContext.CiteParagraph	204	5e0dc026f40c0c510c201cd4	5e0dc026f40c0c510c201d03
5e0dc026f40c0c510c201d05	CitationContext.CiteParagraph	204	5e0dc026f40c0c510c201cd6	5e0dc026f40c0c510c201d03
5e0dc026f40c0c510c201d06	CitationContext.CiteParagraph	204	5e0dc026f40c0c510c201cd8	5e0dc026f40c0c510c201d03

After the citation context database for PMC articles is built, we use mongodump command in MongoDB to export our data. This command can export all data in the database to a specified directory. The export of the data is in 8 separate files, while 4 of the files are the data files of the 4 collections in our database (namely citation_context_text, citation_context, cite, literature) with the file extension "bson", 4 of the files are the corresponding metadata file of the collections with the file extension "metadata.json". And these 8 files are the data files of the dataset we present in this paper.

Technical validation

To evaluate the validity of our dataset, we chose to select the most cited document as the sample and manually checked the citation contexts or the text of the cite-paragraph pointing to the most cited document to determine if the records were correct. We sorted the citing-cited pairs data in collection Cite, and we found that the most cited document is the paper with PubMed ID 11846609, cited by 22,833 PMC papers (which is approximately 0.86% the PMC papers in our dataset). The paper's title is "Analysis of Relative Gene Expression Data Using Real-Time Quantitative PCR and the $2^{-\Delta\Delta CT}$ Method" (Livak & Schmittgen, 2001), authored by Kenneth J. Livaka and Thomas D. Schmittgen. The paper presents the derivation, assumptions, and applications of the $2^{-\Delta\Delta CT}$ method, and the derivation and applications of two variations of the $2^{-\Delta\Delta CT}$ Method that may be useful in the analysis of real-time, quantitative PCR data.

For the most cited document from PMC papers, we extracted the related data from 3 collections in our MongoDB database, which are Cite, CitationContextText and CitationContext. In total, we found no errors in this sample dataset, however, there are some outliers in the dataset that we need to clarify.

For Cite data, we found the most cited document was cited twice by two different PMC citing papers with different reference number. In general, one document only appears once in the reference list with unique reference number or reference ID. However, the two PMC papers wrongfully give the cited document different reference number in the original full text, therefore our Cite data showed that there were two pairs of Cite objects with the same cited and citing documents but different object ID.

For CitationContext, we found three pairs of replicate data with the same position, Cite ID, and CitationContextText ID. After the scrutiny of the full text, we found out these replicate data happened because the same citation marker appears at the same position according to our criterion. For example, in the original full text of the paper, one citation marker might be around the author's name in the full text, and the citation marker with same ID might be around the published year right next to the first citation marker. However, based on our methods, we replaced the XML tag which contains the reference ID (and the text between the tag) with the new unified citation marker, and we also deleted the content between the citation marker in the cite-paragraph. Thus, the citation marker with same reference ID next to each other in the original full text are treated to have same position. The users should be cautious about the issue when using the dataset.

Usage Notes

The data can be accessed freely with the DOI: www.dx.doi.org/10.11922/sciencedb.00393. The users should apply the command mongorestore to load data from the downloaded binary database directory to MongoDB database (see https://docs.mongodb.com/database-tools/mongorestore/). The database directory contains the following files:

- citation_context.bson
- citation_context.metadata.json
- citation_context_text.bson
- citation_context_text.metadata.json
- cite.bson
- cite.metadata.json
- literature.bson
- literature.metadata.json

After the data is loaded in MongoDB by the command mongorestore, the users can then use tools provided by MongoDB to analyze the data.

Limitations

The citation context dataset based on PubMed Central papers we provided is one of the largest citation context datasets, however, the dataset has several limitations.

Firstly, to simplify the processing of the original data, only the relationships between the PubMed Central papers and PubMed documents are revealed. For a document without PubMed ID in the database, there is only one citing PMC paper for it, but in fact, there may be more citing PMC papers for the document. The next version of the dataset might utilize the DOI in the full text and other third-party citation services to cover cited documents without PubMed ID.

Secondly, for a Literature object, there are only four attributes, namely pmc_uid, pmid, local_path, fully_updated, and only pmc_uid and pmid are the metadata of the paper. In the future, we intend to use Entrez Programming Utilities at the National Center for Biotechnology Information to add more metadata (such as the title, authors, publication details) for Literature object. With more metadata of a document, more interesting insights might be discovered from the dataset.

Lastly, unlike general citation database such as the Web of Science, Scopus, Microsoft Academic, Google Scholar, the original PubMed Central Open Access Subset only covers a small part of the papers published, and the papers in the subset are in the field of biomedical and life sciences. The users of the dataset for citation analysis should be cautious about the scope of the dataset and ignorance of the issue might lead to biased conclusion.

Abstract

This research-in-progress paper presents a novel visualization approach to facilitate understanding of interdisciplinary collaboration within a university using a large-scale dataset of research grant projects in Japanese universities. First, we construct a network of departments in a target university, and then visualize the activeness of inter-departmental collaborations using member information of research projects. Second, to compare research features among universities, we quantify the difference in the frequency of research field combinations between the target university and other universities. Collaborations that have characteristic research field combinations are then highlighted in the network, which can be useful for the target university's research promotion strategies. We present a case study at the University of Tokyo to validate the effectiveness of our approach. To enhance our visualization's advantage, we also demonstrate that the average amount of research grants that the characteristic research field combinations received is significantly higher than those of field combinations that are prevalent among several universities.

Introduction

Interdisciplinary collaborations have become increasingly important for providing innovative solutions to complex problems. Research administrators at a university often make efforts to analyze the performance of its research institutes to create an interdisciplinary team from different departments. Understanding the characteristics of research at the university compared with other universities is also crucial for choosing research promotion strategies. However, there is no established visualization framework for such a comparison of research features among universities.

Previous studies have defined measures of interdisciplinarity for several academic entities, such as journals and authors. For example, Rodríguez (2017) proposed a citation-based indicator for classifying scientific journals into four classes based on their degree of interdisciplinarity. Zhang et al., (2020) used a co-author network to assess the interdisciplinarity of each researcher. To examine the status of collaborations across research topics, Rafols and Meyer (2010) evaluated the degree of interdisciplinarity of papers published in bioscience and visualized them on a two-dimensional plane. Some studies focused on using the attributes of researchers listed in individual research projects. L. Zhang et al., (2018) analyzed the diversity of disciplines estimated from the authors' varied affiliations. Abramo, D'Angelo, and Di Costa (2012) analyzed collaboration frequencies among researchers from different fields to identify frequent field combinations. Similarly, Uddin, Imam, and Mozumdar (2020) constructed a network in which each node represents a discipline, while an edge between two nodes represents the participation of corresponding disciplines in grant projects. The line of these science mapping research projects has the potential to be extended to institutional research in a university.

In this research-in-progress paper, we present a novel visualization approach to facilitate understanding of a university's collaboration characteristics in interdisciplinary research. Our study uses a large-scale dataset of research grant projects in Japan. First, we construct a network of departments using member information of research projects to show the activeness of inter-departmental collaborations. Second, to compare universities, we quantify the difference in frequency of research field combinations between the target university and other universities. Collaborations that have characteristic research field combinations are then highlighted in the network, which can be useful for the target university's research promotion strategies. A case study at the University of Tokyo is presented in this paper to validate the effectiveness of our approach. We also investigate the difference in the average amount of research grants received by field combinations judged as characteristic and those deemed common.

Dataset

Our study requires a dataset containing collaborative research project information, including member affiliations and research field labels. To construct such a dataset, we chose KAKEN[1] as an information source. KAKEN is the database of Grants-in-Aid for Scientific Research projects granted by the Ministry of Education, Culture, Sports, Science and Technology and the Japan Society for the Promotion of Science for research projects in all fields in Japan. Among KAKEN research projects from fiscal year (FY) 2004 to FY 2017, we extracted the projects that have at least two researchers and classified them as "collaborative research projects." In KAKEN, each research project is classified into a single field category by the Principal Investigator according to the application year's list of categories. We first manually integrated these field categories, which differ from year to year, into the 13 field labels of the list as of 2017. Although field labels are provided to research projects in KAKEN, and not to individual researchers, our study requires collaborators' field information similar to that used in Abramo, D'Angelo, and Di Costa's study (2012). Thus, we assigned the field label of a research project to the project's Principal Investigator so that each researcher can be associated with one or more field labels. The resulting dataset consisted of 112,722 research projects, 4,054 domestic institutions, and 130,733 unique researchers.

Measures of a university's collaborative research

Activeness of collaborative research

We first aim to investigate the activeness of collaborations between different departments in a target university. Let U be the set of all universities in the dataset. The set of departments in a target university $u \in U$ is denoted by Ω_u. Let $T^u_{d,d'}$ be the set of research projects, which contain at least one researcher from department $d \in \Omega_u$ as well as at least one researcher from department $d' \in \Omega_u$. We represent how active the inter-departmental collaborations between departments d and d' using the cardinality of the project set as follows:

$$Active_{collab}(d,d') = \left|T^u_{d,d'}\right|. \quad (1)$$

Although this simple count-based measurement contributes to finding frequent patterns of inter-departmental collaborations "within" a target university, it cannot reveal how characteristic each pattern is, "compared with" other universities. We solve this problem in the following subsection.

[1] https://kaken.nii.ac.jp/en/

Activeness of characteristic interdisciplinary collaborative research

To characterize features of the university's inter-departmental collaborations, we define a combinatorial set of field categories of researchers participating in a single research project as a "*field combination*." For example, suppose a project is conducted by four researchers whose fields are computer science (CS), humanities (H), CS, and engineering (E), respectively, we can extract from this project the following field combination; (CS, H, E). Note that if a researcher has multiple labels, all the labels are considered to create a combination. We assume that if a certain field combination occurs frequently in a target university compared with other universities, the corresponding topic can be the characteristic of the university. Specifically, the characteristic of a field combination c for a target university $u \in U$ is quantified using the following measure:

$$Measure_{character}(u,c) = t\_ratio(u,c) - \frac{1}{|U-\{u\}|}\sum\nolimits_{j \in U-\{u\}} t\_ratio(j,c)\,, \qquad (2)$$

$$t\_ratio(j,c) = \frac{\text{Number of research projects corresponding to field combination } c \text{ at university } j}{\text{Total number of research projects at university } j}\,.$$

A large value of $Measure_{character}(u,c)$ means the field combination c can represent characteristic collaboration at university u.

Next, we quantify the activeness of "characteristic" interdisciplinary collaborations between departments in a target university $u \in U$. The field combination extracted from project $t \in T^{u}_{d,d'}$ is denoted by $c(t)$. For two departments d, d', focusing on how many of their collaborations were produced by characteristic field combinations, we compute the following activeness measure:

$$Active_{character}(d,d') = \sum\nolimits_{t \in T^{u}_{d,d'}} g(c(t)) \;\; (3),$$

$$g(c) = \begin{cases} Measure_{character}(u,c), & \text{if } Measure_{character}(u,c) > \mu_{u,c} + \sigma_{u,c}, \\ 0, & \text{if } Measure_{character}(u,c) \le \mu_{u,c} + \sigma_{u,c}, \end{cases}$$

where $\mu_{u,c}$ and $\sigma_{u,c}$ are the mean and the standard deviation of the values that satisfy $Measure_{character}(u,c) > 0$, respectively. If $Measure_{character}(u,c(t)) > \mu_{u,c(t)} + \sigma_{u,c(t)}$, the project t is defined as a "characteristic" interdisciplinary collaboration, and its activeness score contributes to $Active_{character}(d,d')$. A large value of $Active_{character}(d,d')$ means that the two departments d and d'actively collaborate, especially in research topics of characteristic field combinations for the university. Using this measurement, we can easily find which department pair conducts collaborations that can be features of the university.

Results

Visualization based on network construction

To verify the effectiveness of the proposed method, we present a case study at the University of Tokyo, which has 13 research departments. We first constructed two networks whose nodes and edges are departments and their collaboration relationships, respectively. In each network, nodes and edges are weighted using Eq. (1) or Eq. (3). Note that for $d = d'$, each measure represents the activeness of "intra-departmental" collaborations in department d, which was used as node weights. Figure 1 shows the network weighted using Eq. (1), in which each edge/node is colored dark when the corresponding weight is high, with a light color used when the value is low. The figure shows that most of collaborations occur within departments (i.e., $d = d'$) and that many collaborative research projects are conducted within the Graduate School of Medicine compared to other departments. Figure 2 shows the network weighted using Eq. (3), in which the edge/node is colored, similar to Fig. 1. From Fig. 2, we can see the following two trends: (a) the Graduate School of Engineering actively conducts characteristic interdisciplinary collaboration within the department; and, (b) the Graduate School of Engineering and the Graduate School of Frontier Sciences actively collaborate in research projects belonging to characteristic field combinations.

Although we found from Fig. 1 that a number of collaborative research projects are conducted within the Graduate School of Medicine, Fig. 2 implies that their research field combinations are similar to other universities. For the Graduate School of Science, Fig. 1 shows that the number of collaborative research projects within the department is not large, while Fig. 2 indicates that researchers in the Graduate School of Science conduct many “characteristic” interdisciplinary collaborations within the department. We can consider that this department has the potential to create interdisciplinary collaboration teams with other the departments.

In addition, Table 1 shows the field combinations evaluated as characteristic interdisciplinary collaborations, sorted in descending order of $Measure_{character}$. We can see that environmental science/engineering is the most characteristic field combination in the University of Tokyo. The table shows that engineering is included in the higher rank of field combinations. We can confirm that the Graduate School of Engineering, to which many researchers assigned under the Engineering label are considered to belong, indeed has darker coloration of nodes and edges from Fig. 2. These findings will facilitate mapping a strategy to promote characteristic collaborations in the university.

The impact of characteristic interdisciplinary collaborations on grant budgets

We further conducted in-depth analyses of the "characteristic" interdisciplinary collaborations found by our approach. Research projects in KAKEN were provided with budgets, whose amounts differ from one another. In this experiment, we compare the budgets' amounts between the research projects that are considered to be characteristic interdisciplinary collaborations and those that are not. Our research question here is: *Can characteristic interdisciplinary collaborations obtain more research budgets than non-characteristic ones?*

Given that the range of budget allocations for research projects varies, depending on the grant application categories, this experiment used only research projects in the category of *Grant-in-Aid for Scientific Research (B)*, which generally presupposes collaboration with multiple researchers. Projects in Grant-in-Aid for Scientific Research (B) are supported by budgets ranging between 5 to 20 million yen. The average of the allocations for research projects belonging to different types of collaboration is shown in Table 2. We used the Mann-Whitney U test to examine whether there is a difference between the two groups. The two-sided test showed that the significance probability p was $p = 0.019 < 0.05$. Interestingly, it is demonstrated that the budget average amount allocated to the research projects judged as characteristic is significantly higher than that allocated to the research projects considered common.

Table 2. Comparison of average amounts of budget allocated to projects.

	Judged as	
	characteristic	*common*
Number of research project*s*	45	131
The average of the allocations (yen)	16,650,666	15,786,564

Conclusion

This research-in-progress paper proposed a novel visualization that facilitates better understanding of interdisciplinary collaborations within a university. We constructed a network representing the activeness of inter-departmental collaboration within a target university. We then found the characteristic field combination in the target university, and the activeness of the characteristic interdisciplinary collaboration is represented in the same network form. In addition, we demonstrated that the average of research grants that the characteristic research field combinations received is significantly higher than that obtained by common ones. In future work, we will apply the method to other research institutions for large-scale comparisons. We will also develop an interdepartmental collaborator recommendation system based on the proposed method like in our previous study (Takahashi, Tango, Chikazawa, & Katsurai, 2020).

Abstract

Publication speed is one of the important aspects of scholarly communication today since a good deal of research performance evaluation systems are based on published articles. This study aims to reveal the factors affecting the publication speed of journals. In this context, six library and information science (LIS) journals, *ASLIB Journal of Information Management, Journal of Documentation, Journal of Informetrics, Journal of the Association for Information Science and Technology, Online Information Review,* and *Scientometrics* are analysed in terms of their publication speed. Results show that being an editorial board member or prolific author for journals significantly shortens the duration of publication. Moreover, when there is at least one editorial board member or prolific author in the author group, the duration of the publication is shorter than the articles from the unknown authors. However, the fact that no significant difference is determined between single- and double-blind peer review and the duration of publication process gives an idea about the scientific levels of articles written by editorial board members or prolific authors. In this regard, our approach is to examine other factors affecting the publication speed by conducting multi-dimensional analysis in future studies.

Introduction

Peer review, which can be carried out blind (single or double) or open (the identities of reviewers are disclosed at least to the authors), is one of the most effective tools used to make decisions on research quality. However, it has various drawbacks. Most of the problems of current peer review systems are related to the reliability of reviewers' ratings and biases such as status bias (institutional or individual level) or gender bias (Cox et al., 1993, p. 313).

Comparisons for measuring the effectiveness of single- and double-blind review systems are important to choose a fairer and balanced system as well as reduce biases. Blank (1991) showed that the reviewers were more critical of double-blind peer review and the authors from peripheral countries received less acceptance in the double-blind review system. It was revealed in a different study that single-blind reviewers were significantly more likely than their double-blind counterparts to accept papers from popular authors, top universities, or top countries (Tomkins et al., 2017). Okike et al. (2016, p. 1316) concluded that if blinding was not applied properly, variables such as gender or popularity affect acceptance or rejection decisions, and Budden et al. (2008) stated that double-blinding increased the representation of women in science. Sun et al. (2021) suggested a double-blind review system to remove prestige bias in the review process. While Snodgrass (2006, p. 10) indicated that the main problem of the single-blind review was the unfairness to unknown authors, on the other hand, according to some others single-blind reviews provided speed in the peer review process by providing personal knowledge about the authors or works (McCormack, 2009). However, according to a study based on the articles published in *American Economic Review* (Blank 1991, p. 1048), the duration of the single-blind review was two weeks longer than the double-blind.

Studies in the literature have confirmed that there are various practices in all types of peer review processes regarding the journal, gender, country, prestige, etc. The common point of almost all these studies is to reveal who the peer review provides an advantage. In this case, it is possible to say that the concept defined as the Matthew Effect in science, which represents the cumulative advantage of science elites (Merton, 1968), is also valid for peer review processes. According to Merton, reputed or distinguished researchers have more credit than researchers who are unknown in the same field, even if their works were quite similar (p. 59).

It is possible to mention Matthew Effect not only in article acceptance decisions but also in the duration of peer review. While some researchers' articles are published in a very short time, this process may take longer for some other researchers. However, publication speed has importance for all researchers who seek tenure and incentives. The fact that long review processes, the lack of standardization in the processes, and differences from discipline to discipline cause researchers to have negative opinions about the journals (Huisman & Smits, 2017).

The main aim of the paper is to reveal factors affecting the duration of peer review processes for library and information science journals. The research questions are:

- How do the types of peer review affect the duration of peer review?
- Does being an editorial board member of a journal shorten the peer review process?
- Does being one of the most prolific authors of the journal shorten the peer review process?
- Does having more than one role in a journal affect the peer review speed?
- What is the difference between the publication speed of researchers who are central in the LIS field and others?

Data and Methods

To achieve the aim of the study, three single-blind journals of library and information science (LIS) field (*Journal of Informetrics* [JOI],[1] *Journal of the Association for Information Science and Technology* [JASIST][2] and *Scientometrics* [SCIM][3]), and three double-blind journals (*ASLIB Journal of Information Management* [ASLIB],[4] *Journal of Documentation* [JDOC][5] *and Online Information Review* [OIR][6]) were chosen. A total of 3,816 articles that were published between 2016 and 2021 were evaluated deeply. Metadata of articles were gathered from Web of Science on January 2, 2021. In the dataset, a total of 2,843 single and 973 double-blind articles were stored. 45% (1,715) of these articles were published in *SCIM*, 20% (753) in *JASIST*, 10% in *JDOC* (381), *JOI* (375), and *OIR* (367), and 5% (225) in *ASLIB*. Therefore, differences between journals should be considered to interpret the results. To achieve this, the average duration for each journal was presented in figures.

To collect the names of editorial board members, the websites of journals were used. All members of the editorial boards were considered. However, considering the important editorial board change for *JOI* in 2019 (Larivière, 2019), two different lists were used for this journal. One for the publications before 2019 and one for publications after 2019. For finding the most prolific authors of each journal, six different searches were done in Web of Science. The last

[6] https://www.emeraldgrouppublishing.com/journal/oir#author-guidelines

10 years (2011-2020) were considered. Only articles and reviews were covered. The first ten authors of each journal were defined as "prolific authors". If the tenth and eleventh authors had the same number of publications, two of them were added to the dataset. After finding the most prolific authors in Web of Science, the articles were classified accordingly.

The codes were written using Python to get publications' timelines automatically from journal websites (Taşkın, 2021). To compare the review durations in terms of the journal and peer review types, Kruskal Wallis, Mann Whitney, and Chi-square tests are applied considering the assumptions required to apply parametric testing are not met. Effect sizes are also calculated for the positive test results. Formula 1 shows the effect size calculation for Kruskal Wallis (η_H^2), and Formula 2 for Mann Whitney U (r_G) tests where H is the Kruskal-Wallis test statistic, k is the number of groups, $\bar{R}_A$ and $\bar{R}_B$ are the average ranks for groups, n and N_T is the total number of observations (Cohen, 2013, p. 10-11, 19-20).

$$\eta_H^2 = (H - k + 1)/(n - k) \qquad \text{(Formula 1)}$$
$$r_G = 2(\bar{R}_A - \bar{R}_B)/N_T \qquad \text{(Formula 2)}$$

We used SPSS (version 21) and RCommander for statistical tests and descriptives; RCommander (with KMggplot2 plugin) and Flourish Studio for visualization.

Findings

Effects of single- and double-blind reviews on the duration of peer review

When it was investigated whether the type of peer review affects the review duration, small differences were found between the two groups (see Figure 1). Although the acceptance periods of the specific journals varied, the average duration of the single- and double-blind review types were very similar. Mann-Whitney U test confirmed this similarity (*U*=1358685.500, *Z*=-0.824, *p*=0.410). On the other hand, significant differences were found between the journals' peer review durations regardless of peer review type. According to the results of the Kruskal Wallis test, significant differences were found for the average duration of peer review (*H*=401.315, p<0.001, η_H^2=0.104). When all journals were compared to understand the source of differences, there were no statistically significant differences found between *ASLIB* & *JOI* and *JDOC* & *JOI* at %99.9 confidence level.

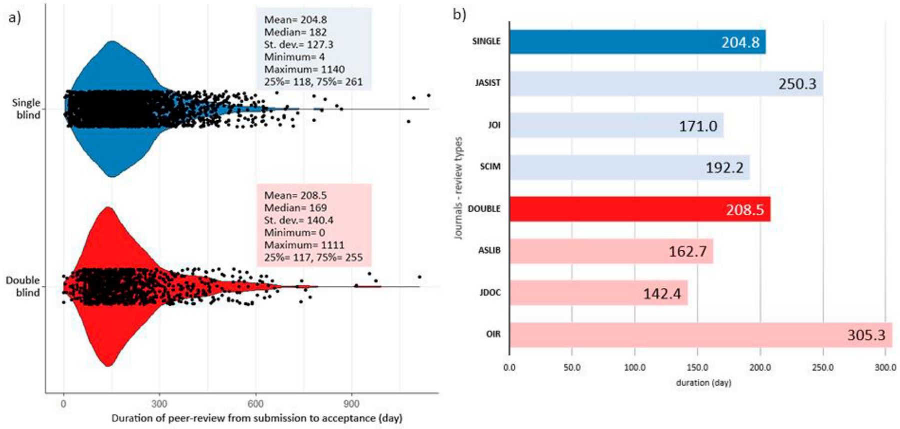

Figure 1. Duration of peer review regarding peer review types

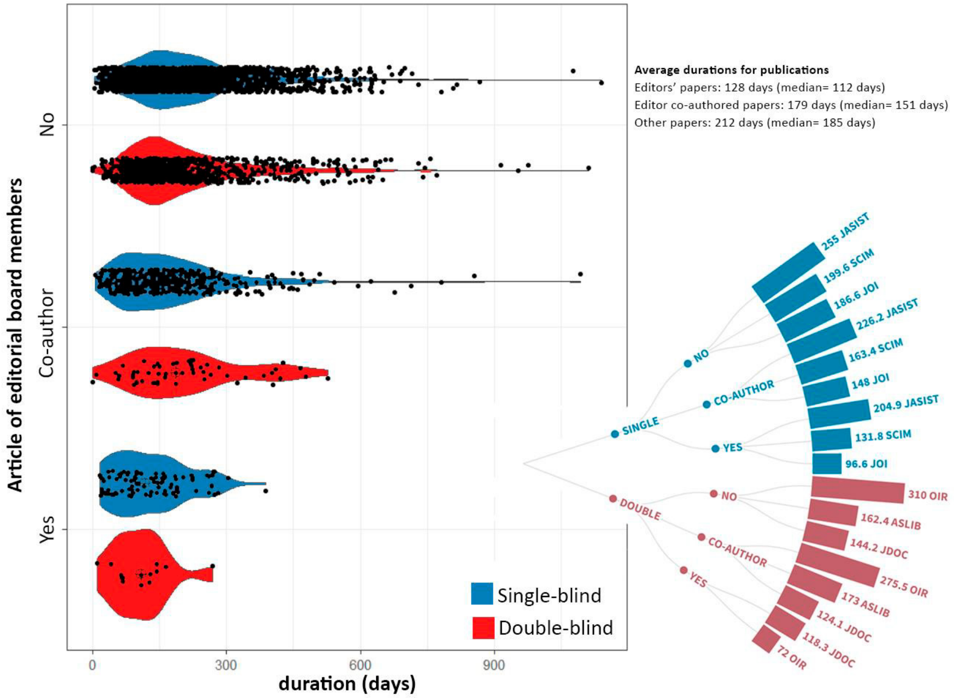
Effects of being an editorial board member on the review durations

Being an editorial board member is important in showing that researchers have achieved a certain scientific level, have proven their scientific merit in the field, and thereby have become a decision-maker for a journal (Bedeian et al., 2009; Pardeck & Meinert, 1999). Members of the editorial boards are often selected among the most popular researchers in their fields with high scientific competencies. Therefore, it is expected that the peer review processes of the articles written by editorial board members may be completed faster in parallel with the recognition, experience, and popularity in the field. The differences between the peer review durations of editorial board members' and other authors' papers (see Figure 2) are statistically significant (H=92.892, p<0.001, η^2_H=0.024).[7] One of the important findings is that, when an editorial board member is a co-author of a study, it makes the peer review process shorter. It confirms a recent study (Zhang et al., 2021) that reveals the positive effects of editorial boards' cooperation with the authors' publications. Furthermore, this difference is more obvious for single-blind journals (η^2_H=0.032).



Average durations for publications
Editors' papers: 128 days (median= 112 days)
Editor co-authored papers: 179 days (median= 151 days)
Other papers: 212 days (median= 185 days)

Figure 2. Peer review duration for papers written by editorial board members

Papers from the prolific authors of the journals

According to Merton (1968, p. 61), the works of scientists who have an outstanding position in science have been validated by judgments of the average quality of their past work. Therefore, it is easier to accept the works of outstanding authors by the journals. To confirm whether this approach affects the review durations, the review durations of the works from the prolific authors of each journal were evaluated in this study (see Fig. 3).

[7] The difference is significant for all the pairs. According the effect sizes calculated, the most significant difference is between the papers of editors (Yes in Figure 2) and papers with no editors (No in Figure 2) (U=106418.000, Z=-7.636, p<0.001, r_G=0.420)

The results show that there are significant differences in peer review durations for the papers from productive authors and others ($H(2)=151.477$, $p<0.001$, $\eta_H^2=0.039$). The effects sizes calculated for each of the three pairs showed that the most significant difference is between the papers of prolific authors (Yes in Figure 3) and papers with no prolific authors (No in Figure 3) ($U=75011.500$, $Z=-9.265$, $p<0.001$, $r_G=0.548$). On the other hand, when the effect of prolific authors on peer review duration evaluated separately for single- and double-blind journals, single-blind journals stand out with the more pronounced difference ($\eta_H^2=0.046$) in comparison with double-blind ones ($\eta_H^2=0.024$).

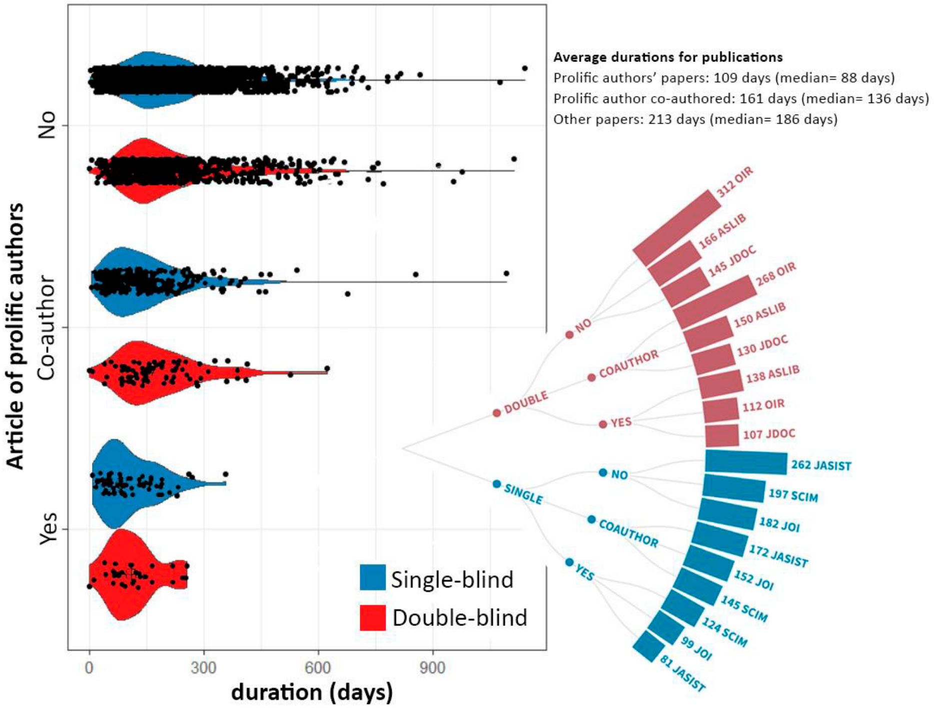


Figure 3. Peer review duration for papers written by prolific authors of the journals in the last 10 years

What if an editorial board member is also a prolific author?

It was revealed that being an editorial board member or a prolific author of a journal shortens the review process. The main question after this finding is that what if an editorial board member is also a prolific author? According to the results (See Figure 4), if the editorial board members in both single and double-blind peer review were also the most prolific authors and submitted their articles to their journals, it took an average of 100 days to complete all processes. Having one editorial board member or a prolific author as a co-author may also shorten the process. The longest evaluation process was identified for the papers written by unknown researchers of the journals.

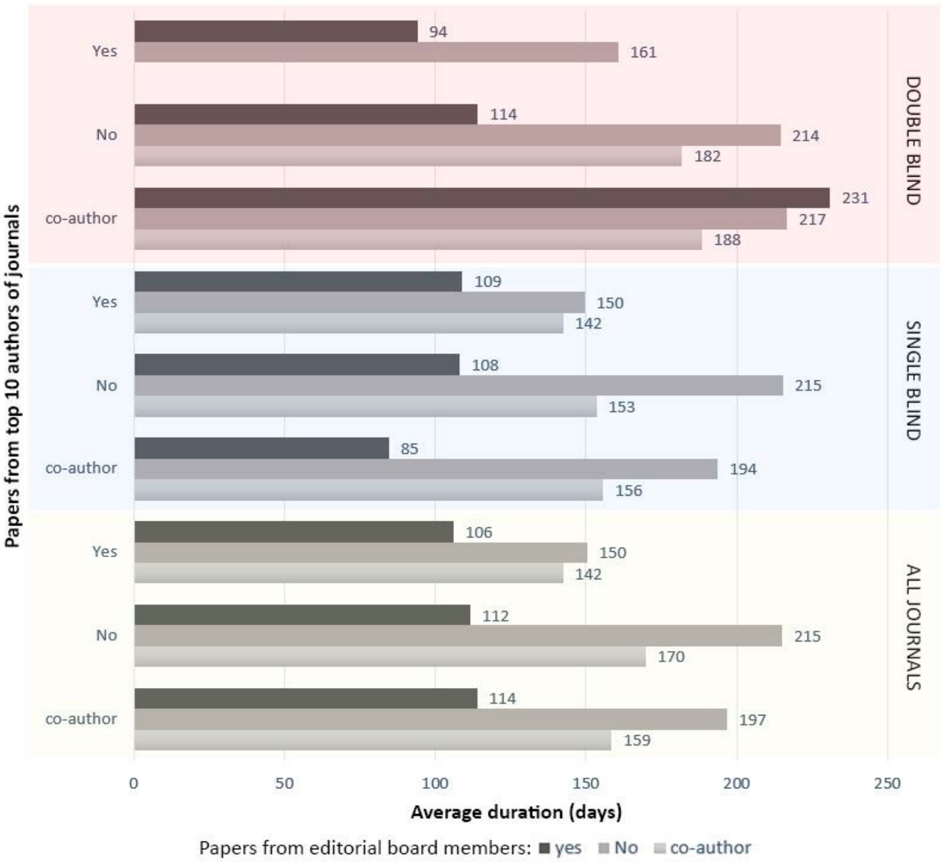

Figure 4. Average durations for the papers written by editorial board members and prolific authors

Peer review durations of central researchers of the LIS field

All the findings of previous parts have proved that there are popular, successful, and experienced researchers working in the LIS field, and their papers published faster than the others, as expected. Looking from the wider perspective, a total of 6,814 unique authors published 3,816 papers in LIS. Some authors serve more than one journal as an editorial board member. Besides, most of the prolific authors of single-blind journals are also editorial board members. Figure 5 shows the distribution of authors with the roles and publication speed of authors placed in the centre of the LIS network.

147 (3.8%) of the articles were single-authored and written by central authors, while 748 (19.6%) of them had central co-authors. Central authors' papers were published in a short time compared to the other authors' papers. Kruskal Wallis test confirms this finding ($H(2)$=146.897, p<0.001, η_H^2=0.038).

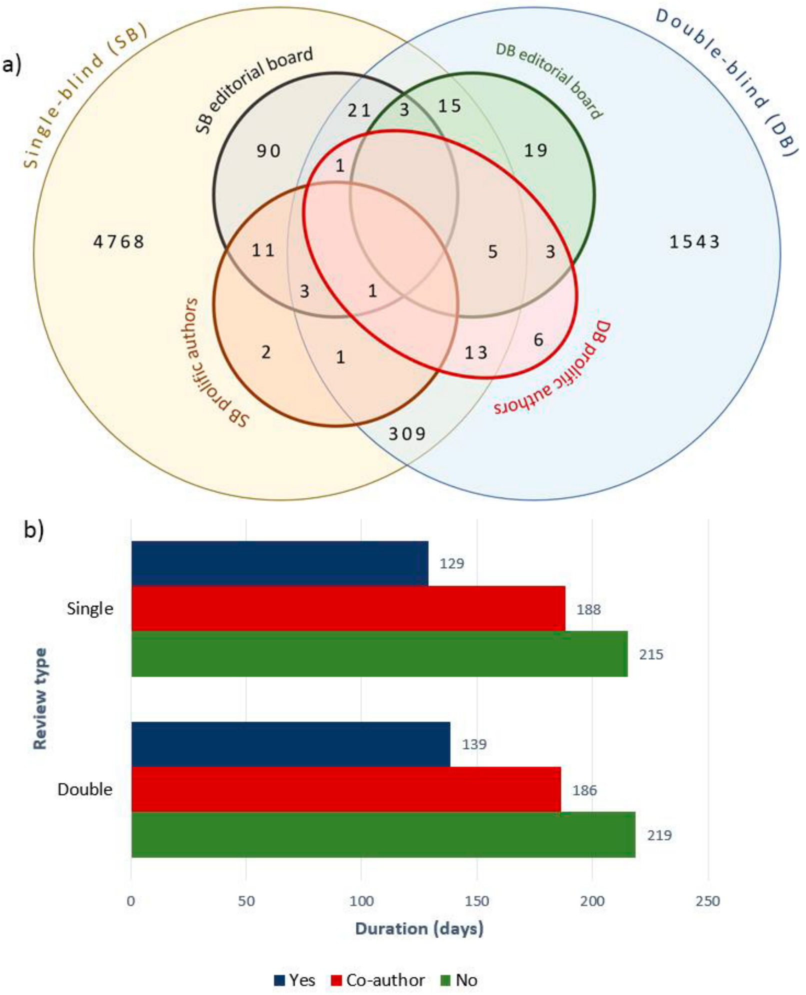

Figure 5. a) Number of unique authors in LIS journals and distribution of their roles, b) Publication speed of articles written by 194 central authors that have two or more roles in LIS

Discussion and Conclusions

According to our results, papers belonging to editorial board members and prolific authors are published faster. This is of course closely related to the experience these people have and the quality of the paper. However, it is also very important in terms of showing the advantage of young researchers who work with these researchers. This study shows that researchers who publish papers with popular and successful researchers have the advantage on the speed of publication.

In addition to the duration advantage of some researchers, this study also shows the importance of sharing the processing dates of research in detail by the publishers. Bilalli et al. (2020) indicated that all dates of review (receive, revision, acceptance, etc.) must be provided by journals. However, the information provided by journals about the review durations is limited especially for single-blind journals. Also, it is not provided as a metadata element in publishers' databases and it requires data mining. To be able to make accurate analyses, this information should be served by publishers and added to databases.

Limitations and Future Studies

This paper seeks author position related factors affecting the publication speed. Many reasons such as the quality of articles, the date of the article submitted, or the workload of editors, can affect the duration of peer review. However, in this study, we aimed to reveal whether there are researchers who have an advantage on publication speed that can be interpreted as Matthew Effect.

The editorial board members and prolific authors have high scientific levels and qualifications, and the outputs produced by these authors have a significant scientific level. It is expected that the papers written by prestigious authors have good quality and so, they are accepted faster than the papers written by others. However, this study is not about the quality of the papers. It aims to reveal the current practices of journals and to present the duration differences in publication processes of articles written by known and unknown authors. Furthermore, the paper is limited to only six journals in the LIS field, but, as indicated in the Methodology part, the volumes of the journals are not the same. It means the workloads of editors are not equal. On the other hand, the audiences of the journals vary. While some journals can be considered as pure library and information science journals such as *ASLIB* or *OIR*, some journals (*SCIM* or *JASIST*) have more authors from different disciplines. All these factors make the comparison harder. Therefore, more investigations are needed to understand all the factors affecting the duration of publications. This research constitutes the first stage of large-scale research.

It is planned to broaden the research by covering the country of affiliation of researchers, country groups, and collaboration statistics. Conducting a multidimensional statistical analysis is the next planned step of this paper. Besides, an author-level analysis covering more journals will be conducted to understand the duration changes for individual researchers. This will provide us with an opportunity to show all the factors affecting publication speed.

Abstract

Current Research Information Systems (CRIS) form an increasingly important part of the digital infrastructure of Higher Education and research institutions. The persons operating these infrastructures and making use of them in research reporting and assessment have so far rarely been studied. In this paper, we report preliminary results of a job advertisement analysis on the task and competency profiles of positions in IT-based research reporting in Germany. We find distinct profiles for system implementation, project coordination, and research reporting, suggesting a division of labor between more traditional research management functions and research information management, especially pertaining to IT and data expertise as well as strategic tasks.

Introduction

The information needs of university and science policy as well as research assessment are addressed by an increasingly complex and differentiated digital infrastructure. So called Current Research Information Systems (CRIS) form part of this infrastructure. They are integrated databases or information systems which can be used both at the national and institutional level to collect, store, process, integrate, exchange, present and analyze research information (RI). RI comprises metadata about research activities such as persons as authors or project investigators, research projects, publications and other forms of output, awards, patents or research infrastructures (Ebert et al., 2015; Petersohn, Biesenbender & Thiedig, 2020; Zhang & Sivertsen, 2020). CRIS serve many different purposes such as documenting, reporting and monitoring research activities, providing information for quality control and funding allocation procedures or showcasing research to the public (Biesenbender, Petersohn & Thiedig, 2019; Sivertsen, 2019a). More and more research organizations adopt institutional CRIS solutions (Ribeiro et al., 2016, p. 11) due to the richer informational yield of the varied and integrated types of research information collected and processed in CRIS as opposed to common institutional repositories or multidisciplinary citation databases (Sivertsen, 2019b).

Against this backdrop, it seems necessary to look beyond system features and use cases of CRIS and focus on the persons operating CRIS and making use of it in research reporting and assessment instead. The task area is complex, ranging from “frontend” services in training and supporting CRIS users, increasing CRIS acceptance and compliance as well as to assuring data quality. It may be organized centrally or decentrally with responsibility being shared between organizational units such as the library or research administration (Fondermann & van der Togt, 2017; Kaltenbrunner & De Rijcke, 2017; Simons et al., 2017). Knowledge about task profiles, responsibilities as well as underlying competencies and qualifications needed to perform this potentially new specialized area in research management is lacking, with the exception of first efforts undertaken by Blümel et al. (2018) and Dvořák and de Castro (2019). In a current research project, we aim at closing this gap by investigating task profiles, responsibilities and competencies for digitally supported research reporting. In this paper, we report preliminary results of a job advertisement analysis on the task and competency profiles as well as other characteristics of the advertised positions using a trial data set. We further briefly introduce a comprehensive data set of job advertisements that will be the focus of our upcoming research.

Data and methods

In a first step, a comprehensive list of vacancy platforms for the German job market using a list provided by the University of Passau[i] was compiled, which we extended via additional desk and literature research. The relevancy of 229 platforms was assessed based on the search term "research information" (thus also covering mentions of CRIS) as well as the platforms' descriptions. We compiled a trial data set for preliminary analysis from five of these platforms (academics.de, bund.de, interamt.de, jobturbo.de, stepstone.de). Information on vacancies were retrieved based on search terms such as "research reporting", "research documentation", "research service", and "research evaluation", among others. The search results were manually assessed and compiled into an initial trial data set consisting of 32 job advertisements, covering the years 2015 to 2020.

In order to get a more complete picture of the developments of the job market in the realm of IT-based research reporting in Germany, we additionally aimed for the compilation of a comprehensive data set, reaching back to the year 2005, when major CRIS developers first gained traction (Atira, n. d.; Weiss, 2011). Based on our platform assessment and first full-text job offers retrieved as examples, a database query for the creation of a full dataset of job vacancies was developed. Platforms likely to have their own databases were identified and approached with access requests to their full text databases. A corresponding data set was acquired in mid-April of 2021. It contains information on ca. 1100 job openings covering the years 2005 to 2020. We briefly provide first descriptive analyses below.

Analyses of the trial data set was conducted using MaxQDA 2020. A category system was developed covering the following main aspects of the job advertisements: tasks, qualifications, and competencies (understood here as parts of an overarching professional competency; as "…coherent cluster[s] of knowledge, skills and attitudes which can be utilized in real performance contexts", Mulder, 2014, p. 111), as well the type of research institution, year of publication, wage group and further contract of employment characteristics. For example, 226 tasks were coded by 77 inductive categories, such as "development of university-wide reporting and data management", "planning of target group-oriented science communication", etc., which in turn are assigned to one of nine overarching categories - in this case "strategic tasks". While the category system has undergone an intersubjective validation process, no strict intercoder reliability procedure has been conducted yet due to the exploratory nature of the initial analyses and the limited generalizability of the trial data set.

The data were analyzed using qualitative and quantitative content analysis (Mayring, 2001) by drawing on the mixed methods functionalities of MaxQDA. Additional descriptive analyses, correlations and mean comparisons (ANOVAs) were conducted using SPSS and Stata.

Findings

In terms of the characteristics of job vacancies within the realm of IT-based research reporting and CRIS development, we find that most offered contracts are for a limited-term position at a public university requiring a master's degree or equivalent. For IT specialist positions, degree requirements are more diverse and more frequently take previous work experiences into account. Further positions on the "periphery" of operational research information management include department leaders, administrators, and library staff.

Based on the characteristics of the advertisements included in the trial data set, we identify three distinct job profiles: system implementation (n=13), project coordination (n=8) and research reporting (n=9). The profiles are described below, based on our preliminary analysis of tasks (see Figure 1) and competencies (see Figure 2).

System implementation positions are overwhelmingly tasked with the implementation of a CRIS. As such, they are mostly located in the central administration of the institutions. They are characterized by a high number of IT- and data-related tasks ("preparation of research information", "configuration of interfaces") and corresponding competencies ("data visualization skills", "experiences with server environments") as well as frequent and diverse communicative tasks ("user support", "organizing and carrying out events and seminars"). They appear to have almost no association with strategic tasks on an institutional level.

Project coordination positions are further detached from the operational tasks of CRIS implementation, taking a coordinative role and responsibility for both further development and use of a CRIS, sometimes as part of a broader set of responsibilities including, for example, the coordination of external project partners and funding acquisition. Like system implementation positions, they are almost exclusively located in the institution's central administration. "Knowledge of science and university" (for example "knowledge of the research funding landscape" or "knowledge about science communication") are competencies often required for such positions. Department leaders are found in this category. Involvement in the development of reporting systems and research planning is moderate, suggesting that research reporting is a predominantly cross-departmental tasks and thus less the subject of project or department coordination. While a similar amount of IT-related tasks is found in both profiles presented so far, competency requirements pertaining to data expertise and IT systems are significantly more frequent in the former.

In contrast, staff in *research reporting* positions is responsible for developing and extending institutional reporting and service capacities and for strategic purposes such as fulfilling external reporting obligations, research planning, benchmarking or supporting decision-making processes. Positions involving library tasks, for instance "entering data in repositories" or "management of open access funds", are also found in this category. These positions are located in different organizational units relevant to research reporting: institutional leadership, central administration, and on faculty or, in case of extramural research institutions, divisional management level. Involvement in CRIS development, if mentioned at all, is restricted to specific reporting purposes. These positions are more often tasked with data preparation and analyses compared to the other two job profiles. They also more frequently require generic competencies, such as professional communication (e. g. "negotiation skills") and a professional way of working (e. g. "initiative and assertiveness").

Thus, while the differences between the system implementation and project coordination profiles can be said to be of degree and less of kind, the results indicate very distinct job profiles for research reporting on the one hand and CRIS implementation and development on the other.

First analyses of the comprehensive data set indicate a "core" of about 110 positions directly related to research reporting, research information or research documentation, 60 of which explicitly mention a CRIS – a term that first appears in 2009. Another 500 positions are potentially relevant and will need to be assessed further. Perhaps unsurprisingly, the majority of the advertised "core" positions are located at universities (65 percent) and extra-university research institutes (24 percent), most often in central administration (66 percent), with the other positions distributed evenly among the levels of institutional and decentral leadership as well as the library.

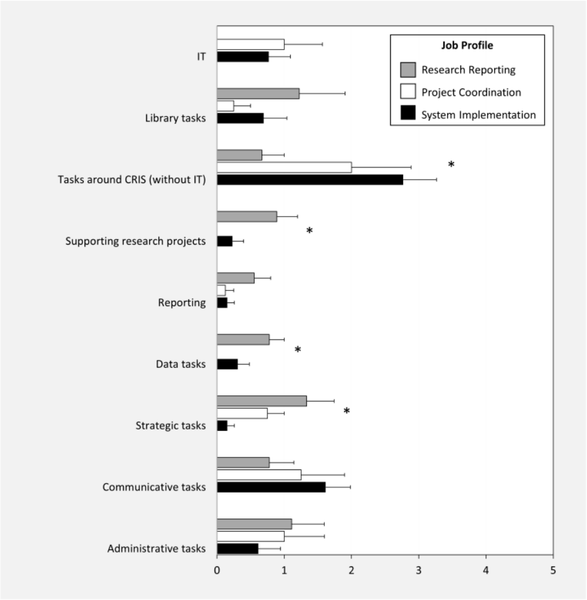

Figure 1. Mean number of tasks by job profile (total number = 226). Error bars show standard errors of the mean. Asterisks highlight significant differences between job profiles within that area of tasks (p < .05, N = 32).

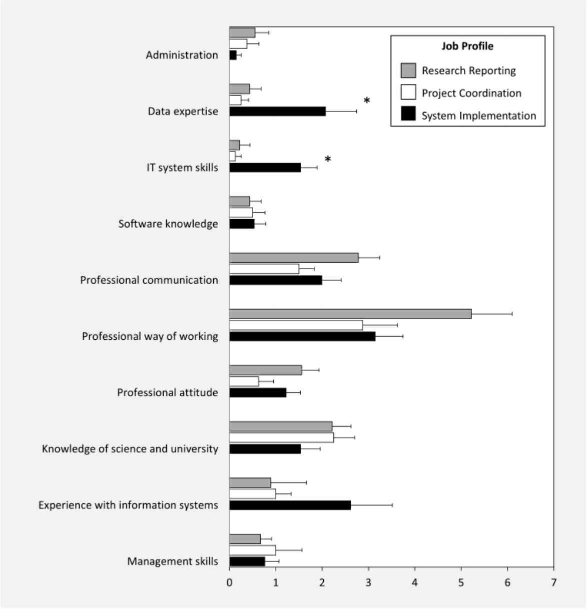

Figure 2. Mean number of required competencies by job profile (total number = 445). Error bars show standard errors of the mean. Asterisks highlight significant differences between job profiles within that area of competence (p < .05, N = 32).

Discussion and conclusion

Digitally supported research reporting is an increasingly relevant task area across all types of research institutions in Germany, and the implementation, development and use of CRIS constitute both benefits and major challenges (Biesenbender & Hornbostel, 2016). Employees are expected to perform a wide range of tasks both in "frontend" and "backend" services. Our study reveals corresponding competency requirements: Personnel responsible for CRIS implementation not only needs to be well versed in project and stakeholder management, but also requires IT and data expertise not commonly requested of other research management positions. The preliminary results thus indicate a rather clear division of labor between these job profiles. Given the exploratory nature of the analyses and the limitations of its underlying data set, further analyses are needed. The comprehensive data set offers several promising avenues for research, allowing for more differentiated analyses of task areas and competencies and the subsequent identification of corresponding job profiles over time, by type of institution, and by type of CRIS (e.g. commercial product vs. in-house development). Analyses on the development of IT and data competency requirements will further gain insights into a common challenge that German research institutions are currently facing: the recruitment and retention of dedicated IT experts. Analytically, the application of competency models from related areas of research support provided by research management and administration, librarians and information professionals, such as the bibliometrics competency model (Cox, Gadd, Petersohn & Sbaffi, 2019), is a promising approach that will be adapted to the field of IT-supported research reporting with a rigorous foundation in the latest developments of research in professional competency (Schelske & Thiedig, 2019). Finally, contextualization with the results of an upcoming online survey on IT-based research reporting in German Higher Education and Research organizations will not only yield further insights into the practices, task areas and competency profiles of personnel in IT-based research reporting beyond their formalization in job advertisements, but also into the kinds and amount of use of research information collected in CRIS and other data bases in institutional (decision-making) contexts – a subject that, so far, little is known about for German research institutions (Hillebrandt, 2020).

Abstract

The recent literature on interdisciplinarity in quantitative science studies focuses on the development and interpretation of measures of diversity. These measures consider the mutual similarity or distance between disciplines in the applied subject scheme. Most of the studies on this topic are well aware of the importance of the choice of the proper classification scheme as it may lead to large differences in the obtained diversity scores. The central objective of the present study is to investigate the underlying properties of distinct similarity matrices used as starting point in quantifications of disparity. The study screens ten combinations of three different classification schemes and five implementations of citation or reference-based similarities using a version of a cosine similarity. In addition, each of the ten combinations are calculated for nine sliding time windows. The ten combinations are scored on different evaluative criteria both of quantitative and qualitative nature: *stability*, *discriminative power*, *density*, *skewness and deviation* and *ease of calculation*. The study provides the required tools for an informed choice on the appropriate similarity measures in future research on and application of diversity measures. Based on the investigated criteria, the study favors the use of bibliographic coupling on a medium-resolution granularity subject classification.

Introduction

In quantitative science studies of interdisciplinarity, the measurement of diversity takes a prominent place. The concept was proposed by scientometricians in analogy to its application in ecology (e.g., Macarthur, 1965) and still there is a spill-over from the latter field to scientometrics. Thus, the relevant work from ecologists, most notably that by Jost (2006, 2007 and 2009) and Leinster & Cobbold (2012) is often cited in the scientometric literature (e.g. Wang et al., 2015; Zhang et al., 2016), who stated that "*choices of different subject schemes may lead to different diversity results*" and demonstrated this at both the level of individual paper and at the aggregated level of scientific journals. It would be remiss to mention in this context, that the question of the choice of the aggregation level for the measurement of diversity forms part of the subject of a separate study by Huang et al. (2021). This is the reason, why we do deal with this issue in our recent study. Furthermore, we will not focus on the development or the improvement of existing indicators for measurement in the context of IDR, either. The central issue of the present study is laid on the scientometric methods *underlying* the quantification and measurement of diversity in IDR. This issue is twofold; on the one hand, one has to choose the particular (dis-)similarity measure to define the distance (similarity) between individual disciplines and, on the other hand, one has to select the scientometric method for analysing the links leading to the knowledge integrated into the interdisciplinary documents under study. The latter aspect is commonly used in the context of cognitive links that are manifested as citation and/or textual relationships in the published scientific literature. The particular objective – be it document-clustering exercises or network analysis – is in this connection secondary. In the present study we will use bibliographic coupling (BC), co-citation (CC) and direct citation/cross-citation (CRC) and their combinations. But analogously to the mapping-of-science exercises, also a combination with text-based similarities (cf. Glänzel & Thijs, 2011) are possible to improve the results, most notably in fields, where citations in periodicals play a less significant role as, for instance, in the humanities and in several disciplines in the social sciences.

A further aspect emerges when applying scientometric methods to IDR studies; apart from the already mentioned aggregation level, the issue of granularity emerges as well. This refers to the question of at what subject level interdisciplinarity is to be investigated, a fine-grained topic level, the more moderate sub-field or discipline level or the more general view at the larger research areas. As this raises not only technical questions but also conceptual ones, granularity related issues are discussed in detail in a separate study by Gänzel et al., (2021). Nonetheless, we will extend our analysis to three different levels of granularity within the Leuven-Budapest subject-classification scheme to give evidence of the significance of this issue.

In the study, we will analyse a combination of various methodological settings and using a large dynamic document set retrieved from the three main journal editions of Clarivate Analytics Web of Science Core Collection to find an optimum solution for the implementation of similarity measures in studying the aspects of variety and disparity in interdisciplinarity.

Methodology and Data

Data Source

All documents indexed as articles, letters or reviews in the three journal editions (SCIE, SSCI, A&HCI) of the 2006-2018 volumes of the Web of Science Core Collection (WoS) have been extracted from this database. The data set contains more than 24.4 million so-called citable publications of types 'article, letter or review'. References indexed with the publications are processed and matched with both the cited paper and with similar references in other publications. Each publication is labelled in three classification systems.

Classification Schemes

Three different levels of classification, each with a distinct level of granularity are selected. At the most fine-grained level are the subject categories from the Web of Science Core Collection also known as 'Web of Science Categories'. This classification system holds 255 subject areas, and each journal indexed in this database is assigned to one or more of these subject categories. The system is dynamic as categories can be added yearly (*'Audiology & Speech-Language Pathology'*, *'Nanoscience & Nanotechnology'*) or can become obsolete (*'Biology, Miscellaneous'*). Changes in the system are not in retrospect applied to issues of journals already indexed earlier in the database.

For the analysis at the meso-level, we use the 74 disciplines or subfields of the updated Leuven-Budapest scheme (Glänzel & Schubert, 2003; Glänzel, Thijs & Chi, 2016). The scheme applies a hierarchical system on top of the Web of Science categories. This system is less prone to changes as the total number of disciplines remains stable. Of course, dynamics at the level of individual journals are captured through yearly assignments, allowing shifting profiles over time.

The highest level of aggregation comes from the 16 major subject fields from the same Leuven-Budapest scheme.

The choice of a particular classification scheme is in concordance with the fixed framework assumption stated by Rousseau (2019) and requires that the classification scheme used for final disparity or diversity calculations cannot be altered through the deletion or addition of any particular class.

Similarity Measures

This study proceeds from a vector space model. One of the applicable native similarity measures in a vector space is the uses the cosine measure, which is actually the cosine of the angle between the reference/citation vectors representing the two documents formed by the scalar product of the two vectors divided by the product of their lengths (see equation below). Moreover, in a Boolean vector space as defined by bibliographic coupling and co-citations between individual documents, the cosine measure becomes simply identical with Salton's measure, i.e., the number of joint references/citations divided by the geometric mean of the total number of references/citations of the two documents. Note that this approach applies to individual documents, while cross-citation measures, although methodologically based on direct citations, are applied to document sets and, therefore, require a different approach, particularly for two reasons: The underlying (direct) citation links are not symmetric and unit self-transactions often result in matrices with dominant main diagonals. We will use the formula proposed by Lin et al. (2015) to avoid possible biases caused by this effect (see second equation below).

Based on the choice of underlying citation link a different matrix is subject to this calculation. At each level of classification, a vector is created for the distinct subject classes, and a scalar product is taken between the vectors, here denoted by a and b.

$$similarity(\boldsymbol{a}, \boldsymbol{b}) = \frac{\sum_i^n a_i \, b_i}{\sqrt{\sum_i^n a_i^2} \sqrt{\sum_i^n b_i^2}}$$

1. *Bibliographic Coupling (BC):*

   The elements (i) of the vector representing a (sub)field in the vector space are integer values, which express the number of references to documents in the database. In particular, these elements take the values 1 or 0 according as the document *i* is cited or not. The length of the vector is equal to the number of citable documents in the database.

2. *Indirect Bibliographic Coupling (BC^{ind}):*

   The elements (i) of the vector representing a (sub)field in the vector space are integer values, which express the number of references to all documents assigned to a particular (sub)field in the database. These elements take the values 0, 1, 2, … according to the absolute frequency of the cited references. The length of the vector is equal to the number of (sub)fields in the applied classification scheme. This approach is referred to as *indirect bibliographic coupling* as it links (sub)fields through the field classification of the shared references. This is an indirect link as it allows two (sub)fields that do not refer to the same publication at all to be linked and it introduces a *partial* aggregation, i.e., on the side of the references. The implementation outlined here is similar to that proposed by Leydesdorff and Rafolds (2009) for the creation of global science maps.

3. *Co-Citation (3-year citation window) (CC^{3yr}):*

   The elements (i) of the vector representing a (sub)field in the vector space are integer values, which express the number of citations from documents in the database. Only citing documents indexed in the same year as the cited document or in the two subsequent years are taken into consideration. The elements take the values 1 or 0 according as the document *i* has cited the document or not in this citation window. The length of the vector is equal to the number of citing documents in the database in the period.

4. *Co-Citation (Open citation window) (CCO):*

The elements (i) of the vector representing a (sub)field in the vector space are integer values, which express the number of citations from documents in the database. All citing documents, without any restriction with respect to the year of indexing are considered. The length of the vector is equal to the number of citing documents in the database.

5. *Cross-Citation (CRC):*
While BC and CC are based on individual-document relationships, which can be aggregated to any level, in our study to the subject level of different granularity, cross-citation links, as a combination of references and citations derived from direct citations, are defined on document sets. The elements (i) of the vector representing a document set, i.e., a field or discipline, in the vector space are integer values, which express the number of references and citations to all documents assigned to a particular field in the database. The length of the vector is equal to the number of fields or disciplines in the applied classification scheme. As similarity is usually understood as a symmetric relationship, the resulting matrix needs to be symmetrised. The field or class vector contains binary values that denote whether the field is at the citing or cited side of a particular reference. The length of the vector is equal to the number of references in the database. In fact, the vectors are rows in the incidence matrix describing the undirected and unweighted version of the citation network between the subject fields. This implementation of the cosine similarity results in exactly the same measure as the similarity based on the normalised cross-citation matrix (Zhang et al., 2016) which is as follows

$$s_{ij} = \frac{c_{ij} + c_{ji}}{\sqrt{(TC_i + TC_i)(TC_j + TR_j)}} \; (with\, i \neq j)\,,$$

where i and j refer to subject fields, (c_{ij} + c_{ji}) denotes to the number of cross-citations between subjects i and j and *TC* (*TR*) the total number of citations received by (given to) the subject i and j, respectively from (to) all other subject fields. This formula is also used by Wang and Schneider (2020) in their study on the inherent relation among interdisciplinary measures.

Selected combinations

From the 15 possible combinations of granularity levels provided by the Leuven-Budapest classification scheme and the proposed similarity measures, ten have been selected for further analysis. These ten combinations are summarised in Table 1. (Direct) bibliographic coupling is calculated for all three schemes. The two variants of co-citation are applied on the two levels of the Leuven-Budapest scheme as is cross-citation. The indirect version of bibliographic coupling is restricted to the 74 disciplines. As nine publication windows are used for each selected combination, the study is finally based on 90 different datasets. For the complete Leuven-Budapest scheme consult the Appendix and Clarivate Analytics database website (Clarivate Analytics, 2021) for the underlying about 250 WoS categories.

Publication Windows

Nine distinct but overlapping publication windows of three years are used. The first window comprises publications between 2008–2010, the followed by 2009–2011, then 2010–2012, … until the last one 2016–2018. This scheme provides a kind of 'moving average' approach with slightly smoothing the observed trends. As a result, 90 different similarity matrices are used in this study.

Table 1. Selected combinations of classification schemes and similarity measures

Classification Scheme	BC	BC^{2nd}	CC^{3yr}	CCO	CRC
16 Major Subject Field	*BC_16*		*CC^{3yr}_16*	*CCO_16*	*CRC_16*
74 Disciplines	*BC_74*	*BC^{ind}_74*	*CC^{3yr}_74*	*CCO_74*	*CRC_74*
255 Subject Categories	*BC_255*				

Evaluation Criteria

Before we present the properties of the different combinations, it is reasonable to discuss the different criteria that will be taken into consideration when evaluating the appropriateness, applicability and usability of these implementations of the similarity measures at different levels of granularity. Both quantitative as qualitative criteria are relevant in this context.

Stability

The interpretation of this first criterion is two-fold. We interpret stability primarily in terms of dynamic robustness, that is, as stability of the distribution of the indicator over time. This includes that changes in general descriptive statistics remain within reasonable boundaries. Large changes or fluctuations would influence the final scores that will be obtained. Hence, this time-based instability is to the detriment of the validity of the statement with respect to the dynamics of final scores. This also implies that the same baseline and reference standards may be applied to different periods.

On the other hand, as subject fields are dynamically evolving and so are the relationships between the fields, the underlying similarity matrices calculated over different periods must be able to capture and mirror those in an adequate manner. Stability should not evolve into high rigidity.

Discriminative Power

Also, this criterion is twofold as it indicates the degree to which the similarity is able to assign different scores to pairs of different subjects and, on the other hand and as a matter of course, different scores must be associated with differences in the strength of the relationship between subjects. As such, the discriminative power of a particular implementation of the class similarity also relates to the ability to detect the dynamics in the relations between (sub-)fields and should be balanced with the stability.

Density

The similarity matrix between the different classes at any granularity level can be considered as the weighted adjacency matrix of the network. Non-zero elements indicate the presence of a link between the subjects. At the global level, the density of the network indicates the number of present links compared to the number of possible links. In this study, the matrix representing the network should be as complete as possible, i.e., the number of zero-elements needs to be minimized. Given the dynamics of science, we cannot exclude that non-existent links between two disciplines will never emerge. Interdisciplinarity and new emerging topics are the most striking examples for such changes. And, as the similarity between subjects is often used in the denominator of the calculation of the indicator, setting the value to zero would result in infinite indicator values.

Skewness and deviation

These two statistical functions reflect important properties of empirical distributions in general. As such, they describe the shape and the asymmetry of the distribution of the similarities in our case. Large standard deviations of the similarity distributions combined with low skewness support the discriminative power at the level of individual pairs of disciplines or fields.

Ease of Calculation

Last but not least, the "computability" of the indicators remains an important criterion of applicability and replicability. This criterion particularly refers to the amount of data required to calculate the matrix and to the availability of the data.

Results

The first results with the descriptive statistics for the comparison of the ten selected scenarios and two different time frames are presented in Table 2. Both the mean of the similarity and the density of the network is given.

Table 2. Mean similarity and network density for 10 selected combination given for the first and last 3-year time period considered

	Mean Similarity		**Density of the network**	
	2008-2010	2016-2018	2008-2010	2016-2018
BC_16	0.073	0.100	100%	100%
BC_74	0.024	0.033	97%	99%
BC_255	0.051	0.050	14%	22%
BC^{ind}_74	0.054	0.066	100%	100%
CC^{3yr}_16	0.090	0.098	100%	100%
CC^{3yr}_74	0.067	0.073	100%	99%
CCO_16	0.098	0.098	100%	100%
CCO_74	0.034	0.033	100%	99%
CRC_16	0.042	0.044	100%	100%
CRC_74	0.010	0.009	97%	98%

The first striking observation is that nine out of the ten combinations result in a complete or near-to-complete network. Only the density of the network at the lowest level of granularity with values from 14% to 22% is much lower. This means that most links between subject categories are not present in the selected time windows. As mentioned above, such an absence of pairs of categories in the matrix might pose problems in the calculation of indicator values as it results in undefined indicators. Some of the scenarios do not show any evolution in their mean score. This is the case for the open-ended Co-Citation (CCO), for the Bibliographic Coupling at the level with the finest granularity and for the Cross-Citation. This reflects extreme stability of the obtained similarities but neglects possible structural dynamics that might occur. Breaking down the 16 fields in the ECOOM classification system to the 74 disciplines versions lowers the mean scores. A further breakdown of the 255 subject categories creates multiple edge cuts in the network removing the lowest weights. This explains the higher mean value as non-edges are not set to zero and considered missing values.

In a next step, probability density functions (PDF) are calculated for all ninety distribution. These functions specify the probability that a value or observed similarity is within a particular range. More formally, this probability would be the result of the integral of that distribution taken over the specific range. Figures 1, 2 and 3 plot these functions for the ten different combinations.

All ten plots confirm the different patterns presented in Table 2. The first four plots in Figure 1 show the PDF for the bibliographic coupling-based combinations. It is immediately clear that the choice of classification scheme has an enormous impact on the obtained similarity measures.

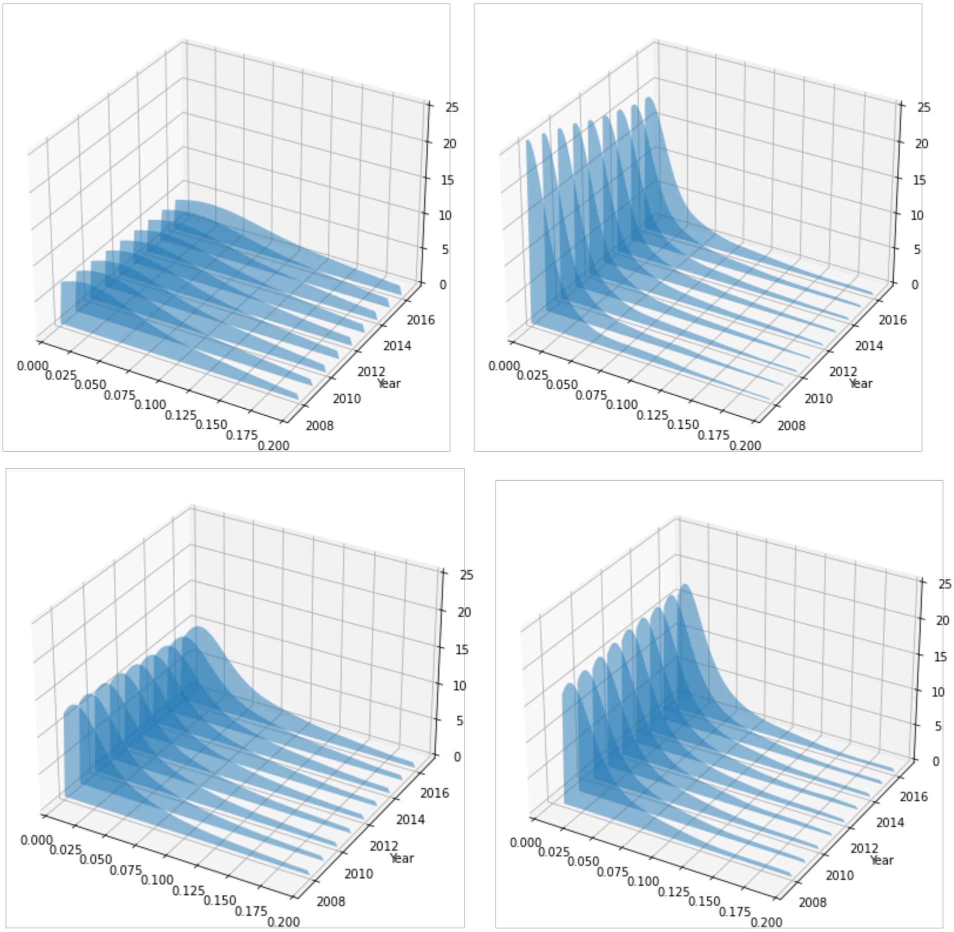

Figure 1. Probability Density Function of the similarities using bibliographic coupling (top left: *BC_16*, top right: *BC_74*, bottom left: *BC*^{ind}*_74*, bottom right: *BC_255*).

The plot in the top-left corner of Figure 1 uses the 16 fields in the ECOOM classification and has a very flat distribution with high standard deviation and low skewness. This is contrasted by the more skewed distribution of the 74 disciplines alternative in the top-right corner. These plots support the capabilities of this combination to capture structural changes. High-rank correlations between the time slices support claims on the stability of this option.

The indirect version of bibliographic coupling on 74 disciplines, bottom-left in Figure1, shows more variation of the scores. The dynamics are retained but less pronounced, and the mean value only increases by 21% compared to 37% in the (direct) BC. The standard deviation starts with a higher value and the skewness is lower. This approach, however, suffers from a more complex calculation.

The Bibliographic coupling with the about 250 subject categories has a similar pattern of the probability density functions. The pattern is only calculated for the existing, non-zero values.

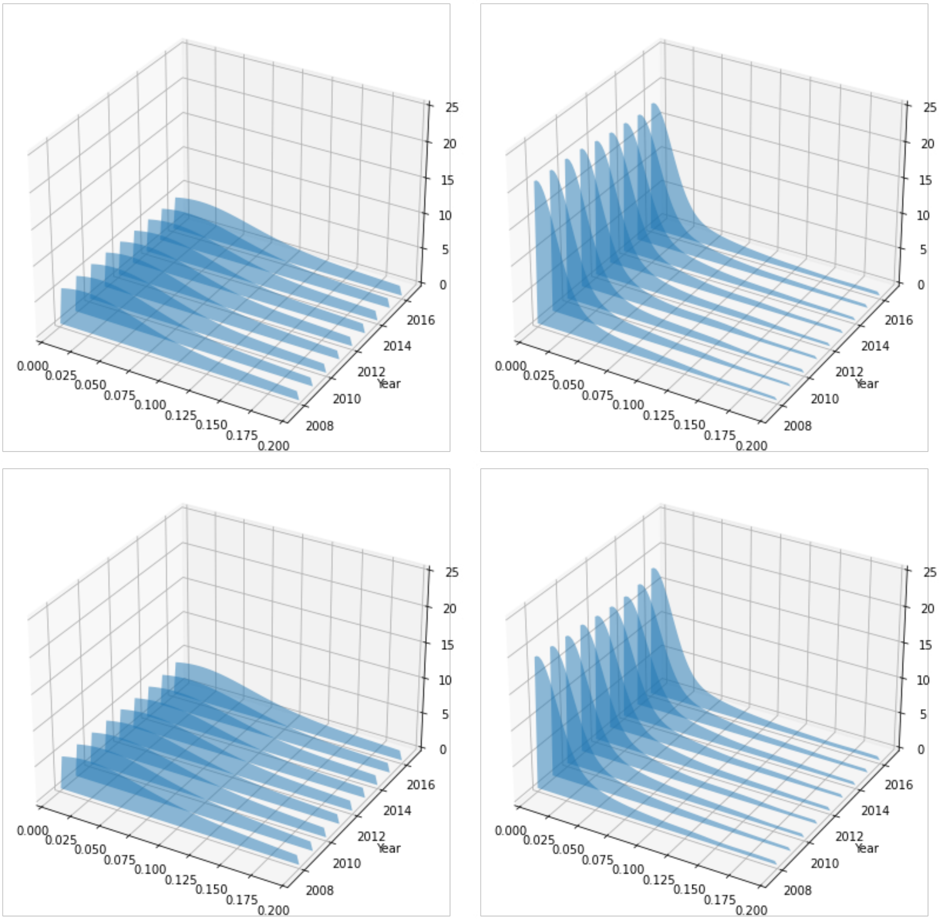

Figure 2. Probability Density Function of the similarities using Co-Citation (top left: *CC*^{3yr}*_16*, top right: *CC*^{3yr}*_74*, bottom left: *CCO_16*, bottom right: *CCO_74*.

Figure 2 holds the four alternative versions of the Co-Citation based approach. The plots on the top are based on a three-year citation window, while the bottom row holds the approaches with an open citation window. The differences in flatness between left and right in Figure 2 is analogous to the top row in Figure 1. It is based on the distinction between the 16 and 74 classes in the applied classification scheme. The effect of the applied citation window is marginal. All four plots show a quite rigid pattern of the similarity distributions and underpin the lack of the ability to capture structural changes over time.

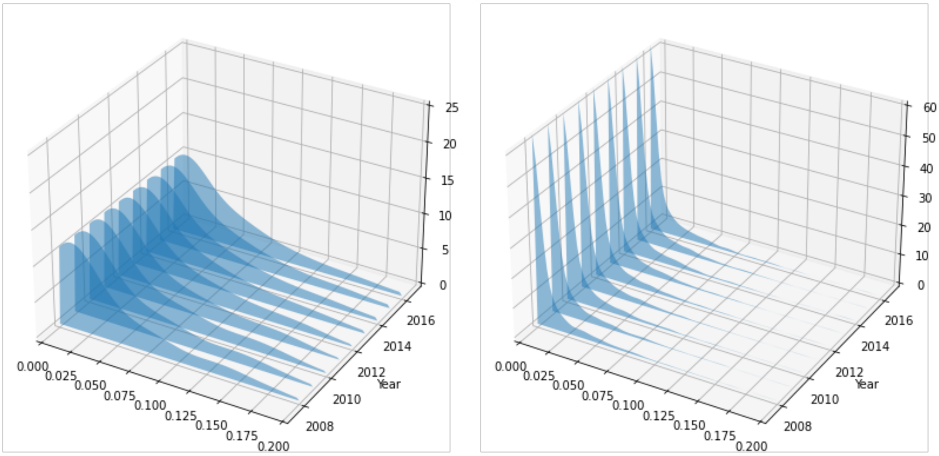

Figure 3. Probability Density Function of the similarities using Cross-Citation (left: *CRC_16*, right: *CRC_74*)

The last two plots are presented in Figure 3. These distributions are more skewed than any of their counterparts with the same underlying classification scheme. In fact, the plot on the right-hand side has an extreme pattern with a steep spike close to zero indicating that almost all obtained similarity scores are very small. This distorts the discriminative power.

Table 3. Summary of the performance of the 10 combinations on five evaluative criteria

	Stability	*Density*	*Discriminative power*	*Skewness & Std Dev*	*Ease of calculation*
BC_16	X	X			X
BC_74	X	X	X	X	X
BC_255	X		X	X	
BC$^{\text{ind}}$_74	X	X	X	X	
CC$^{\text{3yr}}$_16		X			X
CC$^{\text{3yr}}$_74		X	X	X	X
CCO_16		X			X
CCO_74		X	X	X	X
CRC_16		X		X	
CRC_74		X			

Finally, Table 3 provides a summary of the scoring of the ten different scenarios on these five criteria. As mentioned above, these criteria have not only a pure quantitative nature but also require a more qualitative interpretation.

Conclusions

The first observation from the presented analysis relates to the broad range of distributions that are obtained with different combinations of classification schemes and similarity measures. Consequently, this confirms the importance of the proper choice of combination as already raised in the introduction. This choice will have substantial consequences on the final implementation of the disparity and variety measures. Based on the provided material, researchers and users can make the appropriate choice of both classification scheme and similarity measure for their particular application of the diversity score.

Taking all properties and characteristics of each of the combinations into account, this study favors the bibliographic coupling at the level of the 74 disciplines as the most appropriate. This combination provides a nearly complete network. It captures the dynamics in the underlying structure and is still relatively easy to calculate.

Acknowledgments

The research underlying this study is funded by the bibliometric part of the multi-year ECOOM project "Interdisciplinary research & Impact" for the Flemish Government (2019–2023). The authors wish to acknowledge this support.

Abstract

This work presents a retrospective view into forecasts of artificial intelligence (AI) and machine learning (ML) research areas from 2014 to 2017. With the rapid increase of AI and ML technologies being implemented across a wide range of domains, it is important for planners to understand the evolving landscape of AI/ML research. Specifically, planners need information on which areas of AI/ML research to invest in or divest from. Using an automated structuring of scientific research publications from the Scopus database, subsets of broad research areas are defined as research communities and generated from direct citation links in scholarly literature. We select four main categories of AI/ML research (computer vision, miscellaneous AI/ML, natural language processing, and robotics) and investigate which research communities are predicted to grow or decline using a three-year forecasting model. Our informative forecast model achieves a precision of 0.87 and a recall of 0.48 when predicting the growth of the 154 AI/ML-related research communities in 2014.

Introduction

Artificial intelligence and the underlying machine learning technologies driving it (hereafter abbreviated AI/ML) are widely viewed as disruptive forces in today's economy (Wang, 2020). Research analyzing news article mentions of AI/ML highlights the rapid increase in AI/ML references since 2014, indicating that public awareness of new innovations is also recently expanding (Chuan et al., 2019; Fast & Horvitz, 2017). If you had to make AI/ML research investment decisions in 2014, which specific areas would you have predicted to have exceptional growth? How do you choose which areas to invest in? Do you support the most prestigious researchers in the field or those who have made a recent breakthrough? Given lingering questions around AI/ML safety and its future impact on the human experience, the consequences of these decisions are high (Boström, 2014; Russell, 2019).

We present a model, with a calibrated performance record, to help inform longer-term investment and divestment decisions in emerging technology. This forecasting model, introduced by Klavans et al., provides a predicted growth metric for research areas in all of science using Scopus publication data (Klavans et al., 2020). A similar forecasting approach is commonly used in weather predictions, where one needs to evaluate whether emerging storms will (or will not) cause serious damage in three days. Building on these techniques, our model predicts with comparable levels of accuracy which emerging technologies will (or will not) experience extreme growth in three years.

The data-driven research investment input we present here is useful to research leaders, strategic planners, and program managers who need to take into account fundamental research advances and emerging technology development as part of their job responsibilities. We refer to this group of individuals as planners throughout this paper. Forecasting research area growth is designed to help inform decisions, especially when emerging research areas change rapidly and planners are inundated by experts seeking support of their own agendas. By providing a planner with detailed overviews of research communities, they become equipped with comprehensive knowledge that when used in conjunction with their expertise, leads to effective judgements.

In this work, we introduce a method designed to support these decisions within the area of AI/ML research specifically. Each research investment opportunity can be considered a forming storm cell—yet unclear whether it will grow into a full fledged storm. There are various reasons that any given research area stagnates or declines in growth; not all these reasons are indicators that the research area should be abandoned or have their funding withdrawn. For example, a research area could lose the attention of top researchers when it becomes sufficiently applied to the extent that research questions in that domain are no longer compelling. This may indicate that the research community in question requires a different type of investment to achieve desired outcomes.

Prior research has focused on generating large-scale research community networks, analyzing emerging research areas, and characterizing a specific area of research (Boyack et al., 2020; Boyack & Klavans, 2019; Rotolo et al., 2015; Small et al., 2014). However, to the best of the authors' knowledge, our work is the first retrospective forecasting study, specifically on a detailed topic level. AI/ML presents a relevant and compelling case study for retrospective forecasting because of its quickly evolving nature and its increasing integration into new domains.

Our work focuses explicitly on growth forecasts, and we leave detailed interpretations of the best next steps based on our forecasts to future work. We first outline the methods used to implement our model, summarize the structure of the AI/ML research community in 2014, make predictions about which research communities will experience extreme growth, and then evaluate the three-year forecasts in 2017. The research communities with exceptional growth (those that have become full-fledged storms) are identified, along with the nations, labs, and authors leading in these emerging areas.

Methods

In our work, the concept of a research community (RC) is defined by communication patterns (i.e., citations) between researchers and approximates the community explicitly or tacitly working on defined problems (Kuhn, 1970). Using the Scopus database, an automated structuring of the 2014 research landscape identified more than 90,000 research communities from over 30.9 million indexed publications from 1996-2014 (Klavans & Boyack, 2017). Forecasts about RC growth were computed using data on age, citations, sources, and year of peak growth (see (Klavans et al., 2020) for full details). In order to provide research area investment or divestment recommendations, we label RCs based on their broad research areas, identify AI/ML-related RCs, describe the AI/ML RCs, and interpret growth forecasts.

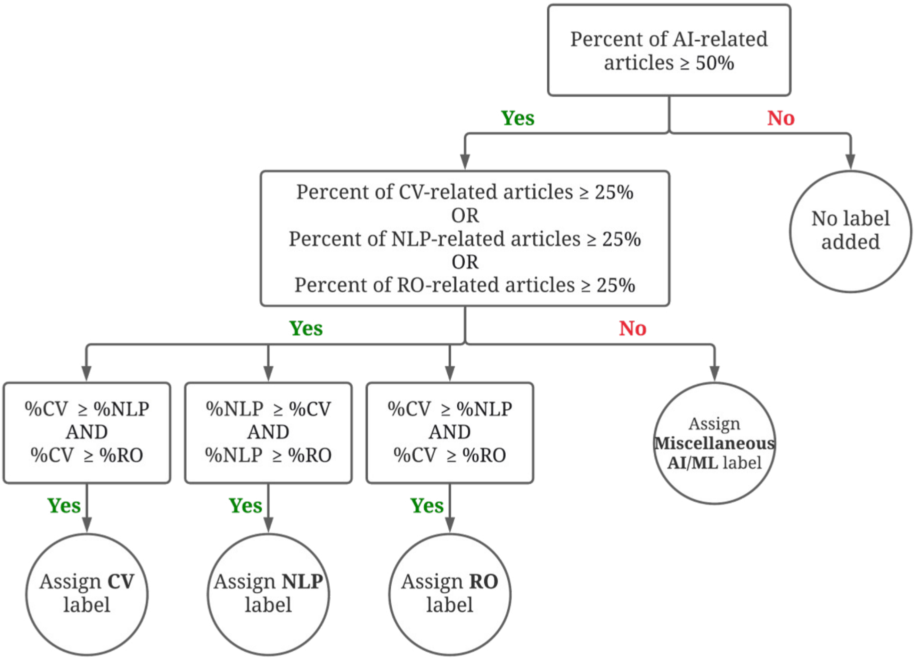
RC labels

Each RC represents a focused subset of scholarly literature derived from a broad research area (e.g., Mathematics). We define broad research areas by grouping related RC documents based on term similarity and labeling the highest level classification based on dominant journal counts using the UCSD science map categories. We label 12 broad research areas: biology, brain science, chemistry, computer science, earth science, engineering, health science, humanities, infectious diseases, medicine, physics/mathematics, and social science. This initial labeling allows us to understand the broad areas of research where AI/ML-related RCs are most active.

AI/ML RCs

To identify AI/ML-related RCs, we first classify AI/ML-related articles in the Scopus database. We apply a SciBERT predictive model trained on arXiv articles (abstract and titles) on the Scopus database (Beltagy et al., 2019; Dunham et al., 2020). SciBERT is a pre-trained language model derived from BERT (Devlin et al., 2018) and is specifically trained on scientific literature text data to support natural language processing tasks, such as classification, in the scholarly literature domain. Dunham et al. implement the SciBERT model on arXiv paper titles and abstracts and train the classifier to identify AI/ML-related articles. Articles published on arXiv are assigned research area labels by their authors. If an article has at least one label of cs.AI, cs.LG, cs.MA, or stat.ML Dunham et al. classified the article as AI/ML; all other research area labels were considered to be non-AI/ML (Dunham et al., 2020).

Dunham et al.'s classifier assigns an AI/ML label, as well as three additional labels for subsets of AI/ML research: computer vision (CV), natural language processing (NLP), and robotics (RO). However, the classifier is not restricted to assigning only one label—an article can be classified as multiple subsets of AI/ML (e.g., CV and RO). We consider an RC to be AI/ML-related if it contains 50% or more AI-related articles. Additionally, if an AI/ML-related RC has 25% or more CV-, NLP-, or RO-related articles we label that RC with the dominant subset of AI/ML; Figure 1 displays a formal diagram of how AI/ML-related RC assignments are made.



Percent of AI-related articles ≥ 50%
Yes
No
Percent of CV-related articles ≥ 25%
OR
Percent of NLP-related articles ≥ 25%

No
%CV ≥ %NLP AND %CV ≥ %RO
%NLP ≥ %CV AND %NLP ≥ %RO
%CV ≥ %NLP AND %CV ≥ %RO
Assign Miscellaneous AI/ML label
Yes
Yes
Yes
Assign CV label
Assign NLP label
Assign RO label

Figure 1. Diagram of AI/ML-related RC assignment.

Interpreting forecast output

Each RC has a predicted growth metric generated by the forecast model, as defined in (Klavans et al., 2020), where an 8% RC annualized growth over three years is considered extreme growth. No additional classifications of growth percentages are labeled. We consider annualized growth percentages that are less than 8% and greater than 0% to be standard growth and growth percentages less than 0% to be declining growth. Table 1 displays the annualized growth percent ranges for each label of growth we reference in the following sections.

Table 1. Growth type labels and characteristics

Growth label	*Annualized growth range (%)*	*Number of AI/ML RCs*
Declining	[-∞, 0)	79
Standard	[0,8)	60
Extreme	[8, ∞)	15

AI RC context

In 2014, 154 research communities were relevant to AI/ML. Of these, 90% of the AI/ML research publication activity was shared within the computer science (CS) literature. Figure 2 displays the AI/ML-related RCs in the context of all of science. The subfigure in the top left corner is the graph of the automated structuring of all RCs in the Scopus database from Klavans et al. (2020), where each dot represents and RC. The location of RCs in Figure 2 is determined by RC citation links, meaning that RCs that have many citation links in common will be closer together. The size of a given RC in Figure 2 corresponds to the number of papers it has in 2014 and the color corresponds to the RC's broad research area label. The main figure highlights AI/ML RCs in the context of all of science, which shows that the majority of AI/ML RCs are in computer science.

We divide the AI/ML-related RCs into the four subset research areas:

1. computer vision, (82 CS and 6 earth science communities),
2. robotics (21 CS and 1 brain science communities),
3. natural language processing (8 CS communities), and
4. miscellaneous AI/ML explorations (36 CS communities).

Planners need to know what communities were likely to have extreme growth and those most likely to shrink. We summarize research community recommendations, based on growth predictions, in the Results section. Of the 154 AI/ML research communities in 2014, 87% of the extreme growth forecasts were accurately predicted for 2017 (i.e., the precision was 0.87). Furthermore, we were able to (in 2014) correctly predict 48% of all RCs that experienced extreme growth in 2017 (i.e., the recall was 0.48).

We use a common weather prediction measure, the Critical Success Index (CSI) (Schaefer, 1990), where CSI = true positives / (true positives + false positives + false negatives), to measure our ability to predict areas of extreme growth. In this case, our CSI = 0.45 is 1.8 times better than the typical three-day weather forecast (CSI = 0.25). The performance of the forecasting model was not highly optimized in order to avoid overfitting future performance to the past, as unforeseen global events can trigger research growth or decline. For example, the COVID-19 outbreak undoubtedly created brand new RCs which our model would be unable to predict accurately. We include further details on the forecasting model performance scores on a public repository (https://github.com/georgetown-cset/AI-research-planning-retrospective-data).

Results

We present results for the four categories of AI/ML-related RCs: 1) Computer vision, 2) Robotics, 3) Natural language processing, and 4) Miscellaneous AI/ML. For each category, we display the RC growth and decline recommendations, as well as additional metadata about the RCs of note (top five highest contributing countries, institutions, and authors). A growth recommendation for an RC is deemed correct if the RC grows at least 8% per year between its most prolific publication year (2014 or before) and 2017—anything less than this extreme growth rate does not merit the recommendation. A decline recommendation is given when a RC's relative growth is predicted to be negative. Incorrect recommendations are highlighted in Tables 2, 4, 6, and 8.

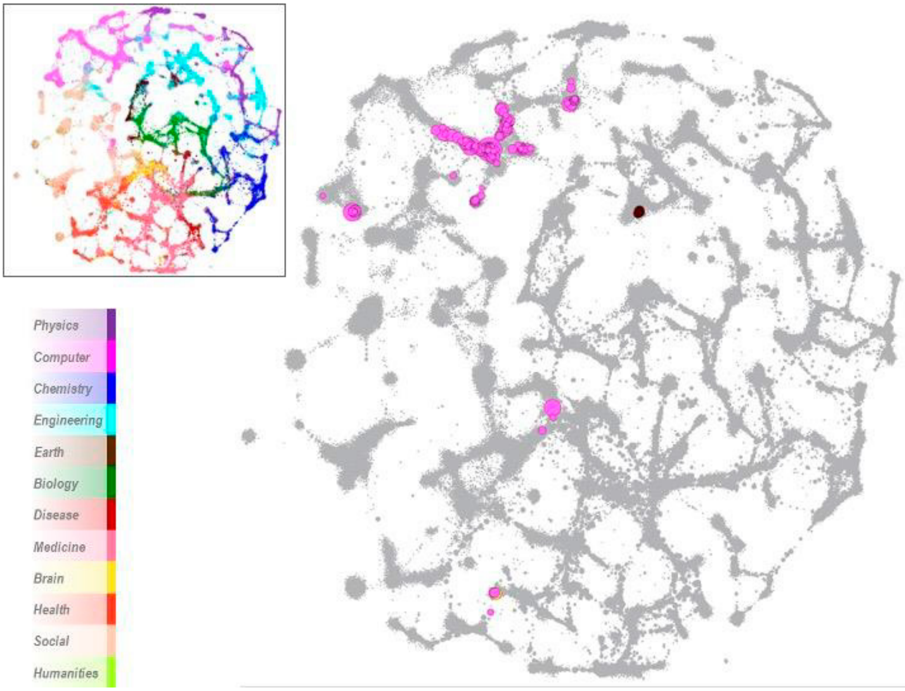

Figure 2. AI/ML-relevant research communities in the context of all of science.

Our results showcase how our forecasting model provides context of RCs and a predictive metric for planners to make a more informed decision about investing in or divesting from a given research area. More details on specific RCs, including information on funding organizations, top cited papers, and predictive features, can be found on a public repository (currently unattached for anonymity).

Computer vision

Computer Vision is an area of computer science and engineering that aims to train computers to gain high-level understanding from images or videos. There are 88 CV RCs, many of which were active and growing in 2014. Of the 88 CV RCs in 2014, 8% are predicted as extreme growth, 39% are predicted as standard growth, and 51% are predicted as declining growth. The top five computer vision RCs with expected extreme growth and expected declining growth are displayed in Table 2. Overall, 90% of the CV RCs are accurately predicted.

Compared to other AI/ML-related RCs (see Tables 4, 6, and 8), computer vision RCs have the highest estimated yearly growth and the "image classification, deep convoluted neural networks" RC has the highest actual yearly growth (103.2%). In the *Research Decline Recommendations*, we incorrectly predict a declining growth (indicated by the highlight in

Table 2) for the "lung cancer, computer-aided diagnosis, computer-aided detection" RC. We consider this a minimal error, as the actual yearly growth was 0.6%. The rest of the *Research Decline Recommendations* are accurate, as well as all of the *Research Growth Recommendations*.

Table 2. Top five computer vision growth and decline recommendations from 2014. Results ordered by estimated three-year annualized growth rate estimated in 2014.

RC#	*Descriptive phrases*	*# Papers (2014)*	*Est. yearly growth (%)*	*Act. yearly growth (%)*
	Research Growth Recommendations			
11244	image classification, deep convolutional neural networks	526	16.1%	103.2%
27987	hash functions, Hamming distance, compact binary codes	132	14.1%	27.5%
8360	scene understanding, scene labeling, convolutional neural networks	350	13.9%	25.9%
17235	image classification, image annotation, image search and retrieval, zero-shot learning	181	13.3%	42.2%
714	visual object tracking, target tracking	770	10.9%	1.7%
	Research Decline Recommendations			
3240	face modeling, facial animation, mouth animation	113	-10.1%	-7.7%
681	video summarization, video retrieval, key frame extraction	177	-9.6%	-5.0%
5826	image enhancement, image processing, anisotropic diffusion	101	-9.6%	-8.7%
7594	image resolution enhancement, image scaling, image interpolation	109	-9.3%	-7.4%
5967	lung cancer, computer-aided diagnosis, computer-aided detection	135	-9.0%	0.6%

Table 3. Top five producers of computer vision research by country, institution and author for the time period 2013-2017.

Country	*Institution (Country)*	*Author (Institution)*
1. China	1. Anna University (India)	1. Zhang, Liangpei (Wuhan University)
2. USA	2. Chinese Academy of Sciences (China)	2. Plaza, Antonio (University of Extremadura)
3. India	3. Tsinghua University (China)	3. Tian, Qi (University of Texas at San Antonio)
4. France	4. Wuhan University (China)	4. Lin, Weisi (Nanyang Technological University)
5. UK	5. Beihang University (China)	5. Shen, Dinggang (University of North Carolina)

We display the top five contributing countries, institutions, and authors across all computer vision RCs in Table 3. These results provide context for the top contributors of the computer vision research area. There is noticeably high contribution from China, and computer vision is the only area of AI/ML where France appears as a top five contributor.

Robotics

Robotics is an area of computer science and engineering research that aims to enable the effective design, construction, operation, and use of robots. In 2014, the robotics research area was relatively smaller (22 RCs) in its application of AI/ML methods than computer vision and had a smaller number of research communities expected to achieve extreme growth in 2017.

Table 4. Top five robotics growth and decline recommendations from 2014. Results ordered by estimated three-year annualized growth rate estimated in 2014.

RC#	*Descriptive phrases*	*# Papers (2014)*	*Est. yearly growth (%)*	*Act. yearly growth (%)*
	Research Growth Recommendations			
21668	soft robotics, continuum robotics, kinematics	119	9.3%	21.4%
	Research Decline Recommendations			
3831	robotic hand, grasp ability, multi-fingered hand	125	-7.3%	-4.1%
4159	self-reconfigurable robot, modular robot, adaptive robots	129	-7.1%	-4.3%
7117	dynamic walking, biped robot, target walking	121	-7.1%	-2.4%
2263	vision-based robotics control, image-based robotics control, mobile robotics	171	-7.0%	-3.8%
3227	robot manipulator, adaptive control, flexible joint robots	126	-6.8%	-4.2%

Of the 22 robotics RCs in 2014, 4% are predicted as extreme growth, 45% are predicted as standard growth, and 50% are predicted as declining growth. Overall, 91% of RO RCs have accurate growth predictions. Table 4 highlights the smaller scale of robotics research activity, as there is only one research cluster with predicted extreme growth. All growth and declining recommendations in Table 4 are predicted correctly.

We display the top five contributing countries, institutions, and authors across all robotics RCs in Table 5. Japan reaches its highest contributor rank in robotics RCs, and robotics is the only area of AI/ML research where South Korea appears as a top five contributor.

Table 5. Top five producers of robotics research by country, institution and author for the time period 2013-2017.

Country	*Institution (Country)*	*Author (Institution)*
1. China	1. Harbin Institute of Tech. (China)	1. Caldwell, Darwin G. (Italian Institute of Technology)
2. USA	2. Italian Institute of Tech. (Italy)	2. Tsagarakis, Nikos G. (Italian Institute of Technology)
3. Japan	3. Carnegie Mellon University (USA)	3. Kubota, Naoyuki (Tokyo Metropolitan University)
4. Germany	4. Mass. Institute of Tech. (USA)	4. Guo, Shuxiang (Kagawa University)
5. S. Korea	5. Beijing Institute of Tech. (China)	5. Vanderborght, Bram (Vrije Universiteit Brussel)

Natural language processing

Natural Language Processing (NLP) is an area of linguistics and computer science seeking to process and analyze large amounts of text and spoken language data to enable effective interactions between computers and human languages. NLP is the smallest area of AI/ML research with only 8 RCs in 2014. Of these 8 NLP RCs, 13% are predicted as extreme growth, 38% are predicted as standard growth, and 50% are predicted as declining growth. Overall, 88% of all NLP RCs have accurate growth predictions. Table 6 displays the one NLP RC with a growth recommendation and the three NLP RCs with declining growth; all recommendations are predicted correctly.

Table 6. Top five NLP growth and decline recommendations from 2014. Results ordered by estimated three-year annualized growth rate estimated in 2014.

RC#	*Descriptive phrases*	*# Papers (2014)*	*Est. yearly growth (%)*	*Act. yearly growth (%)*
	Research Growth Recommendations			
1417	sentiment analysis, opinion mining, sentiment classification	924	11.1%	16.9%
	Research Decline Recommendations			
4613	computational linguistics, human-computer interaction, spoken dialogue systems	108	-8.6%	-4.5%
4882	speech recognition, spoken queries, spoken term detection	136	-7.9%	-3.0%
1621	text classification, term frequency, text mining	393	-7.1%	-2.9%

In 2014, the number of NLP RCs is comparatively small to other AI/ML-related RCs, but the number of papers in the predicted extreme growth cluster (sentiment analysis) is the highest number of all AI/ML-related RCs with 924 articles.

We display the top five contributing countries, institutions, and authors across all natural language processing RCs in Table 7. NLP is the only research area of AI/ML where a UK university (University of Edinburgh) and a company (IBM) appear in the top five contributing institutions.

Table 7. Top five producers of NLP research by country, institution and author for the time period 2013-2017.

Country	*Institution (Country)*	*Author (Institution)*
1. China	1. Tsinghua University (China)	1. Cambria, Erik (Nanyang Technological University)
2. USA	2. Anna University (India)	2. Griol, David (Universidad Carlos III de Madrid)
3. India	3. IBM (USA)	3. Li, Haizhou (National University of Singapore)
4. Japan	4. University of Edinburgh (UK)	4. Yamagishi, Junichi (University of Edinburgh)
5. UK	5. Carnegie Mellon University (USA)	5. Molina, José M. (Universidad Carlos III de Madrid)

Miscellaneous AI/ML

The remaining 36 AI/ML areas cover a wide range of fundamental and applied research tasks. Of the 36 miscellaneous AI/ML RCs in 2014, 17% are predicted as extreme growth, 33% are predicted as standard growth, and 50% are predicted as declining growth. Overall, 89% of all miscellaneous AI/ML RCs have accurate growth predictions.

The top five miscellaneous AI/ML RCs with expected extreme and declining growth are shown in Table 8. In the Research Decline Recommendations, we incorrectly predict a declining growth (indicated by the highlight in Table 8) for the "music genre classification, music recommendation, music information retrieval, and music emotion recognition" RC. We consider this a minimal error, as the actual yearly growth was 0.3%; the rest of the growth recommendations are predicted correctly.

Table 8. Top five miscellaneous AI/ML growth and decline recommendations from 2014. Results ordered by estimated three-year annualized growth rate estimated in 2014.

RC#	*Descriptive phrases*	*# Papers (2014)*	*Est. yearly growth (%)*	*Act. yearly growth (%)*
	Research Growth Recommendations			
32953	extreme learning machine, neural network, incremental extreme learning machine	217	12.9%	18.1%
3437	decision making, intuitionistic fuzzy sets, multiple attribute decision makers	439	12.4%	8.4%
4155	activity recognition, fall detection, wearable sensors	594	10.5%	16.3%
10520	transfer learning, domain adaptation, unsupervised learning	206	9.8%	11.7%
16529	multilabel classification, multi-label learning	179	9.0%	12.3%
	Research Decline Recommendations			
4455	self-organizing map, neural network, topology learning	123	-9.7%	-8.4%
3125	feature selection, cancer classification, gene selection	217	-9.1%	-3.3%
5152	fuzzy rule-based systems, membership functions, genetic algorithms	101	-6.8%	-3.2%
6616	graph matching, pattern recognition, graph classification	121	-6.6%	-2.0%
4335	music genre classification, music recommendation, music information retrieval, music emotion recognition	164	-5.4%	0.3%

We display the top five contributing countries, institutions, and authors across all miscellaneous AI/ML RCs in Table 9. Similar to computer vision results (Table 3), the top five highest contributing institutions are located in China and India, even though the USA is listed above India in the highest contributing countries.

Table 9. Top five producers of miscellaneous AI/ML research by country, institution and author for the time period 2013-2017.

Country	*Institution (Country)*	*Author (Institution)*
1. China	1. Anna University (India)	1. Zhang, Liangpei (Wuhan University)
2. USA	2. Tsinghua University (China)	2. Plaza, Antonio (University of Extremadura)
3. India	3. Chinese Academy of Sciences (China)	3. Caldwell, Darwin G. (Italian Institute of Technology)
4. Japan	4. Harbin Institute of Tech. (China)	4. Tian, Qi (University of Texas at San Antonio)
5. Germany	5. Beihang University (China)	5. Lin, Weisi (Nanyang Technological University)

Conclusion

We have developed a prototype system to forecast growth of research communities in a large-scale highly detailed model of science. This prototype system offers a useful component of a strategic analysis capability. Currently, when planners are asked to make decisions about where to invest their resources in research and development, they lack the global perspective of scientific research as a whole and the estimated growth or decline of specific research areas of interest. Our work provides a unique view into research communities by including growth predictions and metadata about research communities of interest.

We focused our analysis on AI/ML-related research communities, since AI/ML research production is rapidly growing and integrated in many research and applied domains. Our forecasting approach achieved a precision of 0.87 and a recall of 0.48 when predicting the three-year growth of the 154 AI/ML-related research communities in 2014, which is better than most three-day weather forecasts, highlighting its usefulness. We note that these high precision and recall rates may not be maintained in other areas of science and acknowledge that unforeseeable world events are not captured in our predictive capability. Generally, however, our model and forecasting approach have already been evaluated broadly in other fields (Klavans et al., 2020) and have been shown to be a practical and valuable tool for planners who need to make well-informed decisions and currently lack certain important details about the scientific research landscape.

Abstract

We present a forecasting analysis on the growth of scientific literature related to COVID-19 expected for 2021. Considering the paramount scientific and financial efforts made by the research community to find solutions to end the COVID-19 pandemic, an unprecedented volume of scientific outputs is being produced. This questions the capacity of scientists, politicians and citizens to maintain infrastructure, digest content and take scientifically informed decisions. A crucial aspect is to make predictions to prepare for such a large corpus of scientific literature. Here we base our predictions on the ARIMA model and use two different data sources: the Dimensions and World Health Organization COVID-19 databases. These two sources have the particularity of including in the metadata information the date in which papers were indexed. We present global predictions, plus predictions in three specific settings: type of access (Open Access), NLM source (PubMed and PMC), and domain-specific repository (SSRN and MedRxiv). We conclude by discussing our findings.

Introduction

The average growth in journal articles published is estimated to be at around 3.0% per annum (Johnson et al., 2018) with an increase to 3.9% between 2006 and 2016. The total for developing countries grew more than twice as fast (about 8.6%) (National Science Board, 2018). Unsurprisingly, and given the scale of scientific output, one of the main research topics within the field of scientometrics has been the study of the growth of scientific literature. Indeed, in the 1960s Derek de Solla Price (1963) had already developed a model of the exponential growth of science in what is considered one of the seminal contributions to the field. Although his contribution was not the first attempt to do model growth (e.g., Coles & Eales, 1917; Hulme, 1923), it reflects the predominant role that the study of bibliometric distributions, dynamics of growth and ageing laws of scientific literature has had in the field.

According to Price's model, there are three distinct phases by which literature increases over time. In the first phase there is a slow increment of publications, followed by an exponential increase, and a third phase in which the curve reaches a saturation point. Since then, different studies have tried to refine his approach, by trying to identify the models which can accurately adjust growth curves for the observed increase in scientific literature (i.e., logistic, power or Gumpertz models)[1]. These studies reflect continued efforts to identify models and distributions which can best adjust to different types of scientific literature. Examples of such studies are those conducted by Egghe and Ravichandra (1992) who observe that Social Sciences literature

[1] An overview is provided by Fernandez-Cano et al. (2004).

appears to fit a Gompertz-S-shaped distribution, while other literatures follow a power law distribution. Similarly, Zhou (2010) analyses the growth of science in China, while Urbizagástegui and Restrepo (2015) apply exponential models to analyse the Brazilian literature.

In this paper we look at scientific growth in exceptional circumstances such as the COVID-19 pandemic. Scientific production on COVID-19 has rocketed in the last year (Torres-Salinas, 2020), reflecting the paramount effort that is being made globally both scientifically and financially to end the global pandemic and to minimize the negative consequences it is having on society. From the scientometric community, efforts have been made to describe the contents of new data sources liberated specifically on the topic of COVID-19 (Colavizza et al., 2020), to compare the coverage of different data sources (Kousha & Thewall, 2020), to analyze the effectiveness of scholarly communication in these pressing times (Homolaket al., 2020; Soltani & Patini, 2020), and its consumption in social media (Colavizza et al., 2020; Thelwall, 2020). The present study is integrated within this stream of literature, building on preliminary findings (Torres-Salinas et al., 2020), and aims to forecast the potential growth of COVID-19 literature to better understand the magnitude of data expected by scientists to cope with the flood of scientific knowledge being produced (Brainard, 2020). We present predictions on the number of COVID-19 publications for 2021. We base our predictions on the Auto-Regressive Moving Average (ARIMA) model and forecast growth in three specific settings. The specific objectives of the paper are summarized as follows:

1. To forecast the growth of publications on COVID-19 in two different databases: Dimensions and WHO.
2. To forecast the growth of publications on COVID-19 in three specific settings to explore the (dis)similarities between them. These are:
    - National Library of Medicine (NLM) databases: Pubmed and PMC
    - Domain-specific scientific repositories: medRxiv and SSRN
    - Type of access to the publications: Open Access and non-Open Access (paywall).

Material and methods

We make use of two different databases: Dimensions and World Health Organization (WHO). The former provides a COVID-19-specific dataset named "*Dimensions COVID-19 publications, datasets and clinical trials*" which is available on FigShare. This dataset contains information on four document types: publications, datasets, clinical trials and grants. In this study, we work only with publications, which have a volume of 168,053 records. The second database is the "*COVID-19 global literature on coronavirus disease*", produced by the WHO. In this case we collected metadata for a total of 113,563 records using the export results option that allows for the downloading of the complete database. These two datasets were collected in December 2020. Like Dimensions, the WHO database contains publications from different sources such as international databases (e.g., Pubmed, Elsevier), databases of international organizations (e.g., WHO COVID-19) and repositories (e.g., medRxiv, SSRN, etc.). One of the characteristics of these two specific databases is that they include for each record the exact date on which publications were indexed. In this sense, we have observed a two-day delay in the indexing dates for the WHO database with respect to Dimensions. This information allows us to establish the daily growth in the number of publications. Table 1 presents a summary of the main characteristics of both databases.

Three different datasets were generated for each database, producing a total of eight time series (Table 2). The first two time series account for the total number of records per day in each database. Two additional time series include the number of published Open Access (OA) and non-OA documents per day. The last four time series refer to the number of documents published by repository. We report predictions of growth for the following repositories: PubMed, PMC, medRxiv and SSRN.

The prediction of publication growth requires adequate tools to analyze historical data. There are several types of models that can be used for time-series forecasting. In this study we make use of ARIMA, which is a widely used forecasting method (Hyndman & Athanasopoulos, 2018). In the ARIMA model, only historical data of the variable of interest are used and forecasts are modelled as a linear combination of past observations and past error terms of the model (Hyndman & Khandakar, 2008). An ARIMA model is characterized by three parameters (p, d, q) where:

- p refers to the number of past values accounted in the model,
- d indicates the order of difference for attaining stationarity, and
- q specifies the number of error terms included in the model.

The ARIMA model can be used for non-stationary data, that is, for data in which the average and variance change over time. Since all eight time series exhibit a trend, the data are non-stationary and ARIMA handles non-stationarity by differencing subsequent observations. The necessary number of differencing to ensure stationarity is indicated by the parameter d. The three parameters are estimated from data, usually via maximum likelihood estimation (Hyndman & Athanasopoulos, 2018).

ARIMA models were fitted to the eight time series included in Table 2. All the analyses were conducted on an Ubuntu 18.04.1 machine, with R version 3.6.3 and RStudio version 1.1.456. The forecast analysis was carried out with a one-year window and specific results are offered for three-month windows. Along with point estimates, a 95% confidence interval accounts for the forecast uncertainty. Datasets and analyses of this study are openly accessible at https://doi.org/10.5281/zenodo.4478251.

Results

Evolution of COVID-19 scientific literature

The cumulated number of publications in Dimensions and WHO are presented in Figure 1. Dimensions indexed a total of 168,053 records and WHO a total of 118,200. As reported in Table 1, there are differences in the coverage of each source; while Dimensions covers records published in the last 10 months, WHO only does so for the last 8 months. Along with differences in size and period covered, we observe differences in the growth rate. In the case of Dimensions, it is more pronounced, especially from June onward. Both general time series fit a linear model, with R^2 values above 0.9 (R^2= 0.931 in WHO; R^2 = 0.851 in Dimensions).

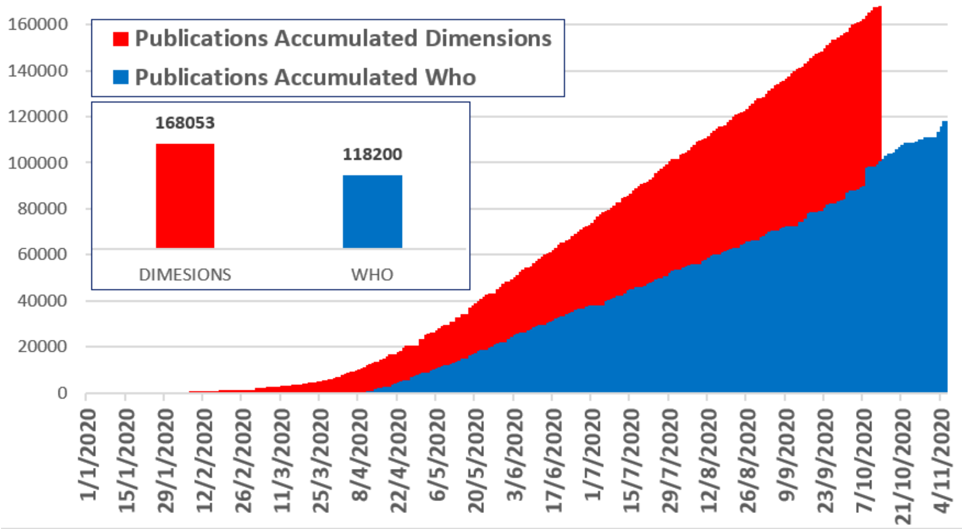

Figure 1. Accumulated number of records in Dimensions and WHO

Figure 2 shows the results for six time series. Figure 2A shows the results for Pubmed and PMC. These two repositories are the most prevalent sources in the Dimensions dataset, with PubMed alone including 47% of the share in this database (78,841 records). Figure 2B shows the time trend for medRxiv and SSRN. In this case we observe that both sources have similar volumes (7,002 and 6,002 records respectively) and a similar growth trend, with exponential growth until June 2020. Finally, Figure 2C compares the time series of OA and non-OA publications. Here the differences both in size and growth trends are very significant. OA literature is approximately five times larger than the non-OA and follows an exponential trend. In comparison, the growth of the non-OA publications is low.

Figure 2. Time trend on the accumulated number of records in NLM databases, main repositories, and open access (OA)

Forecasting

Figure 3 and Figure 4 present the predictions for the Dimensions and WHO time series. We include our predictions along their uncertainty bounds. As observed, the lower bound shows a deceleration of growth, while in the two other cases it reflects a sustained rate of growth over time.

	3 Months 11/01/2021	6 Months 11/04/2021	9 Months 11/07/2021	12 Months 09/10/2021
High	280101	410215	554895	708791
Forecasting	250870	333533	416905	499398
Low	221638	256851	278915	290006

Figure 3. Forecasted growth of overall publications in Dimensions for 2021. Predicted growth (green) and upper (red) and lower bounds (blue) accounting for a 95% uncertainty interval. Forecasts are provided every three months

According to the ARIMA model, the forecast is that by the beginning of October 2021, the number of COVID-19 publications will reach half a million (499,398) according to Dimensions, with an upper bound of 708,791 records. This means that we expect the volume of COVID-19 publications to double by June 14th, 2021. If we consider the upper bound, the number of publications will double by February 20th, 2021.

A similar growth trend is observed for publications in the WHO database (Figure 4); the forecast is that 389,418 publications will be reached by the beginning of November 2021. The most likely maximum number of publications that is expected to be reached in the WHO database is 559,404. Based on the total number of records included on the date the data was collected, we should expect this number to double on June 11th, 2021. If we consider the upper bound of the forecast, the number of publications will double on February 24th, 2021 with 236,282. In both cases, the dates of growth and figures are similar, with Dimensions doubling the number of records in 7.8 months (243 days) and the WHO database in 7.13 months (217 days).

	3 Months 05/02/2021	6 Months 06/05/2021	9 Months 04/08/2021	12 Months 06/11/2021
High	215433	320079	433091	559404
Forecasting	185945	252979	319544	389418
Low	156458	185879	205996	219432

Figure 4. Forecasted growth of overall publications in the WHO for 2021. Predicted growth (green) and upper (red) and lower bounds (blue) accounting for a 95% uncertainty interval. Forecasts are provided every three months

Publication settings

Table 3 complements the general predictions in Dimensions and the WHO databases. The data is disaggregated and filtered based on three different settings: 1) type of access, 2) NLM source, and 3) domain-specific repository.

There are a total of 132,281 OA publications in the dataset (Table 3A). We observe an increase of 40% in their volume by the 14th of September, 2021. But the most intriguing growth is that of non-OA publications. Starting at an initial size of 29,133 at the time of the data retrieval, we expect an increase by a factor of 3.7 in the six following months, and 6.2 a year later. This spectacular increase is given by the rapid increase during the last period of registered data, as observed in Figure 2C. The upper growth scenario multiplies the starting non-OA papers by a factor of almost 11.

Similar forecast growth estimates are registered for PubMed and PMC (Table 3B). We estimate both sources will double their number of publications in a year. These two databases currently have a significant number of documents indexed, thus the effort required to double their size. Table 3C shows that these time windows are shorter for the two repositories analyzed, probably due to their smaller size. In the case of medRxiv, we estimate that the number of COVID-19 publications will increase by a factor of 15 in the next six months, and by a factor of 19 in a year (from 7,004 publications to 133,328). For SSRN, a more pronounced growth rate is estimated. In six months, the number of publications is expected to multiply by a factor of 17 and in twelve months by a factor of 25 (from 6,008 publications to 151,185).

Table 3. Forecast growth of publications by case scenario: A) type of access, B) NLM source and C) domain-specific repositories. It includes the predicted value and the upper bound of a 95% uncertainty level. Predictions are provided every three months

Discussion and concluding remarks

In this paper we present a forecasting analysis on the production of COVID-19-related scientific literature for 2021. We contribute to existing literature analysing the growth of science, a topic of interest since the very inception of scientometrics, with the pioneering works of Derek de Solla Price. However, we focus on a very particular type of scientific literature, that is, publications related to the COVID-19 pandemic. The scientific communication system has never generated as much interest, both scientific and societal, as it is generating during the COVID-19 crisis (Zastrow, 2020). Our results point towards potential scenarios for which infrastructure, communication strategies and policy actions must be coordinated to maximize the result of such paramount scientific effort (Brainard, 2020). We use the ARIMA model to predict literature growth as, despite the simplicity of this model, it proved to be highly accurate in our preliminary findings (Torres-Salinas et al., 2020). In times of social mistrust and fake news (Lazer et al., 2018), the production of new scientific knowledge must be accompanied by effective science communication strategies. The emergence of sources such as the WHO database and the CORD19 dataset already reflect a contribution to such efforts.

Although there is still debate as to what constitutes COVID-19-related literature (Kousha & Thelwall, 2020), the two databases have the unique feature of indicating daily indexing dates, which helps modelling data for predicting growth. Also, the level of transparency of these sources allows one to determine potential misrepresentations in certain fields (e.g., the inclusion of SocArxiv shows promise as to having a good coverage of social science fields). Our analysis by scenario points towards different levels (and, potentially, models) of growth depending on the data source used. Further steps will require looking into differences in growth rate by fields as well as considering external socio-economic and health factors which may affect the growth of scientific literature on this research front.

The urgency of the extraordinary health and financial crisis triggered by the pandemic has pushed the expansion of Open Acess and the inclusion of preprints as tacitly accepted scientific publications (although with many cautionary notes). This presents further challenges related to the control of scientific quality, certainty and rigour, although it is still too early to tell whether quality is being compromised in these pressing times of accelerated scientific discovery (Abritis, Marcus & Oransky, 2020). The fact that science is squarely in the social spotlight makes it especially vulnerable when errors are committed or when messages are misinterpreted. In the light of this framing, we believe that further research on this matter should continue to further our understanding of the growth not only of scientific publications, but also of the social reaction to science, and of the types of access by which scientific publications are made available.

Acknowledgments

This study is part of the project ‘Scientific communication in times of Corona virus’ funded by the TU Delft COVID-19 Response Fund.

Abstract

The role of gender in science is a frequently debated subject. Papers on this subject use various terms to describe their findings, such as “gender bias”, “gender disparity”, “gender difference” or sometimes "gender gap". The different terms sometimes seem to be used interchangeably, making it unclear what researchers try to communicate with each term. To facilitate a clear discussion, we propose explicit definitions of these terms that emphasise the importance of the underlying causal mechanisms. Additionally, this causal language allows us to reason about concepts of fairness and their implications. The proposed terminology may contribute to a better understanding of the policy implications of a study.

Introduction

Science thrives on an open exchange of arguments and a plurality of perspectives. Scientific discussions should be open, frank and blind: only arguments should matter, not who presents them. Different viewpoints strengthen the scientific debate, and the inclusion of women and minorities in science will only contribute to this. Understanding the role of gender in science is crucial for improving the representation of women.

Gender differences in science are frequently studied in the literature. There are clear gender differences in citations, also when focusing on lead author positions (Sugimoto et al., 2013). A possible explanation of this might be gender differences in seniority: there are often more men than women in more senior positions. Other research corroborates this explanation and finds that gender differences in citations seem the result of gender differences in academic career trajectories and productivity (Huang et al., 2020). Another study attributed gender differences in citation to gender differences in journal prestige and collaboration patterns (Andersen et al., 2019). Similarly, gender differences in self-citation rates were reported (King et al., 2017), which are likely due to gender differences in careers and productivity (Mishra et al., 2018).

Women seem to transition into more senior positions less frequently, which can be partly explained by gender differences in productivity (Lerchenmueller & Sorenson, 2018). Although this is sometimes portrayed as a “leaky pipeline”, there seems to be a particular point in this pipeline in which these gender differences are most pronounced: the transition from postdoc to principal investigator (Lerchenmueller & Sorenson, 2018). After this transition, men and women seem to show similar career trajectories (Kaminski & Geisler, 2012; Hechtman et al., 2018). There is also evidence that men and women are not evaluated similarly when applying for academic positions, even when both have identical curricula vitae (Steinpreis et al., 1999).

Receiving funding is an important factor in making this transition towards principal investigator successfully. Experimental evidence suggests that gender identities on funding applications do not lead to gender differences in funding outcomes (Forscher et al., 2019). Other research suggests that gender differences in funding outcomes may depend on what criteria are used to evaluate the funding application (Witteman et al., 2019). An analysis of Dutch data suggests gender differences in funding rates (Van der Lee & Ellemers, 2015), although this may result from differences across fields (Albers, 2015).

Many findings point towards gender differences in productivity that may explain other observed gender differences. The gender difference in productivity is termed a “productivity puzzle” in earlier literature (Cole & Zuckerman, 1984). Some research suggests that articles submitted by women are reviewed differently than those written by men, and changing to double-blind review procedures attenuates gender differences (Budden et al., 2008). In contrast, recent research suggests that gender differences in publishing do not emerge as a result of being reviewed differently (Squazzoni et al., 2021). Although family formation, and related childcare, might be an explanation, early studies find no evidence of this (Cole & Zuckerman, 1987). There may be relevant field differences, where some fields have more intense periods around the time of family formation, while other fields may show such more intense periods at other times (Adamo, 2013). In math-intensive fields, family formation is suggested to be a key factor in explaining resulting gender differences (Ceci & Williams, 2011). Preliminary results from a large-scale survey suggests that women scientists indeed take on a caregiver role more frequently, although the implications on productivity are not clear (Derrick et al., 2019).

In our admittedly brief review of some of the literature on the role of gender in science, we intentionally used only the term “gender difference”. However, different studies use different terms to describe their findings. Several studies use the term “gender bias”, but its meaning is not always clear. Instead of “gender bias”, some studies use the term “gender disparity”, while others employ “gender difference” or occasionally "gender gap". The different terms sometimes seem to be used interchangeably, making it unclear what researchers try to communicate with each term. To facilitate a clear discussion, we propose explicit definitions of these terms. Defining such terms explicitly may help to clarify discussions about this topic.

As is clear from our brief review of some of the literature, many studies try to explain some gender differences by other gender differences. For example, gender differences in citation rates may be explained by differences in career trajectories and productivity (Huang et al., 2020). The idea of explaining gender differences by other gender differences is at the core of our definitions of gender bias, gender disparity and gender difference and builds on a fundamental concept: causality. We believe that the focus on causal reasoning may help to understand results in the literature, may sharpen the debate, and may lead to improved policy proposals.

The definitions of gender bias, gender disparity and gender difference that we propose are intentionally distinct from considerations of fairness. Nonetheless, this aspect is very important, and we also provide explicit definitions of fairness, distinguishing between procedural fairness and outcome fairness. Unlike our definitions of bias, disparity and difference, our fairness definitions rely on moral and normative judgements. The proposed definitions will help clarify some aspects of discussions around gender.

Structural causal models

The definitions we provide are based on the framework of structural causal models introduced by Judea Pearl (2009). Before we introduce our definitions of gender bias, gender disparity, gender difference and fairness, we need to introduce some of the concepts of structural causal models. We here only include a very brief introduction of the parts that are critical to our argument. For more information, please refer to Pearl (2009). A more accessible introduction is available from Dablander (2020) and a popular science account is provided by Pearl & MacKenzie (2018).

The basis for structural causal models is provided by directed acyclic graphs (DAG), which represent the causal relationships between variables. Each node in such a DAG represents a variable, and we may interchangeably use the term node or variable. We represent a link from a node X to a node Y by $X \rightarrow Y$, which represents a direct causal effect of X on Y. Acyclic means that there are no directed cycles, for example, if $X \rightarrow Y \rightarrow Z$ then a DAG may not contain the causal effect Z → X. Note that a DAG does allow X → Y → Z and X → Z, that is, there may be undirected cycles (i.e., ignoring the direction).

Any node X that has a directed path to Y is said to causally affect Y. Stated differently: if X were different, Y would also be different. The simplest example would be X → Y. Causality has a clear directionality: here X causally affects Y, but Y does not causally affect X. That is, if Y were different, this would not change X, since Y is a result of X, but X is not a result of Y. A simple example would be fire (X) and smoke (Y). Starting a fire will cause smoke, but creating smoke does not cause a fire. Note that there is a crucial difference between *observing* smoke and *creating* smoke: if we see smoke somewhere, it might be more likely that we can see a fire somewhere, whereas just creating smoke does not in itself start a fire.

The nodes that are directly affected by some node X are called its children, while the nodes that directly affect X are called its parents. For example, if X → Y we call X the parent of Y and Y the child of X. Similarly, children, children of children, and any nodes further downstream are called descendants. Parents, parents of parents, and any nodes further upstream are called ancestors. Hence, parents directly causally affect their children and ancestors causally affect descendants, possibly indirectly so.

Two variables may be associated, even if the one is not causally affected by the other. That is, two nodes X and Y may show some correlation or dependency, such that knowing X tells you something about Y and vice-versa. Determining which nodes are related is not straightforward, but DAGs are very helpful for this task. In order to properly explain how to determine whether two variables are associated, we need to introduce a number of other concepts.

d-connectedness and d-separation

The concepts of d-connectedness and d-separation indicate whether two variables are related or not in a DAG. The concepts of d-connectedness and d-separation may be somewhat difficult to comprehend. Below we explain these concepts briefly, but fully, because they are critical for some of our discussions around gender. For a more extensive introduction to d-connectedness and d-separation please see Pearl (2009), especially chapter 11.1.2 appropriately titled "d-separation without tears".

First of all, we require the concept of open or closed undirected paths between two nodes in a DAG. An undirected path consists of a sequence of nodes connected through links that may point in either direction. For example, X → Z → Y is an undirected path, but so are X ← Z → Y and X → Z ← Y. An undirected path is open if all nodes on the path are open. A node Z on a path is open if it is connected as ... → Z → …, called a mediator or if it is connected as ... ← Z → …, called a confounder, while a node Z is considered closed if it is connected as … → Z ← …., called a collider. Note that the same variable may play the role of mediator on one undirected path, a confounder on another undirected path, and a collider on yet another undirected path. Colliders will play an important role when we discuss the collider fallacy later in this paper. In short, undirected paths without any colliders are open while undirected paths with one or more colliders are closed. Instead of open or closed undirected paths, we will simply refer to these as open or closed paths.

In a sense, open paths allow information to flow freely between variables, while closed paths somehow block the information flow. If a pair of nodes X and Y is connected through at least one open path it is said to be d-connected, and information can flow freely between X and Y. If there are no open paths between X and Y they are d-separated, and no information can flow between X and Y. Two variables X and Y that are d-connected are associated. That is, if two variables X and Y are d-connected, knowing X tells you something about Y and vice-versa. Two variables X and Y that are d-separated are independent: knowing X tells you nothing about Y. The association between two variables that are d-connected does not need to reflect causality. The simplest example is X ← Z → Y, where the confounder Z affects both X and Y, so that X and Y are correlated only because of the common factor Z. In contrast, if X → Z → Y, the variable Z acts as a mediator and X and Y are d-connected, and the association between X and Y does reflect causality. Instead of open and closed paths others may sometimes use the terminology of unblocked and blocked paths.

In summary, variables are d-connected if there is at least one path with only confounders and mediators, see Figure 1 for an illustration. However, there is an important twist to d-connectedness and d-separation, which we discuss next.

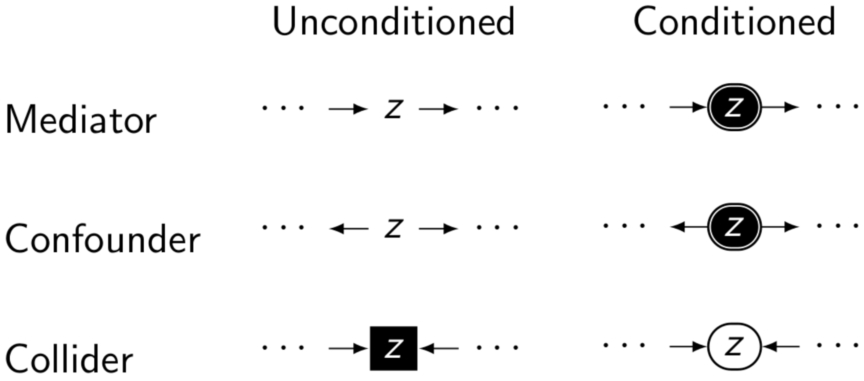

Figure 1. Illustration of when a node on an undirected path should be considered open (illustrated by white nodes) or closed (illustrated by black nodes). Conditioning on a variable "flips" a node from open to closed and vice-versa.

Conditioning and selection

Many studies condition on some variables. For example, quantitative studies frequently control for some variables by including them in a regression, which amounts to conditioning on those variables. Some studies may include only certain people in their analysis, for example considering only tenured professors or scholars that have published at least five publications. Such a type of selection amounts to conditioning on that variable. Other studies perform analyses on separate subsets of the data. A common example in science studies is for example analysing different scientific fields separately. Separating the analyses in distinct subsets amounts to conditioning on the variables that are used to define those subsets, such as the scientific field. Sometimes the fields are not analysed separately, but instead, some indicators, such as citations, may be field-normalised. Again, this amounts to conditioning on that variable. In short, conditioning on variables is a common sight, and it has profound implications for the notion of d-connectedness and d-separation.

When conditioning on a variable Z, a node that was considered open will become closed and vice-versa. That is, if a node Z on a path is conditioned[1] on, it is considered closed if it is connected as a mediator (… → **Z** →) or as a confounder (… ← **Z** → …) and considered open if it is connected as a collider (… → **Z** ← …). This is also illustrated in Figure 1. Hence, if a path is open, you can close it by conditioning on a mediator or confounder in that path, and the other way around, you can thus open a path that is closed by conditioning on a collider[2]. Because

[1] We will denote variables that are conditioned on in a path in bold.

[2] There is one additional complication. A collider becomes open not only if you condition on the collider itself, but also if you condition on any of its descendants. For example, if X → Z ← Y and also Z → **W**, then by

nodes may act as a mediator in one path and act as a collider in another path, it is possible that conditioning on a node closes one path yet opens another path.

Inequality, disparity and bias

We now have the necessary causal language in place to discuss the concepts of gender difference, gender disparity and gender bias in more detail. In particular, we suggest some definitions for these concepts, which we believe are useful for clearly conveying research results. These definitions are based on the framework of the structural causal models and directed acyclic graphs (DAG) that we just reviewed.

We propose to define a "gender difference" simply as any observed difference between people with a different gender. More formally speaking, suppose that the node G represents the variable gender in a DAG. Any node that is d-connected to G will then show a gender difference. Note that this may depend on whether nodes are conditioned on or not. Hence, some gender differences may appear when not conditioning on anything, while other gender differences appear only when condition on some variables.

Our proposal is to use the term "gender disparity" to refer to any difference between people with a different gender that is *causally affected by their gender*. This for instance means that if a woman had been a man (or vice-versa), the outcome of interest would have been different. In our causal language, if the node G again represents the variable gender, then any descendant Y of G (i.e. for which there exists a directed path $G \rightarrow X \rightarrow \ldots \rightarrow Y$) shows a gender disparity.

The strongest term is "gender bias", which we propose to define as any difference between people with a different gender that is *directly* causally affected by their gender. Similar to a gender disparity, this for instance means that if a woman had been a man, the outcome of interest would have been different. However, whereas a gender disparity may be the result of an indirect causal pathway from someone's gender to a particular outcome, a gender bias is a *direct* causal effect. In our causal framework, if G represents gender again, then Y shows a gender bias only if G is a parent of Y, that is $G \rightarrow Y$.

To clarify the distinction between a gender disparity and a gender bias, consider the example of being accepted at a prestigious university. Suppose that the acceptance rates for men and women are equal for each study programme, but that some study programmes have lower acceptance rates than others. Moreover, suppose there is a gender bias in study programme, and that women apply more often for study programmes with lower acceptance rates. This gender bias results in a lower overall acceptance rate for women. In this case, there is then a gender disparity in the overall acceptance rate. Because the causal effect is mediated by study choice, this gender disparity should *not* be called a gender bias in our terminology (see Figure 2). You may recognise this as an example of the famous Simpson's Paradox, which actually took place in Berkeley (Bickley et al., 1975). In contrast, suppose that a change in someone's gender on an application form affects the acceptance decision. In that case, gender does have a direct effect on acceptance, which means there is a gender bias in acceptance rates.

Note that the definitions of gender difference, gender disparity and gender bias are straightforward to apply to other variables of interest. For example, studies about the role of ethnicity, religion, or ideology may all use similar definitions of difference, disparity and bias.

conditioning on W we open the node Z. For more information about this, please refer to Pearl (2009), chapter 11.1.2.

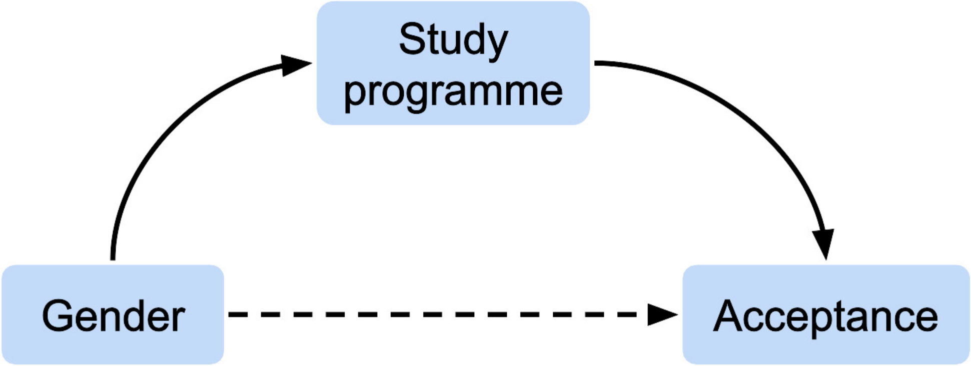

Figure 2. Example causal model. Gender causally affects the study programme, which causally affects acceptance. There is a gender bias in study choice, and a gender disparity in acceptance. If there is a direct causal effect of gender on acceptance (represented by the dashed line) there is a gender bias in acceptance.

Fairness

In colloquial language, disparities and biases are often seen as differences that are unfair. In the definitions we provided above, we intentionally did not include this moral or normative element. However, the issue of fairness is important and we try to clarify this notion here. A related debate is taking place in machine learning and artificial intelligence research, where fairness is an increasingly important consideration (Mitchell et al., 2021). Causal approaches similar to our definitions of gender differences, gender disparities and gender biases are also being developed (Zhang & Bareinboim, 2018; Makhlouf, 2020).

We believe it is pivotal to distinguish between two notions of fairness: procedural fairness and outcome fairness. Procedural fairness concerns the question whether a certain process is fair or not. In the example in the previous section, the acceptance decision depends only on the study programme: some programmes accept fewer applicants, and hence have a lower overall acceptance rate. In reality, such acceptance decisions are of course also influenced by other factors, such as aptitude or actual test scores. We then define procedural fairness as whether the direct causal effect of a variable on an outcome is seen as justified. If these direct causal effects are not seen as justified, the procedure for establishing the outcome is unfair. For example, most people would agree that using body height as a consideration in the acceptance decision for a study programme is unjustified, so this would be an unfair procedure.

An unfair procedure leads to an unfair outcome. However, the inverse is not necessarily true: The outcome of a procedure can be unfair, even if the procedure is fair. We define unfair outcomes as any outcome that results from an unfair procedure or that is causally affected by an earlier outcome that itself is unfair. Let us illustrate this in our previous example. Suppose that men and women have been swayed to apply to different study programmes, leading to the earlier identified gender bias in the choice of study programme. If we see this causal effect as unjustified, and hence as procedurally unfair, then the outcomes of the choice of study programme should be seen as unfair as well. This unfairness in the choice of study programme then propagates through the causal link and also renders the acceptance outcome unfair, even if the procedure used by a study programme to make acceptance decisions is fair.

More formally then, let the causal model again be represented by a DAG. Procedural fairness concerns the links of the DAG, and any direct link in the DAG can be labeled as unfair. Outcome fairness concerns the nodes of the DAG, i.e., the variables. Suppose that a direct causal effect $X \rightarrow Y$ is labeled procedurally unfair. Then the outcome Y is unfair with respect to X. Moreover, any descendant of Y also represents an outcome that is unfair with respect to

X.[3] In this definition, a single procedural unfairness X → Y may hence ripple through the network and render many outcomes unfair.

Procedural unfairness and outcome unfairness are related to gender bias and gender disparity. When there is a gender bias, gender has a direct causal effect on some outcome. If this causal effect is viewed as unjustified, it represents procedural unfairness, which results in an unfair outcome. When there is a gender disparity, but not a gender bias, gender has only an indirect causal effect on some outcome. The procedure for establishing that outcome may possibly be viewed as procedurally fair, but the outcome itself may still be unfair. Stated succinctly: Gender disparities may reflect outcome unfairness, while gender biases may reflect procedural unfairness. Whether something is indeed unfair remains a moral or normative decision. Different people may have different views on whether a specific gender disparity or gender bias reflects unfairness.

Interventions

The distinction between gender disparities and gender biases on the one hand, and outcome fairness and procedural fairness on the other hand helps to suggest where in the system an intervention may be more appropriate. To illustrate this, let us revisit the above example of being accepted at a prestigious university. If the effect of gender on acceptance rates is mediated by study choice, there is a gender bias in the choice of study programme, not in acceptance rates. If the effect of gender on the choice of study programme is viewed as unjustified, it would be procedurally unfair. An intervention targeted at study choice (e.g., making certain study programmes more attractive for women) addresses the procedural unfairness. By addressing the procedural unfairness, we also address any subsequent outcome unfairness that results from it, and address the root cause of the problem.

An intervention could also target the acceptance rates directly, for example by imposing a minimum acceptance rate for women or a certain quotum. Such an intervention does not address the original procedural unfairness, but seeks to rectify a previous wrong. It raises some thorny issues, with the pivotal question: do we intervene in a fair process in order to correct unfair outcomes? Doing so can be seen as an example of affirmative action or positive discrimination. The idea here is that the outcome of interest, the acceptance rate in this case, should be changed with respect to gender. In our causal model, this means that we would add a link G → A, where G and A represent gender and the acceptance decision. This additional link is intended to counter and nullify the undesirable gender disparity in the acceptance rate. Note that, in our terminology, there is now a gender bias in favor of women in the acceptance decision. This may raise other questions of fairness: if it is believed that gender should not have an effect on the acceptance decision, this additional link is procedurally unfair. In addition, introducing such a link may have some unexpected effects. The introduction of the link G → A leads to lower acceptance rates for men who choose the same study programmes as women. This might incentivise men to not choose programmes that traditionally attract more women. Instead of decreasing the gender bias in the choice of study programme, such an intervention may then actually reinforce this gender bias. In other words, even though the intervention may diminish the gender disparity in acceptance rates, it does not remedy the original procedural unfairness. There may still be good reasons for introducing such corrections of gender disparities, but their implications may be more complex than perhaps commonly thought.

Whether an intervention is desirable at all depends on whether the gender bias on study choice is seen as procedurally unfair. The concepts of outcome fairness and procedural fairness help to better understand the implications of different viewpoints that one may have on this issue.

[3] In fact, this line of reasoning can be generalized as follows. If X → Y is unfair, then Y or any descendant of Y is unfair with respect to any ancestor of Y. However, to simplify the discussion we do not consider this generalization here.

Whether a particular causal effect should be seen as procedurally unfair cannot be left to logic. It is a moral and normative judgment that should be subject to political and societal deliberation.

Collider fallacy

A gender difference does not necessarily reflect a gender disparity or a gender bias. Indeed, as we saw in the discussion on structural causal models, any two variables that are d-connected will show some association, but this does not need to represent a causal effect. The distinction between a gender difference on the one hand and a gender disparity and a gender bias on the other hand is inherently causal. Confusing a gender difference with a gender disparity or a gender bias complicates matters greatly in many studies. Collider fallacies may easily lead to such confusion.

To illustrate the problem of collider fallacy, we consider a recent paper about the role of gender in mentorship (AlShebli et al., 2020). The authors find that protégés with female mentors show a lower citation impact than protégés with male mentors. This paper was received quite critically and was recently retracted. Critics of the paper raised a number of concerns, for example about the data[4] and the operationalisation of the idea of mentorship (Lindquist et al., 2020). We illustrate the problem of collider fallacy on the basis of this study as a working example.

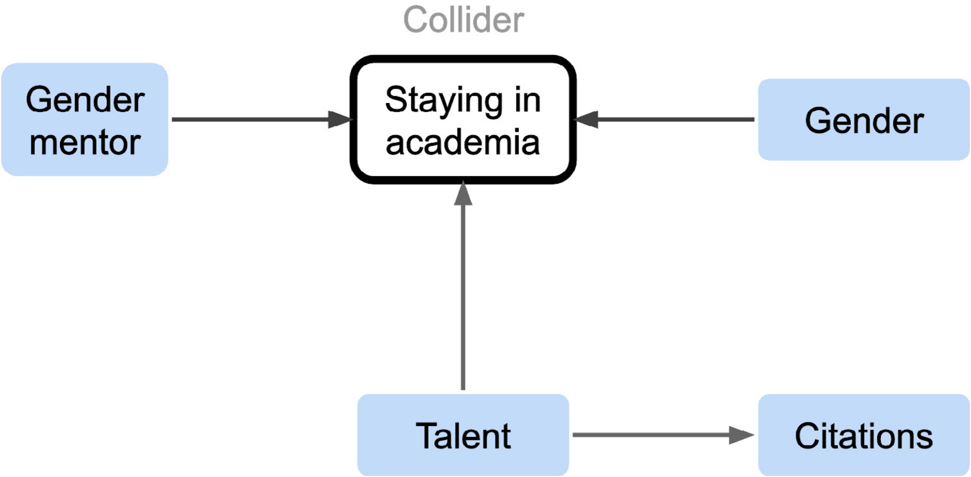

Figure 3. Simplified causal model of the role of gender in science. Each arrow represents a direct causal effect of one factor on another. For example, talent has a direct effect on staying in academia in this model.

We consider a simplistic causal model (see Figure 3) describing mechanisms relevant to interpreting the results by AlShebli et al. (2020). In our model, someone's research talent (T) affects both the citations (C) they receive and their likelihood of staying in academia (A). Independently of this, someone's gender (G) and the gender of their mentor (M) also affects their likelihood of staying in academia. More specifically, we assume that having a female rather than a male mentor makes it more likely for a female protégé to stay in academia.

In this causal model, staying in academia (A) is d-connected to citations (C) because of the path A ← T → C where talent acts as a mediator. This is the only path (longer than a single link) that is d-connected. All other paths are closed by node A, which acts as a collider for all other

[4] https://danieleweeks.github.io/Mentorship

paths. Hence, citations are independent from the gender and the gender of the mentor in this model. It could be discussed whether this is a realistic aspect of the model. However, our goal here is not to construct a fully realistic model, but rather to illustrate the concept of a collider fallacy.

AlShebli et al. (2020) make an explicit selection of the protégés included in the data collection: “we consider protégés who remain scientifically active after the completion of their mentorship period” (p. 2). As we explained before, this amounts to conditioning on the variable used to make a selection. If we condition on the variable “staying in academia”, this opens up a number of paths that were previously closed, leading to more pairs of d-connected nodes. For example, gender (G) will become associated with citations (C) because of the path G → **A** ← T → C. Moreover, the gender of the mentor (M) will become correlated with the citations (C) of the protégé because of the path M → **A** ← T → C. In other words, there will be a gender difference in citations, and also a difference in citations for the gender of the mentor. In our causal model, female protégés with male mentors are less likely to stay in academia, which means that those who do stay in academia can be expected to be more talented, on average, than their colleagues with female mentors. As a result, having female mentors is related to a lower research talent of protégés who stay in academia. Their lower research talent then in turn leads to fewer citations for those protégés. We would like to stress that this association does *not* reflect a causal effect. Instead, it is the result of conditioning on a collider, known as a collider fallacy. This example illustrates the problem of conditioning on colliders when studying causal effects. It leads to wrong conclusions. Depending on the extent to which our causal model captures the relevant causal mechanisms, the main result of AlShebli et al. (2020) may be due to this collider fallacy.

The possibility of a collider fallacy calls into question the policy recommendations made by AlShebli et al. (2020). The authors suggest that women should be paired with a male mentor because this has a positive effect on their citation impact. If the above causal model holds true, this suggestion is not correct. In this model, pairing a female protégé with a male mentor reduces the likelihood that the protégé stays in academia, which means that those protégés who do persevere in academia are likely to be more talented and to receive more citations. In our terminology: the difference between male and female mentors in the citations received by their protégés may be only a gender difference, not a gender disparity and certainly not a gender bias. Without additional evidence or assumptions, the observed gender difference does not support the policy recommendations made in the mentorship paper. In fact, given our conjectured causal model, it can be argued that one should do the opposite of what is suggested in the paper: to increase female participation in science, female protégés should be paired with female mentors. This illustrates the importance of considering the appropriate causal mechanisms for making policy recommendations.

Conclusion

Many papers on gender differences in science use a diffuse terminology and lack a clear causal framework. In an excellent and comprehensive review of the literature on gender differences in science funding, the lack of causal knowledge was identified as a sore point (Cruz-Castro & Sanz-Menéndez, 2020). The literature regularly discusses gender differences, disparities and biases without clear definitions. Moreover, without a clear causal model the findings may possibly lead to ill-conceived policy recommendations, which in some cases may actually hurt progress towards a better gender balance. We hope that our proposed definitions of gender difference, gender disparity and gender bias contribute to an improved appreciation of the causal intricacies in studying the role of gender in science.

Our proposed definitions of gender difference, gender disparity and gender bias do not include any moral or normative elements related to fairness. Instead, we define notions of fairness separately from the notions of difference, disparity and bias. We distinguish between procedural fairness and outcome fairness. Unfair procedures lead to unfair outcomes, which may render subsequent outcomes unfair. The proposed terminology enables us to reason in a systematic way about the consequences of unfair procedures, and whether to see outcomes as unfair. However, judging whether a procedure should be seen as unfair cannot be left to logic or algorithms, and should be the subject of a political and societal debate.

The duality of disciplinary diversity for universities

Angelika Tsivinskaya[1]

Gagarinskaya Street, 191187, St. Petersburg (Russia)

Abstract

In this paper, we investigate whether research and teaching mirror each other in terms of disciplinary structure. The diversity is presented in the conjunction of those two missions. Based on our assumption, we propose a typology that has two principal dimensions related to diversity in teaching and research respectively. As a measure of discrepancy between missions, we chose to assess the distribution of students and publications by scientific fields. We employed clustering analysis to establish disciplinary profiles of universities for publications and students separately. To test our typology we calculated overall diversity in teaching and research for each university and then applied clustering to identify possible types. Such an approach has the potential to reveal which disciplinary profiles have greater overall diversity. Our proposed methodology was applied to higher education institutions in Russia and we observed the greater diversity by scientific fields in publications comparing to students. Found empirical evidence on the connection between teaching and research can suggest that crossing disciplinary borders is easier in research than in teaching.

Introduction

Traditionally, education and research are viewed as being aligned in universities (Clark, 1995). In reality, the macrolevel missions are often coexisting, interlocking, or contradictory in nature (Scott, 2006). Moreover, we well know that the European higher education landscape is marked by a high level of heterogeneity (Huisman et al., 2015). So, it has raised the question of how Higher education institutions (HEIs) responded to increasing demands and being put under the pressure of not only teaching students but also conducting excellent research (Altbach, 2011). Therefore, we argue against the one-size-fits-all university model, which understands HEIs as isomorphic organizations dismissing the diversity of institutional types, and put the emphasis on the idea that universities should be evaluated with disciplinary specialization in mind (Bonaccorsi et al., 2021; Bornmann et al., 2013; Sánchez-Barrioluengo, 2014).

In this paper, we will assess the diversity both in research and in teaching by scientific fields for the whole universities populations on country level. We hope that our study will shed some light on the above issue by analyzing the patterns in research and teaching of Russian HEIs. To accomplish this goal, we use data from two different sources: our main source is the Russian Survey of Performance of Higher Education Institutions that includes data on each university, collected every year; additional data on the research activity are drawn by the RICS database, which is a national bibliometric database. We focus on the connection between diversity in research and teaching through an empirical study of Russian HEIs. Therefore, we present an empirical approach to the concept of diversity by addressing the following questions:

- Diversity of students: What is the distribution of students by educational programs?
- Diversity of publications: What is the distribution of published paper?
- Is there any connection?

Our paper contributes to the extant literature in several ways. First, we proposed a typology for HEIs, which focuses on the possible occurrence of mismatch between research and teaching missions. This gap is the starting point for our empirical analysis of diversity through those missions. The second contribution is related to reviewing the structure of the Russian higher education system using a combination of national databases that can give more comprehensive picture comparing to other sources especially in the case of establishing bibliometric profiles for universities.

Proposed typology

This typology arises from the debate about the alignment between research and teaching missions of universities. To explore the potential source of the discrepancy we chose to examine the distribution of students and publications by scientific fields. We argue that basic division for "generalist" and "specialist" represents only two "pure" types that have the agreement in two functions of research and teaching but in the higher education system can possibly exist universities of "mixed" types. Based on this we propose a typology that has two principal dimensions related to the degree of diversity in teaching and research by scientific fields. Theoretically, there are four possible types (Figure 1).

	Field-focused teaching	Diverse teaching
Field-focused research	type 2	type 3
Diverse research	type 4	type 1

Figure 1. Typology of universities.

Type 1 is what most people imagine talking about classical research universities, so to speak a "true generalist". We assume that most universities are in this category. However, are they representative of the whole higher education system in a particular country? In our case, we predict that big universities so-called flagships will be classified as type 1. These universities not only compete on the national level but also try to gain visibility on the international level.

Other "pure" type is type 2 which represents "true" specialist universities. As vestiges of the Soviet system are still present, some specialist universities continue to exist. They are the main suppliers of workers for domains of their respective ministries and as long as they get financial support from them and continue to be overlooked by separate ministries (Ministry of Agriculture, Medical Care, Transport) they stay in tacked and have more secure position than other universities.

Some would look down on the type 3 institutions as they teach different programs but have only a few that produce research. In many cases, these social programs with paid students considered a support system that gives money to subsidize programs that are able to produce research.

Institutions of type 4 are probably small ones but they make the effort to use external sources, creating projects with other organizations to spread their research but not able to establish they own teaching programs due to limited resources. Probably, they are oriented more towards research than teaching and do not have many students programs.

Data and methods

We have two main data sources are the Russian Science Citation Index (RSCI) which is a national citation database (Moskaleva et al., 2018) and the Russian Survey of Performance of Higher Education Institutions (Guba et al., 2020). The Russian Survey of Performance contains microdata available at the level of individual universities on a census basis about almost the entire population of HEIs in Russia. Initially, we had sample size=823 universities that have been registered as an organization in the RSCI. In this paper, we focused on bibliometric indicators such as the number of publications by scientific fields. Only scientific articles, reviews, short reports, conference proceedings and letters to the editor in journals were taken into account. As for the Russian Survey of Performance, it was used to obtain information about the number of students by study programs. According to the Survey, 769 universities were present in 2017, which was chosen as a target year for analysis. After cross-referencing two datasets and excluding universities with zero number of publications, the final version of the sample included 650 universities. Universities without publications are mostly small private universities oriented towards social sciences. In our final sample, around 74% are public universities. 560 universities are geographically located in regional capital cities. The median number of teaching and research staff is 224. As for median number of students, it is 3982.

For our analysis, we will use fields of science consisting of the following high-level groupings: Natural sciences, Engineering and Technology, Medical and Health Sciences, Agricultural Sciences, Social Sciences and Humanities. We transformed numbers of students and publications into percentages. We used the k-Means clustering algorithm for distributions of students and publications by scientific fields. We resorted to the pragmatic approach of using a sensible value for clusters K which is based on context information about the organization of the higher education system. In our specific case, a reasonable choice for K is a number of clusters equal to or at least comparable with that used in the Russian academic system which is the number K=6. To address our question about the connection between distributions of students and publications by fields, we calculated the Herfindahl-Hirschman Index (HHI) for educational programs and categories of papers. This measure denoted as is defined as:

$$\lambda(X) = \sum_{i=1}^{N} \left(\frac{x_i}{M} \right)^2 = \sum_{i=1}^{N} p_i^2 \text{ with } M = \sum_{i=1}^{N} x_i \text{ (the total number of items)}.$$

Findings

First, we show the result of cluster analysis for the distribution of students by scientific fields, than for publications. Second, we suggest types of profiles for universities which are based on HHI computed for students and publications and cluster assignment for universities employing these two measures as dimensions of differentiation. Finally, we present possible configurations of profiles of universities in the connection between the distribution of students and publications by scientific fields.

The following section shows the result of our clustering solution for distribution of students based on scientific fields. As you can see from Table 1, we have several clusters of universities with high specialization in taught programmes where more than 90% of all students are from one scientific field. These are clusters 1, 2 and 5, corresponding to oriented towards teaching in social sciences, medical sciences and humanities. Clusters 3, 4 and 6 are more diverse in terms of the body of students, but you still definitely prominent scientific fields which more than 50% of students are in them. Universities in the third cluster teach mostly students in the agricultural field but equally has around 20% of students in technical and social sciences. Universities in clusters 4 and 6 could be viewed as what could be called "classical" universities but it is apparent that 4 cluster has the base in social sciences and 6 cluster does in technical sciences. The first cluster is the biggest one and has 211 universities, whereas the second and the third are the smallest with around 50 universities in them. There is some percentage of students in social sciences in all clusters and the biggest number of universities is also the first cluster which oriented in social sciences.

Table 1. Cluster solution by students (cluster means, %).

Cluster	*N*	*fundamental*	*technical*	*medical*	*agricultural*	*social*	*humanities*
1	211	0.69	3.28	0.10	0.04	92.71	2.96
2	52	0.05	0.77	96.59	0.00	2.46	0.03
3	50	1.99	19.98	0.00	57.59	20.35	0.03
4	116	12.53	16.07	4.54	2.47	50.56	13.78
5	90	0.03	1.79	0.01	0.00	6.50	91.63
6	131	2.56	75.11	0.10	0.93	19.64	1.59
Between SS / total SS = 91.8 %							

In term of other characteristics, 75.6% of private universities in our dataset belong to cluster 1 which oriented towards social sciences. All medical universities are located in regional capital cities (cluster 2). The smallest universities with median numbers of students equal to 931 are in cluster 5.

Next, we present the cluster solution for universities but built upon the distribution of publication by scientific fields (Table 2). In comparison to cluster solution by students, it is more diverse in terms of the mixture of papers in different scientific fields, but you can still identify similar cluster considering dominating the scientific field for publication output. Cluster 2 and 6 can be two models for output of "classical" universities as was discussed above with cluster solution by students. Clusters 1, 3 and 4 are most field-focused, especially cluster 1 associated with medical sciences. In term of cluster sizes, we have three small ones – 1, 3, 5 and thee big ones – 2, 4, 6. The biggest one is cluster 6 with publications mostly in social sciences.

Table 2. Cluster solution by publications (cluster means, %).

Cluster	*N*	*fundamental*	*technical*	*medical*	*agricultural*	*social*	*humanities*
1	65	6.01	0.82	79.90	0.59	8.88	3.05
2	129	23.45	40.71	2.54	2.33	23.59	5.60
3	63	0.83	1.30	0.99	0.09	20.44	74.19
4	166	1.52	3.27	1.31	0.89	85.79	5.67
5	56	7.58	8.27	2.58	53.51	22.13	3.67
6	171	11.04	6.62	5.41	2.77	49.11	21.93
Between SS / total SS = 83.2 %							

Our next step is to view the possible configuration of universities based on overall diversity in two dimensions without specificity of considering scientific fields which we presented earlier. We empirically test whether these configurations present in our higher education system. For this purpose, we calculated the Herfindahl-Hirschman Index (HHI) for distributions by educational programs and by papers and viewed the validity of those configurations (Figure 2).

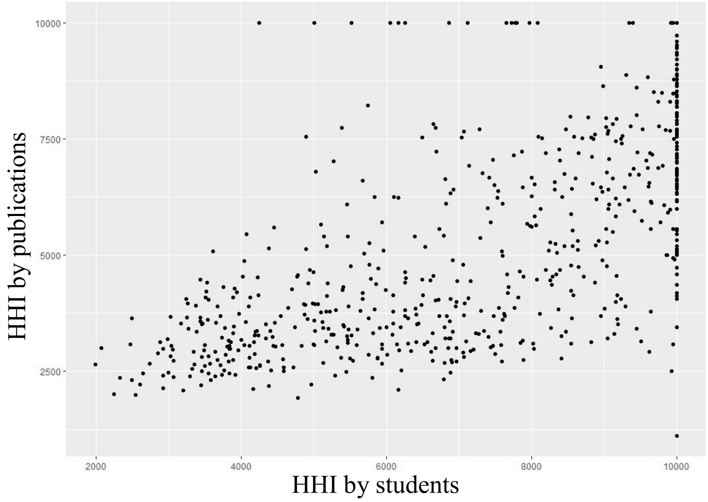

Figure 2. Diversity of disciplinary profiles by HHI.

Using the results of the cluster analysis HEIs can be classified into three clusters. So, we can conclude that universities which have students in different fields but produce papers only in one are rare. On the most basic level, the diversity of taught programs could be assumed as a supportive environment that generates diversity in research too.

Finally, we would like to show whether those profiles of universities based on different approaches have great consolidations among them or only universities with a specific body of students and publications have an inherent propensity to a specific configuration. Using flow diagram we present connections between different cluster solutions (Figure 3). You clearly can see that cluster assignments for universities based on the dominating scientific field by students and by publications are in close concordance for universities oriented towards agricultural, medical, technical-classical sciences and less for social, humanities and social-classical, so to speak it is the "great divide" between natural and social sciences.

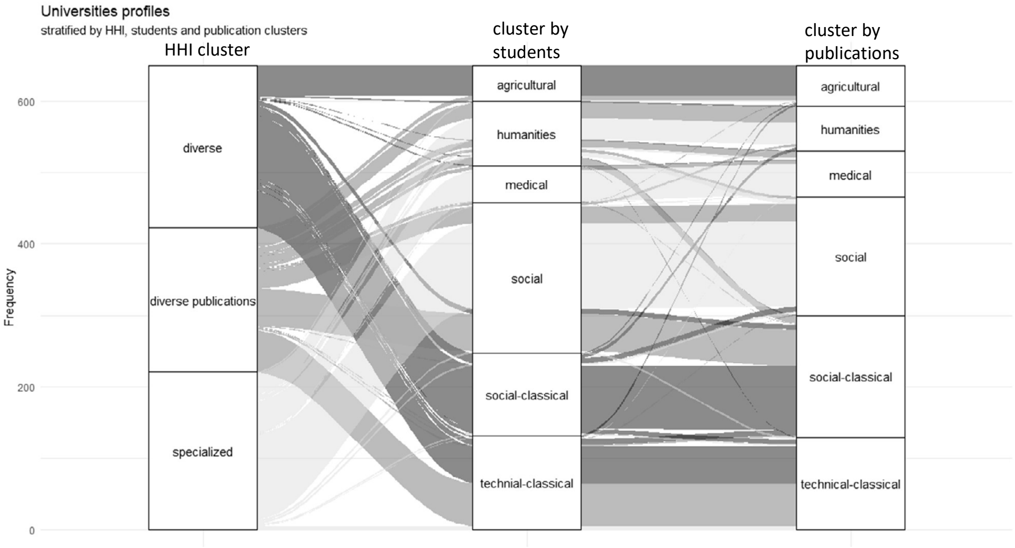

Figure 3. Connections between disciplinary profiles.

To sum up the overview of the insights we gained from our analysis are:

- The high number of universities with the social field as the main profile with specialization in it.
- The universities with different study programmes and publications concentrated only in one field are rare. External links can be detected (for example, technical universities publishing a paper in medicine).
- Migration to publish in close scientific fields (technical universities generate research in fundamental sciences, researchers in social sciences and humanities are also easily cross the border between scientific fields).

Conclusion

The greater diversity in publication comparing to teaching programs can have several possible explanations. Firstly, it is easier to publish a paper in the other field than to establish a teaching program at university. There is no restriction or evaluation beforehand for publishing paper in a different field. For example, using some available data on medical condition, the researcher in applied mathematics can write a relevant paper for a medical journal. Secondly, the greater diversity in publication can be a result of direct collaboration between institutions or with industry. In this case, the data can be supplied by one organization when other is more involved in analyzing it. Thirdly, the classification for teaching programs is more restricted than for publications; however, we aggregated our data on the quite high level in term of scientific fields where this effect should be partially mitigated.

This study can be used to recognize for instance week and strong scientific fields and this information can enrich the knowledge about HEIs in Russia. The findings of this research can be used in several ways by HEI administrators: for redistribution of existing funding system of universities, for restructuring universities teaching programs and for identification of universities' mission. Our findings are not only informative on the individual institutional level but as well as on the HEI system on the whole.

Our analysis evaluates the research performance of universities considering the multi-disciplinary nature of institutions and the sustainability of teaching-research nexus. It is innovative in taking this perspective on higher education in Russia.

This study has some limitations. Our findings are based only on Russian universities so they cannot be generalized on the other HEIs but the suggested research approach can be implemented in other cases with some revision of suitable data sources. In this paper, we did not measure or discuss the quality of publications or educational programs. Another important topic which is not covered but we have great interest to explore in the future research is the temporal aspect of diversity.

Abstract

Why are some research grant applications selected for funding and others not? In this paper we investigate whether the writing style influences the evaluation scores and the decision of selection panels. A linguistic analysis of the grant proposal abstract, the project description and the CV of the applicant do reveal several characteristics of the texts that have a positive effect on the score the grant applications receive, and through that on the probability to be selected for funding. The study suggests that writing style does have moderate a effect on application success, and therefore should not be neglected by applicants.

Introduction

Why are some grant proposals selected, and others not? From a normative perspective, it should be based on merit (Merton 1973), and evaluation panels are expected to base their decisions on the performance of the applicants, and on the quality, novelty, and originality of the proposed research project. However, peer review does not work in this way (Chubin & Hackett 1990; Lamont 2009, Thorngate et al. 2009) and various forms of bias may enter decision making, based on e.g. gender, or on social or cognitive links between the applicant and members of the selection panel.

This paper focuses on other non-merit characteristics of a grant application that may play a role in the evaluation of grant applications: The textual quality of the application. Is it well written, comprehensible, and to the point? And does it show that the applicant has the capabilities to do the proposed research? One may of course argue that peers when evaluating grant proposals should and can look through the presentational form and are able to evaluate the scientific content, but there are indications that this is not always the case. For example, in several grant application procedures, applicants have to present their project in front of the selection panel, and research shows that the scores before and after that presentation can be very different (Van den Besselaar & Van Arensbergen 2013). As applicants and universities are increasingly aware of this, applicants for prestigious career grants are often trained by communication professionals to give a strong and convincing presentation for the panel. If the 'stage performance' influences the evaluation of grant applications, this may also be the case for 'textual performance'. In this paper we focus on the *application text* and answer the question which textual characteristics have effects on the evaluation of the proposal. Does the way a grant proposal is written influence the fate of the application?

Only recently, the impact of language use in science has become a topic of research within science studies. Some research has focused on language use in *scientific articles*. In a recent paper, Lu et al. (2019a) studied the relationship between scientific writing and scientific impact, using linguistic complexity indicators as a proxy for the quality of scientific writing. The study is based on 36400 full text Biology articles and 1797 full-text Psychology articles and found (practically) no significant relationship between linguistic complexity and citation impact. In another paper, Lu et al. (2019b) compared the writing style of native authors with non-native authors in terms of (i) syntactic complexity, such as sentence length and sentence complexity, and (ii) lexical complexity, such as lexical diversity, density, and sophistication. Only marginal differences were found between non-native and native English speaking authors. Hengel (2020) also analyzed the writing of manuscripts, but with another aim. Comparing the submitted manuscripts with the accepted paper, she showed that (i) women submit better written manuscripts than men do, but still (ii) women improve the manuscript during the revision period even more than men do. This suggests that women are held to higher standards in the peer review process than men are. An indirect effect could be that women have to invest more time per paper, which in turn could partly explain the differences in scientific output between male and female authors (Hengel 2020).

Where Hengel used article manuscripts to study gender bias in peer review, Kaatz et al. (2014, 2015, also Magua et al. 2017) did so using linguistic analysis of *peer review reports*. They showed systematic differences in the words used in the review reports about female applicants compared to those about male applicants, suggesting the possibility of gender bias. Van den Besselaar et al. (2018) analyzed the language of *review reports* with the aim of identifying which evaluation criteria are deployed and how the selection is done. One finding is that negative word categories (negation terms and negative evaluation terms) are much stronger predictors of the score applicants receive than superlatives and positive evaluation words, suggesting that panels are much more focused on eliminating applications that are considered weak than on finding the excellent and promising proposals (see also Hume et al. 2015). Another finding was the negative correlation between the percentage of project and research related words, and the received score. This is in line with the theory of Festinger (1950) that disagreement among panel members leads to more discussion in the panel and to lower scores.

Another recent strand of research focuses on the language use in *grant applications*. Do writing style and the textual quality of the application play a role? Explorative qualitative work was done to identify the characteristics of grant writing as a genre (Connor & Mauranen 1999; Feng & Shi 2004). In a recent small-scale study, Boyack et al. (2018) found a positive relation between writing quality of grant applications and application success. In a follow-up study, the same authors used five linguistic variables to predict grant success: (i) proposal size, (ii) the *Gunning fog index* for writing clarity, (iii) male-oriented language, (iv) positive emotional language, and (v) the *story arc* of emotional words. Out of these, only the *story arc* had a significant positive effect on grant application success (Smith et al. 2019). The authors distinguished between six types of *emotional story lines* and found that these result in different average success rates. In a study of anonymous grant applications to the Gates foundation, Kolev et al. (2020) found that even when the sex of the applicant is hidden, women score systematically lower than men, also after controlling for e.g., the topic of research. This suggests that the writing style differs between men and women, and that the way of writing has an effect on the evaluation of the applications. Indeed, the study found that women use more specific words which correlates negative with review scores and success rates. Men use more general words, and those correlate positive with scores and success. Obviously, reviewers like specific project descriptions less than more general claims, and men profit from that.

Markowitz (2019) studied the relation between the writing style and the size (in UD$) of the grant, using a linguistic approach. The study is based on the idea that language reflects psychological characteristics and cognitive abilities (e.g., Tausczik & Pennebaker 2010). The writing style communicates characteristics of the author, such as whether he/she is able to communicate clearly (comprehensibility), able to write and think about complex issues (intellectual capacities), and whether he/she has sufficient self-confidence (for doing the work promised in the application), and these dimensions are expected to be important when evaluating grant applications or conference submissions (Markowitz 2019, 2021).[b]

Based on these considerations, Markowitz (2019) formulated the hypothesis that reviewers may be more convinced by proposals that show (i) a writing style that reflects complex and analytic thinking by the applicant, (ii) clear writing, and (iii) (self-)confidence in the proposal. Text complexity was measured by the number of words (longer texts are more complex), by the number of words per sentence (longer sentences are more complex) and by the use of analytic language. Clarity of the text is measured through the share of common (English) words in the text: the higher that share, the less technical terms (jargon). Finally, confidence in the proposal is measured through the number of certainty terms (pointing at more self-confidence), tentative terms (pointing at a lack of self-confidence) and causal terms (causal terms reflect stronger claims in the proposal). Using a dataset spanning multiple decades and containing approximately 20000 granted proposals across several directorates of the NSF, these linguistic characteristics were expected to predict the grant size.

Most of the hypotheses of Markowitz were supported, but some were not: Common words and analytic language do not positively but negatively affect the size of the grant. These findings may suggest an alternative interpretation of what counts as complex writing and thinking, and what counts as easy to read. Easy to read text is probably not text with more common words, but text with a good narrative structure (Jones & McBeth 2010), and a higher score for narrative writing implies a lower score on analytical writing (Pennebaker et al. 2014). A negative score on common words does not imply that the text is more difficult to read, but that it contains more technical terms, adding to the complexity of the text. Therefore, our expectations would go in the opposite direction: Firstly, a grant application with a more narrative style (= a lower score on analytical writing) receives a higher evaluation score and has a higher probability to get funded, and secondly, a grant application with more technical terms (a lower score on common words) receives a higher evaluation score and has a higher probability to get funded.

The hypothesis that tentative words have a negative effect on the grant size was supported by Markowitz' analysis, but we find that unexpected because tentative words have different functions in scientific texts. Tentative words may indeed indicate that a researcher is uncertain, hesitant, and indecisive, which may negatively influence the assessment of a grant proposal. On the other hand, it is also good practice to use tentative words indicating that findings are always provisional and may be falsified in the future, and that conclusions should be formulated cautiously (Hyland 1996). And tentative words used in the latter way may be positively received by reviewers. These two roles of tentative terms may balance out. We would therefore expect that an application text with more certainty terms and more causal words receives a higher evaluation score and has a higher probability to get funded, but that tentative terms do not have such an effect.

In this paper, we address several limitations of the Markowitz study. (1) We also include *rejected applications*, as the comparison of rejected and successful applications may better show the effect of writing style on grant decisions, than only relating writing style of awarded grants with the size of the grant. (2) We use not only the *abstracts* of the applications, but also other important parts: the *project description*, and the *CV*. The three texts have different functions and may therefore have different writing styles (Feng & Shi 2004). Especially CVs have a distinct structure, and often consist of listings such as previous academic positions, grants, and publications. However, in our case the CV also includes a page where the applicants summarize their main achievements in a narrative. Based on this, we expect that the effects of the linguistic variables will stronger in the project proposal than in the short abstract, and in the abstract stronger than in the CV. (3) All applications are written in English, but most applicants are not native English. One would expect that the quality of the texts also depends on *English language proficiency* of the author, which is included as control variable. (4) We link the analysis to the decision-making process. Our case consists of a two-step procedure, and the impact of language may be different in the two phases. One may expect that the writing style is more important in the first round when a large number of applications have to be evaluated in a short time, than in the second round when a smaller number of only the best are left for the final selection. A panel member may then go in depth through the smaller number of remaining applications – even when these are sometimes not written too well. More generally, this suggests that what counts as adequate text is *context dependent*. We would therefore expect that language does have a much smaller effect in the second step of the procedure than in the first step.

Case description

The dataset consists of 3207 applications for an early career grant, covering the year 2014. The applications are handled by 25 disciplinary panels, covering all disciplines. The overall success rate is 11.7%, indicating that the funding scheme is very competitive. The maximum grant is 1.5 million euro, for 5 years. Almost everyone received the same amount of funding. The process of getting the grant consists of two steps. In the first step proposal and CV are reviewed, and a score is given for both the PI and the proposal. This is translated into a C, B, or A score. Only the proposals with and A proceed to the second step, where another round of reviewing (by more reviewers) takes place and the PI is interviewed by a panel. The final score in the second step can be B (not fundable) of A (fundable), and a part of the proposals that received an A are funded.

Data and methods

The applications cover all fields, grouped into 25 panels. The dataset is almost complete, as 95% of applicants gave informed consent for this study. We deleted one panel for which most of the project descriptions were lacking. After removal of five unreadable proposals documents, the dataset consists of 2900 application texts. The applications are about 11 pages long, with (i) an abstract of one page, (ii) a project description of five pages and (iii) a curriculum vitae (CV) of five pages. The PDF files were converted into TXT, and then split into the three parts. We checked whether the file splitting was done correctly. For example, all file-parts that were small or big in relation to the expected length were manually checked. Where needed, the split was redone manually. In quite some cases this was indeed needed. We also found some other data problems. In some other cases, we manually corrected the data: this was done where a wrong structure of the text misled the automatic parsing of the application texts, and for the application texts that included an empty front page, or included a table of contents. Furthermore, quite some abstract texts that still included formatting instructions were cleaned, as the instruction text would change the linguistic structure of the abstract considerably.

The Abstracts, Project descriptions, and CVs were analyzed with the Linguistic Inquiry and Word Count tool (LIWC), using the 2015 English dictionary (Seih et al. 2017). We deploy the same LIWC categories as described above for operationalization of *discourse and thinking style complexity* (1-3), *clarity of the text* (4), and of *confidence in the proposal* (5-7), but some with another interpretation then in earlier work (Pennebaker et al. 2014; Markowitz 2019):

1. Word count: The longer the text, the more information provided. However, too long texts may be counterproductive, and therefore we also use *word count squared*. The relation between the length of the text and the score may be an inverted U-curve.
2. Words per sentence: Longer sentences reflect more complex arguments. And also here, too long sentences are making the text unnecessary complex and may have a negative effect on readability.
3. Analytic thinking: A higher score on this composite linguistic indicator reflects stronger *complex and analytic thinking*, while a lower score reflects stronger *storytelling and narrative thinking*.[c]
4. Common words: The LIWC dictionary contains common words, but not technical terms – so the higher the score, the less technical terms in the text. One may interpret this as an indicator of readability of a text, but also as in indicator of complexity: the higher the score on common words, the smaller the technical content of a text, and the lower its complexity.

5. Certainty terms, expressing the level of confidence the applicant has in the proposal.
6. Tentative terms, which are interpreted in the Markowitz study as an expression of *hesitation*. However, tentativeness may also mean that the text is *prudent* in its arguments and conclusions. We would expect that these two meanings of tentative terms work in opposite direction, and therefore not relate to the panel score.
7. Causal language indicate that the proposed project has strong claims (Connor & Wagner 1998) and therefore may be more convincing for the panel members or reviewers.

The case covers one year only, so possible changes in language use over time do not affect the analysis. The same holds for possible changes in the implicit or explicit criteria that are used to evaluate the grant proposals. As this study is restricted to a single funding instrument, the dataset is rather homogeneous. This may help to isolate the effect of language use more precisely. In order to reflect possible disciplinary differences in writing, the linguistic variables were standardized at panel level. Furthermore, a few covariates are included. (1) Panels is used as random effect in the mixed model analysis, and as covariate in the ordinal and the logistic regressions. (2) The applicants come from many countries, and only a small minority has English as mother language. Therefore, English language proficiency may therefore differ considerably between the applicants. Using the reports of a large international language training institute (Education First 2013), we created a score for English proficiency at the country level. This is a rather rough measure, so one should interpret the findings with care.

As dependent variables we use the score for the project proposal, the final score, and success of the application. To predict the scores for the *project proposal*, we conduct a multi-level analysis with SPSS26, using linear mixed models, and panel as random effect. The *final score* is an ordinal variable with five values, from low to high: C, B (first step), B (second step) A, A-funded, which were recoded it into numerical values 1 to 5. We use ordinal regression to test whether the linguistic variables affect this score, with panel as covariate to control for disciplinary differences. Finally, we use the dichotomous variables *to-step2/not-to-step2* and *grant/no-grant* as dependent variables, and for predicting these, we use logistic regression. The analyses are done for step 1 and for step 2 of the procedure, as the role of language may differ between the two phases in the procedure. Each of these analyses is done for each of the three texts (project, abstract, and CV).

Results

As the project text is much longer than the abstract, we use the former one for the core analysis. The analysis is repeated for the abstract and for the CV, which may strengthen the findings. Table 1 shows for the project text the correlation between the main variables. The score received in Step-1 for the project proposal correlates positively with word count, certainty terms, causal terms, and the level of English language proficiency. It correlates negative with words per sentence, common words and analytic thinking. There is no correlation with tentative terms. This confirms most of the expected relations.

Table 2 shows the results of the multivariate (mixed models) analysis how the linguistic variables affect the project score in the 1st step of the section procedure, where we control for the level of English language proficiency and include panel as random effect. The analysis shows that more complex texts (longer text, longer sentences and less common words) work positively, but too long text and too long sentences work negatively. And a more narrative style works positively on the score, just as the use of certainty words and causal words, and as expected, tentative words do not play a role. English language proficiency has also a positive effect on the project score.

Ordinal regression. Nagelkerke Pseudo R2 = 0.146;
Panel scores not included in the table.

The proposals also get a *final score* which classifies them into five groups. Do the linguistic variables affect the finale score? Table 3 shows the results of the analysis, which are very similar to the results of the mixed models analysis reported above: Complex texts which are longer, have longer sentences, more technical terms (= fewer common words), and use a narrative style (a lower score on analytical language) get higher scores. Causal language and certainty also have a positive effect, as has English proficiency. The use of tentative terms has again no effect on the score. The explained variance is 0.146 (Nagelkerke pseudo R^2).

The linguistic variables may also influence the *decisions*. In the first step, the decision is whether a proposal is selected to progress to the second step. About 25% of all proposals go into the second step, where half of them receive the grant. A logistic regression shows that most of the independent variables have similar regression coefficients as in the previous analyses (Table with results not included in this paper). The explained variance (Nagelkerke pseudo R^2) is 0.106. The findings of the various analyses support our first three expectations.

Above, the expectation was formulated that the effects of the linguistic variables would be much smaller in the second step of the procedure than in the first step, and the findings support this. In step 2, most of the correlations between the project score and the linguistic variables are not significant (table 4). In the mixed model analysis, the length of the proposal has a positive effect on the evaluation score, but too long texts score lower. And the share of common words has a negative effect on the project evaluation score. All the other linguistic variables and English language proficiency do have no effect. Finally, only the word count variables have a significant effect on the decision in step 2.

Table 4: Pearson correlations between the main variables in step 2 (project text)

1	Project score (step 2)	1	2	3	4	5	6	7	8	9	10	11
2	CV score (step 2)	.691**

** Correlation is significant at the 0.01 level (2-tailed). * Correlation is significant at the 0.05 level (2-tailed). N=754

The previous analyses were done on the *project text*. A similar analysis could be done for the *abstract* text and the *CV* text. Does the writing style of the applicant in these texts have the same effect on scores and decisions? We lack space to show these analyses, but the patterns are similar, although less pronounced.

Further research

Despite the fact that current CVs are rather structured with many listed items and not so much normal text, similar relations between word use and evaluation scores and decisions were found as for the project descriptions. However, recently one observes a trend to ask for a more discursive CV instead of merely lists of positions, experience, and (bibliometric) achievements (VSNU 2019). The linguistic properties of successful CVs are a topic for further research.

This paper studied how elements of self-presentation affects the evaluation scores and application success. However, different social groups may present themselves in different ways, which may affect the evaluation outcomes differently. In a future study we plan to extend the analysis by including more characteristics of applicants, especially gender. We also plan to include other elements of self-presentation such as gendered language use.

Conclusions

In contrast to earlier studies, this study includes *also the non-successful applicants*, and is based on *different texts* belonging to grant applications (abstract, project, CV). The findings suggest that writing style has an effect: The way of writing influences the scores grant applications receive, and through that the probability of success. The linguistic characteristics of the texts do have an effect on the panel scores, on the final score, and on the grant decision. Complex language (longer text and longer sentences), with technical content (lower share of common words) is beneficial, and positively affects the scores and the probability to get funded. In contrast to earlier work (Pennebaker et al. 2014), a more *narrative writing style with technical terms* works better. Finally, confidence in the grant proposal expressed through *certainty* terms and *causal* language has a positive effect, but in contrast to earlier work (Markowitz 2019) we do not find any effect of tentative terms. This was expected, as tentative terms can have two functions: expressing uncertainty but also expressing the necessary tentative nature of scientific findings.

These findings are most visible when analyzing the project text, but the analysis of the proposal abstract and of the CV point in the same direction – this despite the fact that these texts have other functions (Feng & Shi 2004) and, especially the CV, also a different structure.

The study enabled to distinguish between two steps in the project selection process, and language and writing style have an impact in the first phase of the selection process, but not anymore in the second. In the first phase, the writing style and readability may be important as many applications have to be processed by the selection panel within a relative short period, whereas in the second phase more time is available to assess the remaining smaller set of applications. Above that, the applications that make it to the second phase are already perceived by the selection panel as excellent, and therefore the reviewers may be more inclined to carefully read the text even if the writing style is not too good. This suggest that what counts as an adequate text is context dependent.

The linguistic model to predict the final score (using ordinal regression) explained a moderate part of the variance (Nagelkerke pseudo $R^2 = 0.146$). And using logistic regression to predict the first selection decision (proceed to Step 2 or not) resulted in a Nagelkerke pseudo R^2 of 0.1. Concluding, the effect of the writing style may not be very strong, but it is substantial.

Finally, this study suggests that the role of the writing style may be context dependent. We showed that for the two phases of the application procedure, but it may also be the case for e.g., phases in the career: what is perceived as a good text of a novice may be different from what is perceived as a good text of an expert.

Acknowledgments

This paper is a result of the GendERC project, which received funding from the ERC under grant 610706. Contract partners were Joanneum Research (Vienna, Austria), Vrije Universiteit Amsterdam (Amsterdam, the Netherlands), and Tecnalia (Bilbao, Spain). The authors thank Anne Baker (University of Amsterdam) for support on how to interpret the linguistics results, and David Markowitz (University of Oregon) for comments on an earlier version of the paper.

Abstract

Gender bias in selection panels for positions and grants has been studied intensively over the last decades. However, apart from comparing review scores received by men and women, we do not know much about how panel composition, procedures and processes influence selection. This is an omission, as decision making on grants and academic positions is strongly influenced by the prioritizing and selecting in those panels. Based on the relevant social-psychological literature on small group decision making, we distinguish several panel attributes that may influence the decisions in the panel in general and the prevalence of gender bias more specifically: (i) Composition of panels in terms of gender composition and variety of countries represented in the panel, (ii) workload of the panels, (iii) and especially the level of gender stereotyping in the panels. This explorative case study suggest that panel composition indeed correlates with gender bias: the more women the stronger the gender bias against women, the more experience male panelists have, and the more countries represented in the panel, the stronger the bias in favor of women. Workload did not correlate with gender bias, but the level of gender stereotyping does: the stronger stereotyping as found in the review reports, the stronger bias against women applicants.

Introduction

Gender differences within science may have become smaller over time, they have not disappeared. Women are still underrepresented in higher academic positions (Ginter & Kahn 2006; Kahn & Ginter 2018), apply less often for grants (Dickson 1997) and have – not undisputed - lower probability to receive grants (Holman et al. 2018). Many of the relevant decisions with respect to positions and grants are made in panels. Panel members are expected to deploy a variety of merit related selection criteria (Van Arensbergen et al. 2014). However, as social-psychological research on group decision making has shown, also a variety of small group (panel) characteristics does influence the decision outcomes (Olbrecht & Bornmann 2010; Van Arenbergen et al. 2014b), and bias seems unavoidable. Research on review panels is largely qualitative (Lamont 2009), but in this paper we use a quantitative approach to detect what panel characteristics predict gender bias in panels. A core mechanism that we include is in this paper is *gender stereotyping*, that is panelists implicitly assuming men are better suited for science than women (Ellemers 2018; Madera et al. 2009; Sekaquaptewa et al. 2003: Leslie et al. 2015), and which leads to differences in how men and women are assessed. The first aim of this paper is to determine what panel characteristics lead to gender bias. The second aim is to measure gender stereotyping in order to find out whether the level of gender stereotyping predicts the level of gender bias at the panel level. We do this using a case study on gender bias in grant allocation.

Research on bias in grant allocation

Gender bias in grant peer review was put on the research agenda and the research policy agenda by the Wennerås & Wold (1997) study of the Swedish medical research council, a paper which has become a point of reference in the debate. However, the literature on gender bias in grant allocation has resulted in contradicting findings, partly suggesting the absence of gender bias in grant allocation (Ceci et al. 2014; Williams & Ceci 2011, Friessen 1998; Grant et al. 1997;

Dickson 1997; Hosek 2005; Sandstrom & Hallsten 2008; Jayasinghe et al. 2003; Marsch et al. 2008, 2009, 2011; Beck & Halloin 2017), and partly suggesting that gender bias is a real issue in grant decisions (Wennerås & Wold 1997; Bornmann et al. 2007; Ban der Lee & Ellemers 2015; Van den Besselaar et al. 2018; Witteman et al. 2019). However, two problems exist with most of these studies, and these problems may also explain the contradictory results. Firstly, many studies do not include merit (or performance) variables, which is generally acknowledged as a major drawback. As Marsh et al. (2008) argue, "An important limitation in our research program with grant applications, and in peer-review research more generally, is that we had no fully appropriate external criteria against which to validate the outcomes of the peer-review process. We argued that the final panel decision (based on the integration of all available information) was the best criterion available for validating and testing potential biases in the ratings by individual assessors. However, a more external criterion is needed to validate the results of the panel decision itself. (…….) However, at least in terms of ratings of researcher quality, the previous track record of researchers does provide a viable validity criterion. Nevertheless, the need to find more suitable validity criteria remains a critical issue for research into the review of grant applications and for peer-review research more generally"
The other drawback is that the analysis is generally done at the level of a council or a funding instrument, without taking the panel level into account, despite the fact that at the panel level the decisions are made or at least heavily influenced. In this paper we specifically focus on panel decision making and on the panel characteristics that influence the level of gender bias. And more particularly, we focus on measuring the effect of (unconscious) gender stereotyping on gender bias.

Research question

In this paper we address the following research question: What panel characteristics explain the differences in gender bias between the panels? The question is important for a better understanding of the dynamics of - within the science system widely used - panel decision making. Better understanding of these dynamics may also contribute to improving the quality of decision making.

The case

Our case is the 2014 Starting Grant of the European Research Council (ERC). The sample consists of 3030 (out of 3200) applicants are distributed over 25 disciplinary panels. The panel processes in this case are not formalized, neither are the criteria formulated for the panelists. According to the council, the only criterion that should be deployed is the level of excellence of the project and the principle investigator. This is described in the following way: Excellent investigators have shown creative independence thinking, the ability to do ground-breaking research, and have moved beyond the state of the art. As panels members are excellent researchers in their respective fields, the panelists should therefore decide among themselves what excellent applications are. But interviews with panel members have shown that they do not find it easy to operationalize the concept of excellence and its elements such as 'independence' or 'the ability to do groundbreaking research'. This results in uncertainty and in different approaches by different panelists. Panelists doubt about criteria deployed and express the need for clearer and operational criteria for 'excellence'. Inspecting the review reports support this uncertainty. In some cases, a PI will get a low score because his/her "publications are not well cited", in others because "publications are not in the main multidisciplinary journals", and again in others because "the proposal has a high risk", despite that the ERC asks for "high risk – high gain" projects. Additionally, the workload of the panels is rather high, which may lead to heuristics-based decision making, and these heuristics may be stereotype-based (Van Arensbergen et al. 2014b).

The case is interesting, as it contains of panels in which women have a lower success rate than men, panels with an about equal success rate, and panels where women have a higher success rate then men. However, success rates as such are an indicator of gender differences, but not necessarily of gender bias. In order to measure bias, one needs to control for differences in merit – which we did elsewhere for 22[b] out of 25 panels using logistic regression (Van den Besselaar & Mom - forthcoming). The dependent variable was the panel decision, and several independent merit variables were included: (i) Performance variables measuring productivity, impact, and earlier grants), reputation variables such as publications in top journals, ranking of the host institution, and the median ranking of former employers of the applicant, and organizations the applicant collaborated with; and personal characteristics such as age, academic age, and of course gender. Several other relevant merit-variables cannot be included here due to a lack of data: e.g., *prizes and awards*, and *community roles* such as support roles in the work environment, editorships of journals, board member of learned organization, or program chair of conferences.

In order to inspect the gender effect in more detail, the predicted margins (or predicted probabilities: PP) were calculated using STATA 16. When using logistic regression, this is needed as it provides the effect of gender for individual values of independent variables. This would remain unclear from the regression coefficient alone – ass the latter gives the gender effect only for one value (zero) of the independent variables (Mood 2009).

For each panel, a *gender bias indicator* was calculated: the average predicted probability of women (PPw) in a panel divided by the success rate of women in that panel (SRw). When this indicator is larger than one, there is bias against women. When the indicator is smaller than one, the panel shows bias in favor of women. And the higher the value of the indicator, the stronger the bias against women. The advantage of the indicator is that it allows for bias in both directions, as there may be panels with bias against women and panels with bias in favor of women. Indeed, using the gender bias indicator defined above, we do find bias *in different directions*: six of the panels show bias against women, seven show bias in favor of women, and nine other panels are about neutral. Table 1 shows the results of the analysis at panel level.

Table 1. Locus and effects of gender bias at panel level (N=22).

Panels	*All*	*LS*	*PE*	*SH*
Panels with strong advantage for men	4	2	1	1
Panels with advantage for men	2	1		1
Neutral panels	9	5	4	
Panels with advantage for women	3		3	
Panels with strong advantage for women	4	1	2	1
Grants gained (PE) and lost (LS, SH) by women	0.2	3	-4.2	1.4
Share of all grants received by women		7%	11%	16%

Source: Van den Besselaar & Mom (forthcoming)

In the Life Sciences (LS) and the Social Sciences and Humanities (SH), there are more panels with bias against than in favor of women, and in the Physics and Engineering (PE) panels it is the opposite. Table 1 also shows the effects on the gender distribution of the grants. In LS, women should have received 3 more grants, and in SH 1.4 more. On the other hand, in PE women received 4 grants more than expected when taking merit into account. The numbers seem low, but as a share of all grants for women it is substantial: 7%, 16% and 11% in LS, PE and SH respectively.

Panel characteristics and panel decision making

The literature distinguishes several panel characteristics that may influence decision making, such as *panel composition* and *panel dynamics* (Lamont 2009; Thorngate et al. 2009, Olbrecht & Bornmann 2010; Van Arensbergen et al. 2014b). The latter we cannot test here, but the first we can, using available data about the panelists, such as gender, experience (first year member or more years membership) and nationality. Would more female panel members increase the probability for women applicants to be successful? This has been a leading idea behind gender equality policies in research councils, including the case studied here. Or does it work opposite, based on the so-called *queen bee* mechanism (Faniko et al. 2020): Women in the panel are experienced researchers that made a successful career in a male dominated science system. In order to be able to do that, female panelist may have internalized the same stereotypes as men have, and according to the queen bee theory, often even stronger than men.

As the council under study strongly emphasizes gender equality, more *experienced* panel members may have internalized this policy more than those who are in the panels for the first time. If so, one would expect that the higher the (average) experience of panelists, the lower the level of gender bias against women in that panel.

Another factor mentioned in the literature that influences decision making is *work-load*. The higher the work-load, the more decision making is based on heuristics instead of on a detailed assessment of the individual grant applications (Van Arensbergen et al. 2014). And these heuristics can be expected to reflect at least partly *gender stereotypes* panel members may have. The expectation would be that the higher the work-load, the stronger the role of gender stereotypes, and the higher the bias against women applicants.

Measuring gender stereotyping

How can we measure the strength of these stereotypes? Literature has shown that gender stereotypes influence spoken and written language, and that this can take different forms. (i) The same criteria may be used for men and women, but the evaluation of men tends to focus on the *presence* of required qualifications, whereas the evaluation of women tends to focus on the *absence* of qualifications (Uhlmann & Cohen 2005). One therefore would expect that men are evaluated in positive terms (presence of the required quality) and women in negative terms (absence). For example, independence is an important criterion in the grant instrument under study. In the evaluation of men, one would expect that independence is mentioned when the male applicant indeed is independent, but it is not mentioned if the male applicant is not independent. For women it would work in the opposite way. If present, independence is not mentioned, but if absent it would be mentioned as a negative point (Vinkenburg et al. 2014). (ii) Communication theory suggests that stereotyping generally leads to the use of negation words (like not, no, never) for the 'out group': negation bias (Beukenboom et al. 2010). Within a male dominated system, women are the outgroup, and consequently, positive characteristics of women are formulated in negative terms ("She is not bad" versus "he is good"). This would add to the use of negation terms in reviews about women. (iii) As the excellent scientist stereotype is male, male (agentic) traits such as being assertive, confident, ambitious, dominant are considered important (Abele & Wojciszke 2014). One would therefore expect that the stronger the gender stereotypes in a panel, the more agentic terms are used in review reports, and in combination with the previous points differently for men than for women. In review reports about men one would expect agentic terms to be used in a positive way, whereas in review reports of women one would expect that the use of agentic terms refer to the lack of those traits. So for women the frequency of agentic terms would correlate positive with gender bias *against* women, and for men one would expect that the frequency of agentic terms would correlate positively with bias *in favor* of men. (iv) Gender stereotyping depends on implicit and automatic attitudes and opinions of panel members, but other panels characteristics influence the role of stereotyping. For example, high work pressure may result in *decision heuristics* replacing the individual assessment of applicants (Van Arensbergen et al. 2014a), and those heuristics may bring in gender stereotyping.

Data & methods

To analyze the *effects of panel characteristics* on the level of bias, we use the following variables: (i) level of gender stereotyping, measured by the frequency of negation words, and of agentic words in the review reports – aggregated at the panel level; (ii) the number and share of female panel members; (iii) the diversity of panels in terms of countries represented in the panel; (iv) the experience of the panel members (number of years in the panel); and (v) the work load (number of applicants per panelist).

The Linguistic Inquiry and Word Count (LIWC) program (Tausczik & Pennebaker 2010; Seih et al. 2017) was used to produce the linguistic variables based on the review reports. The project proposals were processed with LIWC, using the 2015 English dictionary (Seih et al. 2017). We could use an existing dictionary for *agentic terms* (Madera et al. 2009), and the standard *negation words* category of LIWC. LIWC provides for each of the proposals the percentage of negation words and the percentage of agency words. The resulting percentages of the relevant linguistic categories have been averaged per panel for men and women separately.

An exploratory analysis gives the *correlation* between the gender bias indicator and several panel characteristics. This shows what panel characteristics predict gender bias.

Findings: Gender bias and panel characteristics

Why do the scores for gender bias differ between the panels? One possible interpretation is that random variation in the decision-making process will lead to variety of bias scores at the panel level, without a systematic pattern. At panel level, men and women as a group sometimes win and sometimes lose, but over a longer period at the aggregated level, there may be equality. This would also explain the contradictory findings between studies on gender bias in grant allocation.

Another possibility is that the differences in gender bias relate to panel characteristics, such as panel composition, processes, procedures, and to the opinions and implicit gender stereotypes of the panelists. If there is no gender bias, one would expect no systematic correlation between panel characteristics and the bias indicator. The number of panels (22) in this study does not enable an in-depth multivariate analysis, but it allows for an exploratory analysis.

Differences between the disciplinary domains.

Before analyzing the differences between the panels, we firstly address differences at the higher level of the disciplinary domains. In domains with many female applicants (Social sciences (SH) and in Life sciences (LS)), we found that bias tends to be against women, but in the domain with low percentages of women (Physics and Engineering (PE)) it tends to be the opposite. This is similar to the findings of Van der Lee and Ellemers (2015), who suggested that panelists in fields with many female researchers may become less aware that gender bias is still relevant, and (male and female) panelist may become much more critical towards women. On the other hand, in PE, women have more success than expected. An explanation could be that within these fields a more diverse staff (and student population) is needed and wanted, and panels may therefore have some preference for women when deciding about grants[c]. We indeed found a positive relation between the share of women applicants in a field and the level of gender bias (r = 0.197). If our argument is correct, then a consequence would be that if the share of women in the PE domain increases, the domain may become more similar to LS and SH fields – leading to a stronger overall bias against women.

Work load

The procedure in the studied funding instrument consists of two steps. In the first step we found bias against women, and in the second step the bias was in favor of women (Van den Besselaar & Mom, forthcoming). Small group research suggests that the higher *work-load* in a group, the more members will use heuristics (such as gender stereotypes) for decision-making, instead of assessing individuals on their merit (Olbrecht & Bornmann 2020; Van Arensbergen et al. 2014b). This may explain that in step 1 gender bias is in favor of men, as in that step work pressure is much higher for the panelists who have to assess a huge amount of applications in a short time. In step 2 this is different, as only 25% of the applicants make it to step 2, and consequently work load in step 2 is much lower than in step 1. However, one would also expect to find this pattern at the level of panels: do panels with higher numbers of applicants and so higher work load have a stronger bias against women? If this would be the case here, one would expect a positive correlation between the workload (number of applicants divided by the number of panelists) and the bias indicator. As Table 2 shows, this is not the case (r = - 0.214).

Table 2. Factors influencing gender bias at the panel level

Variables	*Pearson correlation with the bias indicator**	*Significance level*
Workload	-0.214	0.340
Share female applicants	0.290	0.191
Gender stereotyping		
Negation words (women)	0.601	0.003
Negation words (men)	0.350	0.110
Agentic words (review reports women)	0.458	0.032
Agentic words (review reports women)	0.277	0.211
Panel composition		
Number female applicants	0.195	0.385
Number recurring female applicants	0.054	0.812
Number recurring male applicants	-0.441	0.040
Country diversity	-0.460	0.031

* Positive bias score = bias in favor of women, negative bias scores = bias in favor of men. The higher the score, the more beneficial the panel is for women; the lower the score, the more beneficial it is for men.

Gender stereotyping

One of the most discussed causes of gender bias is *gender stereotyping*, which - as discussed earlier - can be identified through the analysis of language use. *Negation* terms in review reports not only indicate negative evaluations of applicants but also reflect gender stereotypes about women (Beukeboom et al 2010; Beukeboom 2014; Beukeboom & Burgers 2017). As gender stereotyping may lead to gender bias against women (Ellemers 2018; Varian 1999; Steward & Valian 2018), one would expect that the higher the amount of negation words in review reports about women (aggregated at the panel level), the higher gender bias score for that panel – which is indeed the case (r = 0.601, p = 0.003). The correlation between the gender bias indicator and negation words in review reports of men is also positive but lower (r = 0.350, p = 0.110), implying that in panels where review reports about men use more negation words, the level of bias in favor of men us higher (Table 2).

Agentic characteristics (Madera et al, 2009) are considered important for scientists. At the same time, men are expected to possess agentic characteristics, but for women this is often seen as an exception. Therefore, one would expect that women are differently assessed in terms of agentic terms than men. We indeed find at panel level a positive relation between the bias indicator and the use of agentic terms in reviews about men (r = 0.273, p = 0.211), implying that the more agentic terms in the review, the higher bias *in favor* of men. For women we find an even stronger correlation between the gender bias indicator and the use of agentic terms (r = 0.458, p = 0.032). So, the more agentic terms, the higher bias *against* women (and in favor of men). Obviously, when agentic characteristics are discussed, it is done in a positive way for men, but in a negative way for women.

Panel composition

Despite the often-used policy of increasing the number of female panelists, we found that the *more* women are in a panel, the higher the panel does score on gender bias (r = 0.195), which also was found in other studies (Border 1993). As discussed, this can be explained by the queen bee phenomenon.

Gender equality is a clear and visible priority within the council, and therefore one would expect that experienced reviewers (= not a first-year panel member) would be more aware of gender bias and act accordingly: a negative correlation between the average experience of panel members and gender bias. This indeed works for men (r = -0.441, p = 0.04) but not for women (r = - 0.054). Experienced women seem to remain critical on women applicants, also in line with the Queen Bee phenomenon (Faniko et al, 2020). Finally, diversity of a panel in terms of nationalities represented has a positive effect for women (r = -0.460, p = 0.031).

We were also able to test this partly also for other years (2009-2014), albeit without using the merit variables as covariates which we only have for 2014. A multiple linear regression was done to investigate the relation between *diversity in the panel* and the *success rate of female applicants*. As panels may differ in success rate, and female applicants are not evenly distributed over the panels, we have to control for the *overall success rate* of panels. We do this analysis for all panels we have this information for, that is 150 panels over the 2009-2014 period. Table 3 shows the results, which are similar to those for 2014 only: Controlling for the panels' overall success rate, the country diversity has a positive effect on the female success rate, but the share of female panel members in a panel has a significant negative effect.

Table 3. Success rate of female applicants by share of female panelists and by country diversity

	Standardized Beta	T	Sig.
(Constant)		-0.977	0.330
Share of female panel members	-0.151	-2.094	0.038
Number of countries in panel	0.122	1.71	0.089
Overall success rate	0.444	6.187	0.000

$R^2 = 0.25$

Conclusions and discussion

In our case, 27% of the panels there is bias *against* women, and in 32% there is gender bias *in favor* of women, leading to an about equal overall result. Women lose in LS and SH, but win in PE. Several panel characteristics were found to correlate with the gender bias against women, such as the share of female panelists (positive correlation), the share of experienced panelists, and the international variety of panel members (both negative correlation). Using a linguistic analysis of the review reports to measure gender stereotyping, we found that the higher the level of gender stereotyping at the panel level, the stronger gender bias against women.

This study has several *limitations:* The findings at the panel level are explorative. Although the initial results are promising, we would welcome a study based on a much larger sample of panels and funding instruments. In that way, it would be possible to systematically relate the level of gender bias with the relevant characteristics of panels and panel members within their organizational and possibly national context. Another limitation relates to the merit variables, as several others could be included representing a variety of other merit dimensions, such as the applicant's independence (van den Besselaar & Sandstrom 2019), and the number of awards and prizes.

Several lines of *further research* can be distinguished. First, women seem to apply for grants less often than men do, which leads to gender differences in winning research grants independently of the decision-making process. The role of self-selection within application behavior is therefore an interesting topic for further research. Second, several other forms of bias exist, based on nepotism, cognitive proximity, or ageism. These forms of bias may work out differently for men and women. Third, as the quality of the textual and (during the interview) the oral presentation of the proposal may play a role in the panel assessment, the question comes up whether men and women differ in terms of self-presentation, and whether this influences the selection process.

Acknowledgements

This paper is a result of the GendERC project, which received funding from the ERC under grant 610706. Contract partners were Vrije Universiteit Amsterdam (Amsterdam, Netherlands), Joanneum Research (Vienna, Austria), and Tecnalia (Bilbao, Spain). The authors are grateful to especially Lucia Polo (Tecnalia), who collected data about the panel members, and to Camiel Beukeboom (Vrije Universiteit Amsterdam) who provided useful advice on how to analyze linguistic bias.

Crossref as a source of open bibliographic metadata

Nees Jan van Eck and Ludo Waltman

{ecknjpvan, waltmanlr}@cwts.leidenuniv.nl
Centre for Science and Technology Studies (CWTS), Leiden University, Leiden (the Netherlands)

Abstract

Several initiatives have been taken to promote the openly availability of bibliographic metadata of scholarly publications in Crossref. We present an up-to-date overview of the availability of six metadata elements in Crossref: reference lists, abstracts, ORCIDs, author affiliations, funding information, and license information. Our analysis shows that the availability of these metadata elements has improved over time. However, it also shows that many publishers need to make additional efforts to realize full openness of bibliographic metadata. To illustrate the value of open metadata, we use the metadata in Crossref to construct and visualize a large citation network of scholarly journals.

Introduction

Many scholarly publishers work together with Crossref (https://www.crossref.org/) to register Digital Object Identifiers (DOIs) for their publications. These publishers have the possibility to submit bibliographic metadata for their publications to Crossref. This metadata is then made openly available by Crossref, with the possible exception of the reference lists of publications, which may be kept closed. By making large amounts of bibliographic metadata openly available, Crossref is becoming an increasingly interesting data source for bibliometric analyses (Hendricks et al., 2020).

The Initiative for Open Citations (https://i4oc.org/), launched in 2017, has led to a major increase in the open availability of bibliographic references in Crossref, especially after Elsevier's recent decision to support the initiative (Plume, 2020; Waltman, 2020a). Likewise, the Initiative for Open Abstracts (https://i4oa.org/), launched in 2020, has contributed to an increase in the availability of abstracts in Crossref. Nevertheless, there are still many publications in Crossref for which the reference list or the abstract has not yet been made openly available. In addition, other metadata elements, such as ORCIDs and affiliations of authors and license and funding information, may not be available either.

In this paper, we present an up-to-date overview of the availability of bibliographic metadata in Crossref, focusing on six metadata elements: reference lists, abstracts, ORCIDs, author affiliations, funding information, and license information. We show how the availability of these metadata elements has improved over time (see also Habermann, 2019; Hendricks et al., 2020), and we analyze the contributions made by different publishers. We illustrate the value of open bibliographic metadata by using the metadata in Crossref to construct and visualize a large citation network of scholarly journals.

Data

We use Crossref's XML Metadata Plus Snapshot. The snapshot was downloaded on March 5, 2021. It includes the reference lists of publications in journals published by Elsevier and the American Chemical Society. These reference lists were opened in, respectively, January and February 2021. We consider only the 86.4 million records classified as journal article. For each article, we determined the year of publication. When a print year was provided, we used this year. When no print year was provided, we used another year field, typically the online year.

Availability of bibliographic metadata in Crossref

Time trend

Crossref includes a total of 52.8 million journal articles in the period 2000–2020. The annual number of articles has strongly increased during this period, from 1.3 million in 2000 to 4.7 million in 2020. Figure 1 shows how the availability of different metadata elements has improved over time. For each year in the period 2000–2020, the figure shows the percentage of articles that have an openly available reference list, an abstract, at least one ORCID, at least one author affiliation, funding information, and license information.

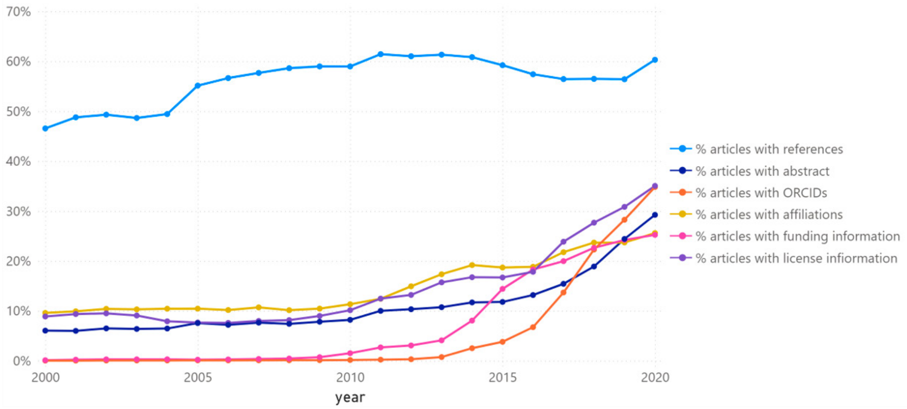

Figure 1. Availability of different metadata elements for journal articles in Crossref.

Thanks to the support publishers have given to the Initiative for Open Citations, reference lists have been made openly available not only for many recent articles but also for many older ones. As can be seen in Figure 1, the percentage of articles with an openly available reference list is fairly constant over time, starting just below 50% in 2000 and ending just above 60% in 2020. The percentage of articles for which an abstract is available has increased from 6% in 2000 to 29% in 2020. Most of the increase took place in recent years, thanks also to publishers' support for the Initiative for Open Abstracts.

In older years, there are almost no articles with ORCIDs. However, in recent years, the percentage of articles with ORCIDs has strongly increased, reaching 35% in 2020. This is an important development for bibliometric analyses in which the careers of researchers are traced. At the moment, such analyses typically rely on algorithms for author name disambiguation (Smalheiser & Torvik, 2009). In the future, when ORCIDs will have been widely adopted, the use of such algorithms may no longer be necessary.

The percentage of articles for which author affiliations are available has increased from 10% in 2000 to 26% in 2020. Affiliations are reported in unstructured strings, so they do not have a standardized format. In the near future, affiliations can be reported in a standardized way using Research Organization Registry (https://ror.org/) identifiers (Gould, 2020). Because this is a very recent development, we do not consider it in more detail in this paper.

Funding information is almost completely missing for older articles, but in recent years the availability of funding information has increased substantially. For 25% of the articles in 2020 funding information is available.

The percentage of articles for which license information is available has increased from 9% in 2000 to 35% in 2020. Crossref distinguishes between license information for three different versions of an article: The author's accepted manuscript, the version of record, and the version intended for text and data mining. In Figure 1, we consider license information only for the author's accepted manuscript and the version of record.

In the interpretation of the above statistics, it is important to be aware that all documents published in a journal are classified as journal article in Crossref. This includes not only research articles, but for instance also letters, editorials, book reviews, and corrections. Some of the documents published in a journal may not have a reference list, an abstract, or funding information. The percentage of journal articles for which all metadata elements are available will therefore never reach 100%.

Publishers

Different publishers handle the submission of bibliographic metadata to Crossref in different ways. Some publishers submit as much metadata as possible, while other publishers submit only specific metadata elements. The latter publishers may prefer not to submit certain metadata elements, such as abstracts or author affiliations, to Crossref. It is also possible that they are not aware of the possibility to submit these metadata elements to Crossref or that they do not have the technical expertise needed to submit them. In the case of reference lists, publishers may also choose to submit them to Crossref but not to make them openly available.

For the 8.8 million journal articles in Crossref in 2019 and 2020, we determined for each publisher the percentage of articles that have an openly available reference list, an abstract, at least one ORCID, at least one author affiliation, funding information, and license information. The resulting statistics are available in Zenodo (Van Eck & Waltman, 2021).

Almost all of the larger publishers support the Initiative for Open Citations, as can be seen on the website of the initiative (https://i4oc.org/). Our statistics indeed confirm that almost all of the larger publishers make the reference lists of their articles openly available in Crossref. The most important exception is IEEE, which submits reference lists to Crossref but does not make them openly available.

The Initiative for Open Abstracts is supported by a substantial number of larger publishers. However, the four largest publishers (i.e., Elsevier, Springer Nature, Wiley, and Taylor & Francis) do not yet support the initiative, even though Springer Nature does submit abstracts to Crossref for some of its articles. Our statistics indeed show that a number of larger publishers do not yet make abstracts available in Crossref. Similar statistics are also presented on the website of the Initiative for Open Abstracts (https://i4oa.org/).

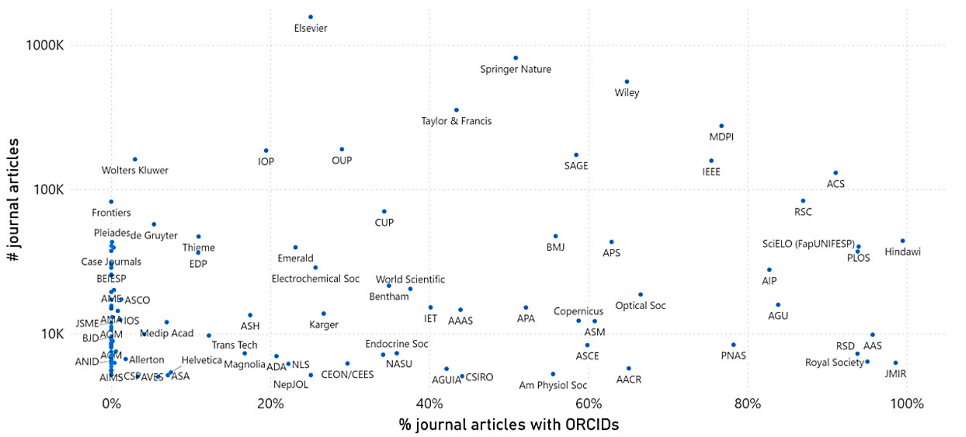

Figure 2. Number of journal articles of a publisher in 2019 and 2020 and percentage of articles with at least one ORCID.

For publishers with at least 5000 articles in 2019 and 2020, Figure 2 shows the percentage of articles with at least one ORCID. All publishers with more than 100,000 articles make ORCIDs available in Crossref. However, for some of these publishers, in particular Wolters Kluwer, the percentage of articles with ORCIDs is still quite low, while for others, such as the American Chemical Society, MDPI, and IEEE, it is already fairly close to 100%.

Figure 3 presents statistics for author affiliations. There is a clear separation between publishers that do not make affiliations available in Crossref and publishers for which almost all articles in 2019 and 2020 have affiliations in Crossref. Looking at the largest publishers, Figure 3 shows that most articles of Wiley and Taylor & Francis have affiliations, while affiliations are completely missing for articles of Elsevier, Springer Nature, and MDPI.

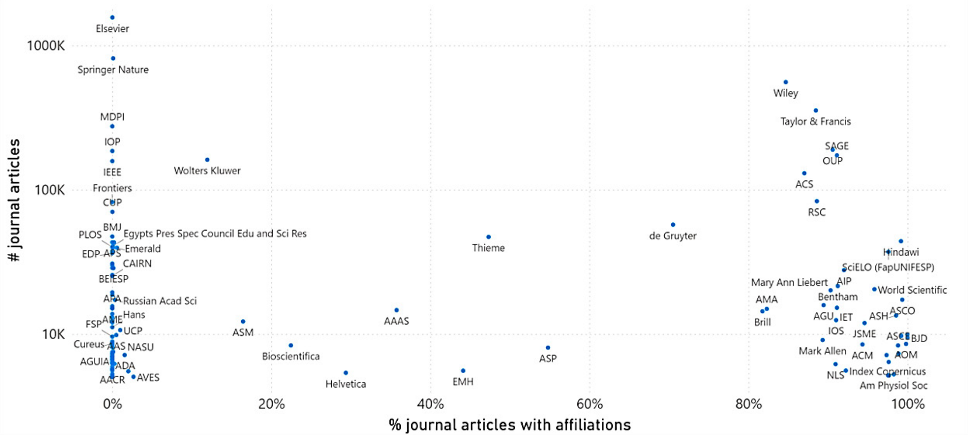

Figure 3. Number of journal articles of a publisher in 2019 and 2020 and percentage of articles with at least one author affiliation.

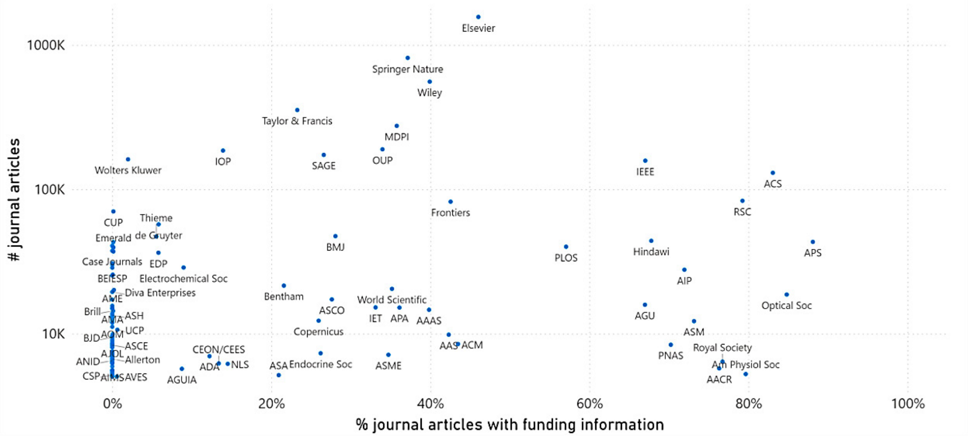

Figure 4. Number of journal articles of a publisher in 2019 and 2020 and percentage of articles with funding information.

As can be seen in Figure 4, all publishers with more than 100,000 articles in 2019 and 2020 make funding information available in Crossref, although for some of them the percentage of articles with funding information is quite low. Differences between publishers in the percentage of articles with funding information may be partly due to differences in the disciplinary profiles of publishers. For articles in the natural sciences it is more common to acknowledge funding than for articles in the social sciences and humanities. Publishers that are active mainly in the natural sciences can therefore be expected to have a higher percentage of articles with funding information than publishers that focus primarily on the social sciences and humanities.

Figure 5 shows that many publishers, including large ones such as Wiley and MDPI, have made license information available for all or almost all their articles in 2019 and 2020. However, many other publishers, including Elsevier, Springer Nature, and Taylor & Francis, have made license information available for only a small share of their articles, or they have not made any license information available at all.

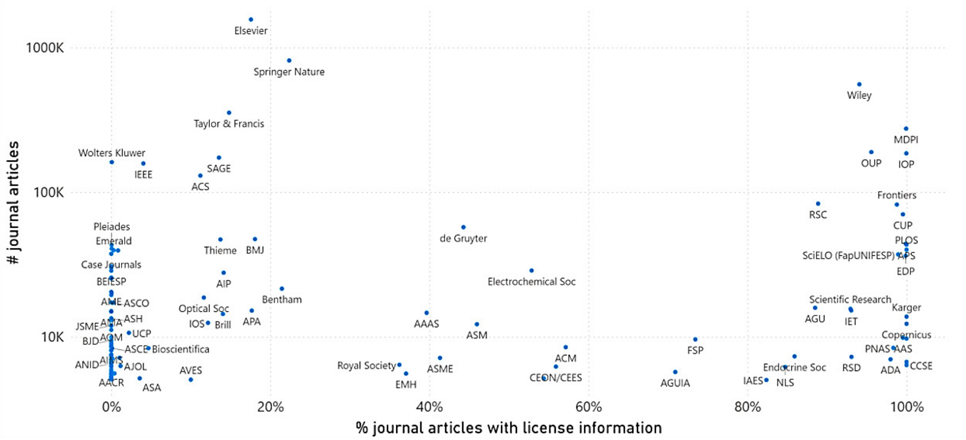

Figure 5. Number of journal articles of a publisher in 2019 and 2020 and percentage of articles with license information.

Constructing and visualizing a journal citation network

To illustrate the value of the open bibliographic metadata, we use the metadata in Crossref to construct and visualize a large citation network of scholarly journals.

Based on openly available reference lists, we identified 0.94 billion citation links between the 86.4 million journal articles in our data. We excluded all journals that have fewer than 300 articles with references to other articles in our data. Of the remaining 14,931 journals, we selected the 10,000 journals with the largest number of (incoming and outgoing) citation links with other journals. We constructed a citation network for the selected journals. This network includes 0.75 billion citation links between the selected journals. Using the VOSviewer software (Van Eck & Waltman, 2010; https://www.vosviewer.com/), we created a visualization of our journal citation network. The visualization can be explored interactively at https://bit.ly/3dNHA2A.

A few years ago we created a similar visualization (Van Eck & Waltman, 2017). The number of journals with openly available reference lists in Crossref was more limited at that time, and the visualization therefore included a smaller number of journals. However, the overall structure of the two visualizations is quite similar. This structure resembles the so-called consensus map of science discussed by Klavans and Boyack (2009).

Conclusion

Openness of bibliographic metadata is as an essential element in the broader development toward openness in scholarly publishing (Waltman, 2020b). Open bibliographic metadata helps to make bibliometric analyses more transparent, reproducible, and inclusive. It also helps to make it easier for researchers and others to find the most relevant scholarly literature.

We have shown that the open availability of different metadata elements in Crossref has improved over time (see also Habermann, 2019; Hendricks et al., 2020). The increasing availability of reference lists, abstracts, ORCIDs, author affiliations, funding information, and license information is an important development. However, many publishers need to make additional efforts to realize full openness of bibliographic metadata. Publishers often do a good job in making certain metadata elements openly available, but they fail to do the same for other metadata elements. For instance, Wiley is among the leading publishers in terms of the availability of ORCIDs, author affiliations, and license information in Crossref, but it has not made any abstracts openly available. We hope that the statistics presented in this paper will help publishers to move toward full openness of bibliographic metadata.

A more in-depth analysis is currently in preparation. We plan to calculate more detailed statistics on the availability of different metadata elements in Crossref. In addition to journal articles, other content types, such as articles in conference proceedings, books and book chapters, preprints, data sets, and peer review reports, will be considered as well. We also plan to analyze the availability of links between different content types, for instance between journal articles on the one hand and preprints, data sets, and peer review reports on the other hand.

Acknowledgments

We are grateful to our CWTS colleagues Henri de Winter and Patrick Kooij for their help in processing the Crossref data. We thank Bianca Kramer and Catriona MacCallum for helpful feedback on an earlier version of this paper.

Abstract

This research in progress paper provides preliminary results of an analysis of the uptake of the Flemish GPRC label for peer-reviewed books by scholars in the Social Sciences and Humanities (SSH). The GPRC label (Guaranteed Peer Reviewed Content, see www.gprc.be; Verleysen & Engels, 2013) was adopted in 2010 and is being used in the context of the regional performance based university research funding system. In the period 2010 to 2018 a total of 2312 GPRC-labelled publications have been included in the VABB-SHW, a regional database for SSH publications. Our analysis focuses on the uptake of the label across disciplines, the use of Dutch, English and other languages and the type of publications (monographs, book chapters, edited volumes and proceedings papers). The results show that the GPRC label is particularly relevant for the disciplines of Criminology and Law and for publications in Dutch.

Introduction

In recent years, the problem of how to include books in national databases and evaluation systems has generated some attention. The importance of books to many Social Sciences and Humanities (SSH) disciplines in conjunction with the difficulty of identifying peer-reviewed books and assessing their quality, has prompted several European countries to adopt new strategies for 'taking books into account' in national research evaluation systems, for the allocation of funding and for the creation of comprehensive national databases (see Giménez-Toledo et al., 2016; Giménez-Toledo et al., 2019*)*.

In Flanders, the GPRC label was created to indicate the peer-review status of books, particularly in the SSH. The GPRC label (Guaranteed Peer Reviewed Content label, see www.gprc.be; Verleysen & Engels, 2013) was created by the Flemish Publishers' Association to enable academic books and chapters published by Flemish publishers to be included in the VABB-SHW (henceforth VABB), a Flemish regional database for the SSH used in the context of the Flemish performance-based research funding system (PRFS). The rationale behind the creation of the label was to increase the coverage of books in the VABB and to enable local publishers with a hybrid portfolio of peer-reviewed books and books that are not peer-reviewed to have their peer-reviewed content included in the VABB. The GPRC label allows publishers to indicate that a book has been subjected to peer review prior to publication. The GPRC label can be seen as a testcase for the inclusion of books on an individual level. The potential wider international relevance of the label was mentioned by Verleysen and Engels, who argue that the development of similar labels in other countries could facilitate the coverage of SSH books in international databases and citation indexes (Verleysen & Engels, 2013). Meanwhile, a similar label has been created in Finland (see Giménez-Toledo et al., 2016 and www.tsv.fi/tunnus). Apart from the GPRC label, books can also be included in the VABB based on the publisher and by book series. This last option is more recent, and becoming more important as more book series are added.

We use data available in the VABB database to document the use of the label from its inception in 2010 until 2018. Earlier publications have explained the rationale for the creation of the GPRC label (Verleysen & Engels, 2013) and its potential pitfalls (Borghart, 2013), and have compared it to open-identity labels in book publishing (Kulczycki et al 2019). The current study documents the use of the GPRC label between 2010 and 2018 and takes a closer look at the language of GPRC publications as well as the distribution of the label among SSH disciplines.

The creation of the GPRC label

In Flanders, the size of the research fund universities can allocate at their own discretion is determined by the BOF-key, which takes into account several aspects of research performance including the number of peer-reviewed publications (see Engels & Guns, 2018). While the original BOF-key relied heavily on inclusion in the Web of Science indexes for all disciplines, public debate about the lack of coverage of the SSH disciplines in the Web of Science indexes prompted the Flemish government to provide funding to the Centre for R&D Monitoring (ECOOM) for the creation of the VABB database to cover the publications of scholars in the SSH more comprehensively. In order to be eligible for inclusion in the VABB, publications must (1) be publicly accessible, (2) be unambiguously identifiable by an ISSN or ISBN, (3) contribute to the development of new insights or the application thereof, (4) be peer-reviewed by independent experts in the field prior to publication and (5) consist of at least four pages (see Engels & Guns, 2018).

Bibliographic information on the publications in the SSH is submitted yearly by each Flemish university. The Authoritative Panel (GP), a panel of 18 eminent SSH scholars, decides which publication channels used by the SSH researchers who are affiliated to a Flemish university in previous years are included in the VABB. Their decision is informed by the criteria mentioned above. The lack of a consensus on what peer review for books is and how to evaluate whether a book has been subjected to peer review, is one of the major difficulties for including books in research evaluation systems (Verleysen & Engels, 2013). Moreover, book publishers often have hybrid portfolios of academic books directed at peers, textbooks for students and books for a wider audience. This makes the identification of a peer review process on the level of the publication channel -in this case the book publisher- problematic. Initially, only a limited set of prestigious publishers were automatically included in the VABB (Engels et al., 2012). The GPRC label focuses on the fourth criterion for inclusion in the VABB: peer review. In order to qualify for a GPRC label, the publisher has to hold on to a dossier that demonstrates the peer review process of the book. By introducing the requirement of a peer review dossier, the GPRC label has formalized and harmonized the peer review process of SSH book publications at Flemish publishers.

Publication patterns in the SSH

Several studies have analyzed publication patterns in the SSH in European countries (see Engels et al., 2012; Engels et al., 2018; Kulczycki et al., 2018; Kulczycki et al. 2020). The following section introduces a few general trends of publication patterns in the SSH in Flanders and internationally as well as some hypotheses about the uptake of the GPRC label.

Firstly, studies into publication patterns in non-English speaking European countries have looked at the use of English in academic publications. Kulczycki et al. (2018) reported an increase in the use of English in SSH publications in eight different countries, including Flanders. For Flanders, a steady rise of the percentage of publications in English with a corresponding drop in the share of Dutch language publications and publications in other languages is evident (Guns & Engels, n.d). However, there are large differences between SSH disciplines. While the majority of publications are written in English in most SSH disciplines, disciplines such as Law and Criminology still publish mostly in Dutch. The use of English in publications is associated with an international orientation while the use of Dutch indicates a local audience.

In terms of publication type, book publications make up about 21% of all VABB publications (Guns & Engels, n.d.). The VABB distinguishes between three types of book publications: chapters in books, monographs and edited volumes. The largest share of book publications, 16% of all publications are book chapters. In an analysis of publication practices in the Flemish SSH disciplines, 'no overall shift towards the journal article as the chosen publication vehicle is observed' (Engels et al., 2012, p. 387). Again, there are differences between the disciplines. Considering the differences between the Humanities and the Social Sciences, the Humanities, on the whole, publish more books and write more frequently in Dutch (Engels et al., 2012). It is to be expected that the Humanities, as relatively more book-oriented and locally oriented disciplines, use the GPRC label more often than the Social Sciences. In an international context, Kulczycki et al. (2018) find different evolutions of book publications in different European countries. While there is a relatively stable share of book chapters and monographs for Flanders, in other countries, most notably Poland, the share of book publications has dropped considerably because of changes in research policy (Kulczycki et al., 2018, p. 475).

While earlier studies reported on a rapid increase in the number of publications included in the VABB (Engels et al., 2012), the latest figures on the VABB show a decline in the number of publications for the past few years. Looking at the data on publications across all types, there has been a drop in the number of articles in journals and proceedings papers as well as book chapters (see Guns & Engels, n.d.).

Based on the previous studies about publication patterns in the SSH, we put forward three hypotheses. Firstly, the continued importance of books for SSH disciplines coupled with the lack of (non-English language) books in commercial databases might have created an impetus for the use of the label. We therefore expect to see the use of the label increase over the time period. Secondly, the use of the label may differ between disciplines. Some disciplines are more book-oriented than others. Moreover, the GPRC label has a local focus, only including books by local publishers, and thus might show a higher share of Dutch language publications and a higher share of publications among disciplines with a local focus.

Description of the data

Uptake of the label

The total number of publications in the dataset is 2312. Of these, 257 are monographs, 321 are edited volumes, 1717 are book chapters and 17 are proceedings papers. Until 2015, the use of the GPRC label increased steadily (Figure 1). However, the data show a significant drop in the use of the label since 2015, when the number of GPRC publications reached a maximum of 421. Among GPRC publications, the drop is most clearly visible among book chapters and edited volumes. As mentioned above, there has been a general decline in the number of publications in the VABB in the past couple of years. The number of GPRC-labelled monographs has fluctuated in recent years.

Language

Contrary to other types of VABB publications, GPRC publications are predominantly written in Dutch (68,3 %) and only to a lesser degree in English (28,6 %). This may indicate that book publications are more often targeted towards local audiences, especially when they are written for 'enlightenment purposes' (Engels et al., 2018, p. 595; Hicks, 2005). Another explanation for the larger share of publications in Dutch is the fact that the GPRC label can only be used by local publishers. Still, almost 30% of GPRC-labelled books are written in English. Only around three percent of publications are written in languages other than Dutch and English. They are mainly written in French or German, the other national languages of Belgium.

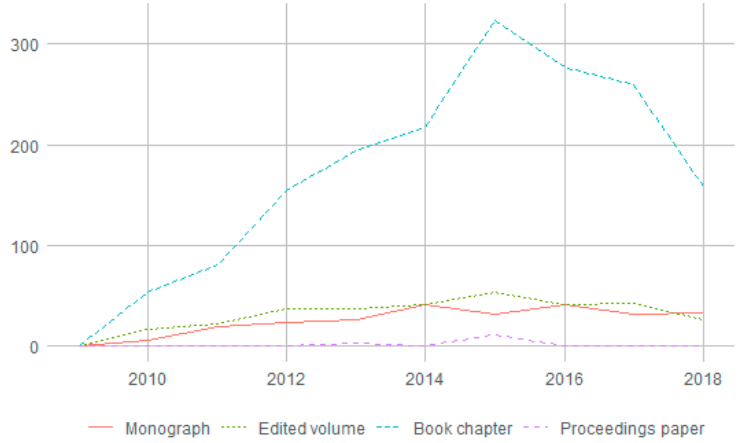

Figure 1: The evolution of the number of GPRC publications by year (by type).

Discipline

In terms of disciplines, we used the organizational classification of the VABB, which links each publication to disciplines based on the institutional affiliation of the researchers. In the VABB classification system, there are nine Humanities disciplines, seven Social Sciences disciplines and two general categories (Humanities-general, Social Sciences-general). For this analysis, whole counting was used: publications that were assigned to multiple disciplines were counted for each of the disciplines. As can be seen in Table 1, the discipline Law counts the highest number of GPRC publications in absolute terms- more than twice as many GPRC publications as the next discipline. Law has a local orientation. It has the largest share of publications in Dutch, followed by Criminology. Criminology takes the lead when the size of the disciplines is taken into account. Apart from Criminology and Law, and not taking into account the general categories, the other disciplines that use the GPRC label most often relative to their size are Sociology, Art History and History. This seems to corroborate the idea that disciplines with a local orientation would use the label more frequently. The disciplines that appear low on the list are Psychology, Social Health Sciences and Theology. Clearly, the GPRC label has not been taken up by all disciplines equally. Psychology, one of the larger SS disciplines, accounts for only 39 GPRC-labelled publications. Economics & Business, roughly as large as Law, also accounts for a relatively low number of GPRC publications (only 145). These disciplines are also known to be quite internationally oriented, with a large share of publications in English and a bigger presence in the Web of Science. While it is to be expected that more locally oriented disciplines such as Law and Criminology, but also History and Sociology use the local book label more frequently, the discrepancy between Criminology and Law and all other disciplines is striking and warrants further analysis. One important determining factor to be studied in particular is the influence of the location of the publisher and to what extent researchers publish in the local market (Flanders). A first look at the data showed that for the disciplines Law and Criminology, the GPRC-publishers are also the most used publishers for the discipline, while for the discipline History, this is not the case. This aspect will be explored further in the complete study.

Table 1: The distribution across disciplines ordered by share of GPRC publications

Disciplines	*Mono-graphs*	*Edited Volumes*	*Chapters, proceedings*	*All GPRC*	*Total VABB*	*GPRC/ VABB*
Criminology	23	79	294	396	2.590	15.29
Law	82	118	688	888	10.914	8.14
Sociology	16	27	208	251	4.727	5.31
Art History	33	28	146	207	4.032	5.13
History	44	33	133	210	4.184	5.02
Literature	15	33	106	154	3.479	4.43
Philosophy	27	26	115	168	5.233	3.21
Political Sciences	16	11	92	119	3.988	2.98
Archaeology	12	7	35	54	1.816	2.97
Humanities (General)	44	46	213	303	10.377	2.92
Linguistics	22	31	129	182	7.223	2.52
Communication Studies	11	7	65	83	3.358	2.47
Educational Sciences	20	9	76	105	4.330	2.42
Social Sciences (General)	24	35	183	242	12.250	1.98
Economics & Business	24	30	91	145	11.081	1.31
Theology	3	0	10	13	2.252	0.58
Social Health Sciences	5	6	43	54	12.208	0.44
Psychology	9	3	27	39	9.062	0.43

Table 1 also shows the distribution between the different publication types. It is possible that some disciplines tend to publish more monographs while other disciplines publish more book chapters and edited volumes. However, because the total amount of GPRC-labelled monographs is quite small (only 257), it is difficult to make statements about the differences between disciplines. Many SSH disciplines published roughly the same number of monographs. The highest count is found for law, with 82 publications. However, the second disciplines for GPRC monographs are History and Humanities General. As mentioned by Verleysen & Engels (2012), monographs are important to historians.

Conclusion

The GPRC label has enabled books published by local publishers to be included in the VABB database. It has also been a way for SSH researchers to have their locally published peer reviewed books be counted in the performance-based research funding system. Since its introduction in 2010, there has been an increase in the use of the label. However, since 2015, the use of the label has declined. We are currently analyzing the data in more detail to understand why this has happened.

While the GPRC label is open to all SSH researchers, some disciplines have used the label a lot more than others. The disciplines Criminology and Law take the lead in terms of number and share of GPRC-labelled publications. A discipline that appears to publish a lot of GPRC-labelled monographs relative to its size, is History. In terms of language, GPRC publications are written mostly in Dutch, this underwrites the idea that books are more often targeted towards a local audience, but also indicates that the GPRC label has been beneficial to the inclusion of non-English language books in the VABB. The location of the publisher could also have an effect on the use of the label.

The following parts of this study will take into account the publishers of GPRC-labelled books as well as the characteristics of GPRC publications in terms of authorship and the location of the publishers. We will also look at the alternatives to the GPRC label and the effect the GPRC label has had on the peer review practices among book publishers and conduct an in-depth interview with a member of the Authoritative Panel to get their view on the uptake of the label and the quality of the peer review dossiers submitted by publishers. Lastly, we aim to look at the GPRC label in the larger context of the SSH publications in the VABB and study whether the GPRC label has had an effect on the inclusion rate of books in the VABB.

Abstract

Integrating the societal impact of university research (SIUR) into research policy and evaluation is increasingly advocated – based on the conviction that traditional conceptions of academic quality insufficiently address how research can excel. Calls for the expansion of objects and activities considered in assessment models have led to the development of new methods. Altmetrics, for instance, track the "popular" dissemination of published outcomes, while methods to map impact pathways identify the productive interactions researchers have with societal stakeholders to evaluate SIUR. Balancing feasibility with precision remains an issue, and existing methods tend to fall short in one of them. Hence, there is need for methodological expansion.

We demonstrate how presence in the written press offers a partial indication of SIUR. Discussing a case study conducted in Flanders, the Dutch-speaking Northern region of Belgium, we first demonstrate the objects referred to by the written press in relation to university research. Subsequently, we distinguish between coverage of, operationalizations of and interventions by research in the public debate. Based on this taxonomy, we argue that an extension of altmetrics to press coverage has potential, but operationalization must differentiate between popular attention for research and its outcomes and active research-based contributions to public debates.

Assessing the societal impact of university research (SIUR): Contribution and attribution

Increasingly, research quality assessment recognizes the legitimacy of integrating the societal impact of university research (SIUR) in evaluation efforts (Chowdhury, Koya, & Philipson, 2016). Whereas traditional evaluation models prioritize scholarly quality – measured with bibliometric indicators – recent years have witnessed growing calls to move beyond peer-reviewed publications as the primary modality to determine academic merit (Benneworth & Olmos-Peñuela, 2018; Chowdhury et al., 2016; Donovan, 2011; Hill, 2016). Policy attention for such calls is reflected to an extent by the introduction of indicators that aim to monitor and compare economic impacts of university research – often with patents and spin-offs as objects of analysis (Agrawal & Henderson, 2002; Czarnitzki, Rammer, & Toole, 2014). But even though (positive) economic effects of university research can be satisfactorily charted, they offer at best partial indications of SIUR (Bornmann, 2013). In fact, SIUR is generally distinguished from the economic impacts brought by university research, primarily to avoid its reduction to simplistic econometric assessment models (Hill, 2016). Hence, when and where SIUR is integrated in performance assessment models and allocation mechanisms – most notably in the UK, Australia and the Netherlands (Heyeres, Tsey, Yang, Yan, & Jiang, 2019; Rijcke, Wouters, Rushforth, Franssen, & Hammarfelt, 2016; Watermeyer & Hedgecoe, 2019), it tends to be defined in rather broad and generic terms. Insofar a certain degree of consensus has formed to contemporary perspectives on SIUR in scholarship and governance: SIUR cannot be narrowed down solely to academic impact nor economic impact. The consensus is thus negatively formulated.

Existing SIUR assessment models reflect the expansiveness of this negative conceptualization. Although traditional tools to gauge academic excellence face growing criticism for their reductive nature (Donovan, 2019) and harmful effects on science and its practitioners (Fochler, Felt, & Muller, 2016), they benefit from a degree of clarity and operability not yet available to SIUR evaluation practices. For instance, it is not hard to see how using bibliometric analysis to determine academic excellence is less demanding for parties involved (e.g. researchers, reviewers, funding bodies) than qualitative assessments based on impact narratives – like those required by the UK's Research Excellence Framework (REF) (Watermeyer & Hedgecoe, 2019). Indeed, integrating SIUR in research evaluation models clearly necessitates adopting decidedly more labour-intensive techniques and tools than those in place to measure academic or economic impact (Sivertsen & Meijer, 2020). The need to take a qualitative approach to SIUR– taxing as this may be – is based in no small part on the recognition that societal impact can rarely be causally attributed (Matt, Gaunand, Joly, & Colinet, 2017). Instead, SIUR emerges primarily through organic and contingent contributions to the agendas of societal stakeholders, as well as broader efforts to address societal challenges or even less defined segments of society at large (Robinson-Garcia, van Leeuwen, & Rafols, 2018). In fact, in many cases it is fairly implausible for SIUR to be an intentional, calculable outcome (Sivertsen & Meijer, 2020).

Consequently, scholarship on SIUR has explored in recent years how societal contributions made by university research can be identified, monitored and assessed (Muhonen, Benneworth, & Olmos-Penuela, 2020). Interviews, focus groups and other qualitative methods (e.g. document analysis), are increasingly being used to investigate productive interactions between researchers and societal stakeholders to identify various impact pathways through which science contributes to society (Boshoff & Sefatsa, 2019; Molas-Gallart & Tang, 2011; Spaapen & van Drooge, 2011). This line of inquiry reveals a general distinction between direct, indirect and financial forms of "productive interactions" (Spaapen & van Drooge, 2011) – facilitated by diverse and contingent impact pathways. Contributions of university research to society at large hinge on complex interplays between scholars, the knowledge they produce and the socio-cultural context they are situated in (Muhonen et al., 2020) Its study is primarily aimed at demonstrating which strategies researchers can adopt to achieve SIUR (de Jong, Barker, Cox, Sveinsdottir, & Van den Besselaar, 2014).This body of work is therefore less concerned with exploring how SIUR can be integrated in existing evaluation models, and more about demonstrating how it can be successfully pursued (Boshoff & Sefatsa, 2019).

Although the complicated and interactive nature of SIUR is now broadly recognized (Muhonen et al., 2020) and the view that it generally consists of iterative processes of contribution is uncontroversial (Sivertsen & Meijer, 2020), some studies remain committed to demonstrate how SIUR can be causally attributed to some extent (Noyons, 2019). Based on the recognition that a multiplicity of societal impact forms arise from the broad dissemination and popular uptake of knowledge created by university research, metric approaches have been applied to alternative circuits of communication (Bornmann, 2014). Generally, these altmetrics attribute a certain degree of SIUR to particular publications based on their diffusion on social media platforms, mostly Twitter (Robinson-Garcia et al., 2018). Here, the argument is that tracking the circulation of research outcomes among social media users offers an indication of societal interest and appreciation, which differs considerably from SIUR assessments made by peer reviewers (Bornmann, Haunschild, & Adams, 2019). But due to the affordances of social media platforms, even its advocates caution against simplistic impact attributions using altmetrics (Noyons, 2019). For example, it is fairly easy to boost altmetrics scores artificially through "academic spamming" (Erdt, Nagarajan, Sin, & Theng, 2016). At the same time, social media are also segmented into online communities, and in some disciplines scholarly work tends to circulate primarily among academic users (Zhou & Na, 2019), again dissuading all too simplistic attributions of SIUR using altmetrics.

Calibrated attributions: Written press articles as alternative objects for SIUR assessment

While attribution-based approaches towards SIUR continue to offer only partial indications of societal impact, it is at this time not warranted to disregard them altogether. It is certainly productive to emphasize the longitudinal, iterative and contingent nature of SIUR (Muhonen et al., 2020), but in some cases the possibility remains of causally attributing certain forms of societal impact (Sivertsen & Meijer, 2020). Indeed, many research activities address issues of direct societal relevance, and are carried out with the express intention to achieve some form of demonstrable impact, of which projects funded to meet "grand societal challenges" or the UN Sustainable Development Goals are evident examples (Holbrook & Frodeman, 2011). When researchers predetermine particular activities to accomplish societal impact, these can offer a modality to assess SIUR. Accordingly, it is opportune to explore how such instances might be integrated in quality evaluations and scientific excellence assessments. In the first place, this hinges on categorizing particular ambitions associated with the achievement of societal impact by university research. Secondly, it requires the identification of objects that can substantiate such accomplishments and allow for (partial) attribution of SIUR. Impact narratives like those required by the REF (Chowdhury et al., 2016; Hill, 2016) and multimethodological inquiry into productive interactions and impact pathways (Boshoff & Sefatsa, 2019; de Jong et al., 2014) are less concerned with demonstrating linear, causal results, but hint at particular measures taken by researchers to accomplish impact. Many of these do not lend themselves to systematic measurement, but others do provide opportunities for partial, less labour-intensive forms of SIUR assessment. Of specific interest here is the potential some see in (non-academic) media to pursue SIUR, particularly for humanities and social sciences (Muhonen et al., 2020). Inquiry into social and cultural phenomena may invite some to disseminate ideas an observations not only through formal circuits of communication of peer-reviewed scientific publications, but also to articulate them in the wider public sphere (Benneworth, Gulbrandsen, & Hazelkorn, 2016). Of course, the adoption of outreach strategies and science communication is not restricted to the social sciences and humanities; most scientific areas can plausibly effectuate some form of SIUR by communicating to larger audiences (Kassab, 2019). Accordingly, in qualitative assessments like the REF – which requires self-reported impact narratives enriched with documentation (Watermeyer & Chubb, 2019) – participation in public debate by pursuing mainstream media presence is both proposed and accepted as indicative of SIUR (Kassab, 2019).

At a glance, one could surmise that the documented presence of research or researchers in the written press provides a suitable object to systematically attribute (a degree of) SIUR by. In fact, doing so could compare favourably to the circulation on social media platforms currently prioritized by altmetrics – given that academic spamming is less likely in linear outlets, where its expected readership is more diverse (Erdt et al., 2016; Zhou & Na, 2019). Yet various complexities do arise when reflecting on the relation between popular media and SIUR that require consideration and mediation. Naturally, newspaper articles are largely "citable", and in many cases offer a disambiguated object of analysis and measurement (Didegah, Bowman, & Holmberg, 2018). However, their substance – and logically their presentation of research and researchers – varies considerably, and it is simply inappropriate to accept every substantiated instance of written press attention or intervention as an indication of SIUR. Indeed, in attributing some form of societal impact based on the analysis of written press documents, care must be taken not only to avoid undue accreditation, because researchers or their work are not necessarily included for reasons that appeal to a conceptualisation of SIUR. Equal care must go to circumventing undesirable behavioural changes, of which the subjection of the research agenda to considerations of popular appeal is but one example. Before written press coverage can be seriously considered as a partial indicator in systematic SIUR assessment, the presentation of research and researchers must be explored to further calibrate its use as an evaluation object.

Scholars in broadsheets: A disciplinary case on Flemish sociologists in the written press

A case study into written press coverage on Flemish sociologists offers an initial, descriptive exploration of these complexities. Here, the focus on sociology reflects the more pressing demand for alternative quality indicators in social sciences and humanities disciplines (Gijselinckx & Steenssens, 2011), but it goes without saying that the future operationalisation of written press articles in SIUR assessment must be predicated on multifocal analysis of its benefits and pitfalls. The study inquired when and how 360 faculty members (from researchers to full professors), recently employed at one of the four Flemish sociology departments were present in domestic written media with national circulation. This was effectuated by querying their full names and the term "onderzoek" (research) in the 2010-2020 period in Gopress – an online database operated by press agency Belga that collects all articles published by outlets with national circulation (e.g. newspapers, broadcaster websites, magazines). In doing so, it differs from existing studies on scholarly attention in the written press, which have mostly employed self-reporting (e.g. Bauer and Jensen (2011), Dudo (2012)). The present study, by contrast, includes not only coverage of which researchers are aware, but also written press documents in which they are cited, mentioned or referred to without their knowledge – thus providing a more in-depth perspective crucial to SIUR assessment.

When looking at observable differences in written press coverage (#1656 articles) of sociology researchers ($N = 360$) in the 2010-2020 period, data show that less than half of all sociologists (40.3%) were present at least once in mainstream reporting, with an average of 9.2 ($SD = 38.9$) and a median value of 0 mentions. When observing for a recent one-year period (2019-2020) the percentage is less than a quarter (23.3%), with an average of 1.9 ($SD = 9.5$) and a median value of 0 mentions. These averages are misleading however, as there are substantial outliers present: the distribution of media mentions is skewed as the bulk of the mentions come from a small number of outliers. In addition, these numbers must be nuanced due to the presence of early career researchers and professorial staff in the same data set, and due to double entries because of media concentration in the domestic press landscape (Hendrickx & Ranaivoson, 2019).

After correcting for outliers, predoctoral researchers found themselves 1.1 ($SD = 0.3$) times on average in the written press, mid-level (i.e. junior & senior) researchers did so 4.9 ($SD = 1.2$) and 4.5 ($SD = 1.6$) times respectively, and those with a professorial position boasted 15.9 ($SD = 2.9$) instances on average. Researcher status (measured by #publications and career position standardized) was found to correlate positively ($\beta = .45$, $p < .001$) with press attention (#mentions in 2010-2020 period) – suggesting that higher status researchers have easier access to popular reporting.

Although the foregoing cautions against all too simplistic conclusions about the number of instances of researchers appearing in the written press, it does not address whether it is in the first place legitimate or desirable to attribute a degree of SIUR to such instances.

Further analysis of the collected documents revealed that more than half of the articles (54.3%) were short (less than 250 words) and declarative in nature – offering factual coverage of conducted studies and their results. Even though this type of presence in the written press could effectuate some form of SIUR (Morton, 2015), it is mostly descriptive in nature, and is in the first place committed to informing the general public about sociological research and its results.

A second type of presence is found in so called "think pieces" (in-depth discussion of one theme) that make up almost a quarter of the sample (23%), and is characterized by active operationalisations of research – either in the form of direct quotes of researchers or their publications, or through paraphrases and references. These longer texts featured in-depth engagements with sociological research – often including the views of various scholars – to substantially address a particular societal issue. These subjects tended to reflect the core disciplinary expertise of sociology, as socio-economical topics, discrimination, politics, integration and education were the dominant topics respectively. Opinion pieces, finally, comprised a third important category, with 12.1% of samples. In contrast to other types, these tended to be authored by researchers themselves, and often constituted a public intervention based on their particular scholarly expertise. While these were not necessarily a research outcome in the strict sense, they tended to apply common sociological analytics to applied societal phenomena.

These exploratory observations point to a distinction between coverage of, operationalizations of, and interventions by research in the public debate. Based on this taxonomy, an extension of altmetrics to press coverage appears to have potential, but operationalizations must differentiate between popular attention for research and its outcomes and active research-based contributions to public debates. Accordingly, further research is needed to develop tools that efficiently differentiate between written press documents that demonstrate the popularity of research – and successful science communication – and public operationalizations of research that indicate a more profound societal impact.

Abstract

With the rapid growth in research publications, automated solutions to tackle scholarly information overload is growing more relevant. Correctly identifying the intent of the citations is one such task that finds applications ranging from predicting scholarly impact, finding idea propagation, to text summarization to establishing more informative citation indexers. In this in-progress work, we leverage the cited paper's information and demonstrate that this helps in the effective classification of citation intents. We propose a neural multi-task learning framework that harnesses the structural information of the research papers and the relation between the citation context and the cited paper for citation classification. Our initial experiments on three benchmark citation classification datasets show that with incorporating cited paper information (title), our neural model achieves a new state of the art on the ACL-ARC dataset with an absolute increase of **5.3%** in the F1 score over the previous best model. Our approach also outperforms the submissions made in the 3C Shared task: Citation Context Classification with an increase of **8%** and **3.6%** over the previous best Public F1-macro and Private F1-macro scores respectively.

Introduction

Citations are crucial in analyzing scientific works and for understanding the link between different research articles. They act as trackers of the direction of research in a field and as an important measure in understanding the impact of research articles, venues, researchers, etc. Citations may also have different nature. Authors may cite a research publication in different ways. For example - a citation might indicate motivation or usage of a method from a previous work or a comparison of results of various works. So, identification of the intent behind a citation is crucial for automated analysis of academic literature. Most of the research works in the field of citation classification provide too fine-grained citation categories, example-(Stevens and Giuliano (1965); Moravcsik and Murugesan (1975)), so only a handful of these are used for automated analysis of the scientific publications. To overcome these problems, Jurgens et al. (2018) proposed a six category classification scheme. Then, Cohan et al. (2019) used a different scheme that had only three classification categories. More recently, Pride et al. (2020) proposed a classification scheme similar to Jurgens et al. (2018).

Table 1. Examples of citations with cited paper titles and intents.

Citation context	*Cited Paper Title*	*True Label*
She evaluates 3,000 German verbs with a token frequency between 10 and 2,000 against the Duden (@@CITATION).	duden—das stilworterbuch duden—the style dictionary	BACKGROUND

Jurgens et al. (2018) used a set of engineered features like (1) Pattern based features (2) Topic based features (3) Prototypical Argument features for this task. While recently, Cohan et al. (2019) argued that features based on the structural properties related to scientific literature are more effective than the predefined hand engineered domain-dependent features or external resources. We argue that in addition to leveraging the structural information related to the scientific discourse, utilizing the cited paper information as additional context can significantly improve the performance. In the example from table 1, it is evident that the instance seems less ambiguous and easier to classify after accessing the cited paper title information in addition to the citation context. To tackle these problems, we propose a Multi Task Learning framework that incorporates three scaffolds, including a cited paper title scaffold that leverages the relationship between the citation context and the cited paper title. The other two scaffolds are the structural scaffolds to leverage the relationship between the structure of the research papers and the intent of the citations. These two scaffolds are inspired by the work done in Cohan et al. (2019). We explain these scaffolds in detail in Table 4 under the Model Section.

Dataset Description

Table 2 shows the classification categories of different datasets and Table 3 shows the corresponding data statistics. Please note that we retrieve the cited paper title scaffold data from the target datasets and the SciCite dataset includes the data corresponding to the structural scaffolds.

Table 2.Intent categories of different datasets.

Dataset	*Citation Intent Categories*
SciCite	BACKGROUND, METHOD, RESULT_COMPARISON
ACL-ARC/3C Challenge dataset	BACKGROUND, USES, COMPARE_CONTRAST, MOTIVATION, EXTENSION, FUTURE.
Section title scaffold data (91412 instances)	INTRODUCTION, CONCLUSION, EXPERIMENTS, METHOD, RELATED WORK
Citation worthiness scaffold data (73484 instances)	TRUE, FALSE

Table 3.Cross-study comparison of different datasets.

Dataset	*Papers*	*Annotated by*	*Citations*	*Intent categories*	*Discipline(s)*
SciCite	6,627	Volunteers	11,020	3	Comp. Sci/Medicine
3C Challenge	883	Paper authors	3,000	6	Multi-disciplinary
ACL-ARC	185	Domain Experts	1,989	6	Comp. Science

Model

We propose a Multitask Learning (Caruana, 1997) model with the main task of citation intent classification along with a total of three auxiliary tasks (scaffolds). The knowledge acquired by the auxiliary tasks helps the model to learn optimal parameters for the main task.

Table 4. Scaffolds in our Multi-tasking Approach

Scaffolds	*Description*
Section Title	This task is related to predicting the section under which the citation occurs, given a citation context. In general, researchers follow a standard order while presenting their scientific work in the form of sections. Citations may have different nature according to the section under which they are cited. Hence, the intent of the citation and the section are related to each other. For example, the results-comparison related citations are often cited under the Results section.
Citation Worthiness	This task is related to predicting whether a sentence needs a citation or not, i.e., it is the task of classifying whether a sentence is a citation text or not.
Cited Paper Title	Sometimes a citation context might be ambiguous, making it difficult to predict the intent of the citation correctly. In such cases, information from the cited paper like the abstract of the paper, title of the paper, etc. may provide some additional context that can assist in identifying the appropriate intent behind that citation. This auxiliary task helps the model to learn these nuances by leveraging the relationship between the citation context and the cited paper. We use a concatenated vector of citation context and the cited paper title fields from the target dataset as the input for this task.

We use these auxiliary tasks only while training/fine-tuning the model. Our model architecture is shown in Figure 1.

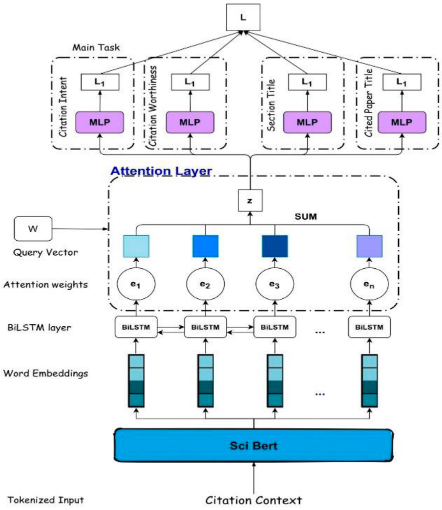

Figure 1. The architecture of our proposed model. The main task MLP is for prediction of citation intents (top left) followed by three MLPs for section title, citation worthiness, and cited paper title scaffolds

Model Structure

Let C be the tokenized citation context of size n. We pass it onto the SciBERT (Beltagy, 2019) model with pre-trained weights to get the word embeddings of size (n,d_1) i.e. we have the output as $x = \{ x_1, x_2, x_3, \ldots\ldots x_n \}$ where $x_i \in R^{d1}$. Then we use a Bidirectional long short-term memory (BiLSTM) network with a hidden size d_2 to get an output vector h of size ($n,2d_2$). We pass h to the dot-product attention layer with query vector w to get an output vector z which represents the whole input sequence.

$$h_i = [LSTM(x,i); LSTM(x,i)] \quad (1)$$

$$\alpha_i = softmax(w^T h_i) \quad (2)$$

Here, α_i represents the attention weights.

$$z = \sum_{i=1}^{n} \alpha_i h_i \quad (3)$$

Now, we pass the attention representation vector z to m MLPs related to the m tasks with $Task_1$ as the main task and $Task_i$ as the m-1 scaffold tasks, where $i \in [2, m]$, to get an output vector $y = \{ y_1, y_2, y_3, \ldots\ldots y_m \}$:

$$y_i = softmax(MLP_i(z)) \quad (4)$$

For each task, we use a Multi Layer Perceptron (MLP) followed by a softmax layer to obtain the class with the highest class probability. The parameters of a task's MLP are the specific parameters of that task and the parameters in the lower layers (parameters till the attention layer) are the shared parameters.

Training

We train our model only on the SciCite dataset. Then we fine-tune on the target dataset (ACL-ARC or 3C Challenge). We use the pre-trained scibert scivocab uncased model trained on a corpus of 1.14M papers and 3.1B tokens to get the 768-dimensional Word Embeddings. While training on the SciCite dataset, we only train the two structural scaffolds which are - 1. Citation Worthiness scaffold, 2. Section Title scaffold, along with the main task. While fine-tuning on the target datasets, we use the Cited paper title scaffold only, while freezing the task specific parameters of the other two scaffolds, learned during the training on the SciCite dataset. We compute the loss function as:

$$L = \sum_{(x,y) \in D_1} L_1(x,y) + \sum_{i=2}^{n} \lambda_i \sum_{(x,y) \in D_i} L_i(x,y) \quad (5)$$

where D_i is the labeled dataset corresponding to $task_i$, λ_i is the hyperparameter that specifies the sensitivity of the model to each specific task, L_i is the loss corresponding to $task_i$. In each training epoch, we take a batch with equal number of instances from all the tasks and calculate the loss as specified in Equation 5, where $L_i = 0$ for all the instances of other tasks, $task_k$ where $k \neq i$. Then, we perform back propagation and update the parameters using the AdaDelta optimizer with gradient clipping.

Experiments

Baselines

We have worked on multiple baseline models to compare their performance on the ACL-ARC and the 3C Challenge datasets.

Table 5. Baselines and Proposed System.

Baselines	*Description*
BiLSTM+Attention (with SciBERT)	This baseline has a similar structure as our proposed model until the attention layer. It only has one MLP related to the main task and optimizes the network for the main loss.
3C Shared Task Submission 1	This system submission has achieved the best submission results on the 3C Challenge dataset in the Kaggle 3C Shared Task. The model is a Passive Aggressive Classifier with a concatenated vector (including the citing paper title, cited paper title and the citation context) as the input.
Cohan et al. (2019)	The model has reported state-of-the-art results on the ACL-ARC dataset. It incorporates a multi task learning framework with two structural scaffolds predicting the section title and citation worthiness, given the citation context.
Representation Model	The model framework for this baseline incorporates the concatenation of two representation vectors which is passed on to a MLP for classification. We get the first representation from the attention layer of the pretrained first baseline by passing citation context and the cited title as input. We use the pre-trained Cohan et al. (2019) model, trained on SciCite to get the predicted labels on the target dataset. Then, we infuse this external knowledge with the citation context and pass it to the first baseline to obtain the second attention layer representation.
Late Fusion Model	This baseline model has a similar structure to that of the first baseline. We use the pre-trained Cohan et al. (2019) model, trained on SciCite to get the citation intent, section title and the citation worthiness labels. We concatenate these labels with the output of the attention layer of this baseline and pass it to a MLP for prediction.

Table 6. Results on the ACL-ARC and the 3C Challenge datasets. The first two columns (Macro F1 score and Accuracy) correspond to the results on the ACL-ARC dataset. The last two columns (Public and Private F1 scores) are the results on the 3C Challenge dataset.

Category	*ACL-ARC*		*3C Challenge dataset*	
	Macro F1 Score	*Accuracy*	*Public F1*	*Private F1*
BiLSTM + Attention (with SciBERT)	57.1	63.3	27.8	23.9
Cohan et al. (2019)	67.9	76.2	22.4	**25.2**
Kaggle 3C Shared Task Submission 1	-	-	21.5	20.6
Our Model	**73.2**	**77.0**	**29.5**	24.2
Representation Model	38.2	54.7	20.6	23.1
Late Fusion Model	48.3	61.9	22.4	22.4

Results

Our results for the ACL-ARC and the 3C challenge datasets are shown in Table 6. We observe that as compared to the first baseline "BiLSTM+Attention (with SciBERT)", Cohan et al. (2019) achieves an F1 macro score of 67.9 (Δ = 10.8) and a validation accuracy of 76.2 (Δ =

12.9) on the ACL-ARC dataset indicating the fact that leveraging the structural information of a research work helps the model to learn more effectively. Out of all the other baselines, our model achieves the best results with an F1 score of 73.2, a significant improvement over the previous state of the art results of Cohan et al. (2019) (Δ = 5.3) and a validation accuracy of 77.0 (Δ = 0.8) on the ACL-ARC dataset. This clearly demonstrates the efficacy of using the three scaffolds in a transfer learning framework for this task. For the last two baselines that are mainly based on fusing external knowledge obtained by using the pre trained Cohan et al. (2019) model, we find a significant dip in the performance. This suggests that this external knowledge does not provide any useful signals beyond what the first baseline already learns from the data. The results on the 3C Challenge dataset also show similar patterns.

Analysis

To gain more insight into how the scaffolds are helping the model, we consider examples from the ACL-ARC and the 3C Challenge datasets and compare the predictions of the simple baseline *'BiLSTM+Attention (with SciBERT)'*, the previous state of the art *'Cohan et al. (2019)'*, and our best-proposed model *'BiLSTM+Attention (with SciBERT)+three scaffolds'*. In table 7, the first example is from the ACL-ARC dataset with true label *COMPARE*, the simple baseline and the Cohan et al. (2019) incorrectly predict it as *MOTIVATION* and *BACKGROUND* respectively, whereas our model predicts it correctly. The simple baseline does not include any scaffold, while the Cohan et al. (2019) and our model incorporate a multi task learning framework. Note that our model is similar to that of Cohan et al. (2019) but includes three scaffolds (two structural scaffolds + cited paper title scaffold). The second example is from the 3C Challenge dataset where the true label is *BACKGROUND*, the Cohan et al. (2019) model is probably distracted by the phrase "use", so it classifies it incorrectly as *USE*, whereas our model correctly classifies it. Note that our model also consists of additional information from the cited paper (title) which provides additional context, thus helping it to classify better.

Table 7. A sample of predictions of the models on examples from the ACL-ARC and the 3C Challenge datasets.

Example	*Model*	*Predicted Label*	*True Label*
The advantage of tuning similarity to the application of interest has been shown previously by CITATION.	BiLSTM + Attention (with SciBERT)	MOTIVATION	COMPARE
	Cohan et al.	BACKGROUND	COMPARE
	Our Model	COMPARE	COMPARE
Others use concepts such as expansion and contraction (Mattsson, 1987); extension and consolidation CITATION and splitting and joining (Hertz, 1996)	Cohan et al.	USE	BACKGROUND
	Our Model	BACKGROUND	BACKGROUND
We experiment with four learners commonly employed in language learning: Decision List (DL): We use the DL learner as described in CITATION, motivated by its success in the related tasks of word sense disambiguation (Yarowsky , 1995) and NE classification (Collins and Singer , 1999) .	Our Model	USE	MOTIVATION

Error Analysis

We investigate the type of errors made by our proposed model on the two datasets. We found it surprising to note that in case of the ACL-ARC dataset, the model has more tendency to make false positive errors in the *COMPARE* category, although it being the second most dominating category. Whereas in the case of the 3C Challenge dataset, it makes many false positive errors in the *BACKGROUND* category. To overcome this problem of overfitting, we decided to use some oversampling techniques like SMOTE, but we still did not get any significant improvements. Figure 2 shows the confusion matrix of our best model on the two datasets. We also found out that some errors are due to ambiguity in the citation context as well as the title of the cited paper. We can avoid them by providing some additional context apart from the cited paper title information (for example, providing abstract from the cited paper, etc). In the last example from Table 7, the model is probably distracted by the phrases "We use" and "as described in CITATION", leading to an inference that there is a usage of a method from the cited paper, instead of considering the latter part of the sentence that describes the motivation. This is likely due to the small number of training instances in the *MOTIVATION* category, preventing the model from learning such subtle details.

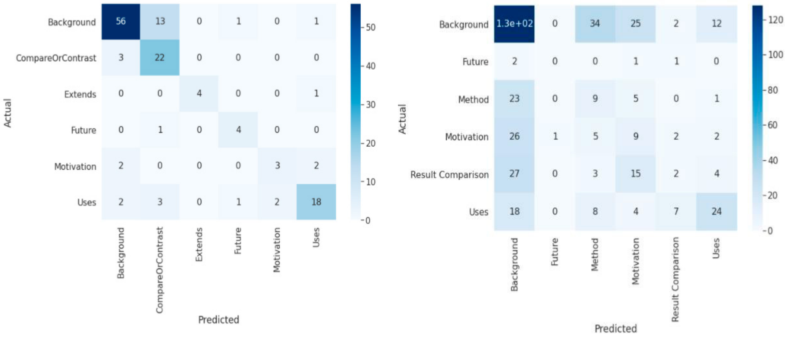

Figure 2. Confusion matrix showing the classification errors of our best model on the ACL-ARC (test size: 139) and the 3C Challenge datasets (test size: 400) respectively.

Conclusion and Future Work

In this work, we demonstrate that the structural information related to a research paper and additional context (title information) of the cited paper can be leveraged to effectively classify the intent of the citations. A future line of research would be to use the abstract of the cited paper as further contextual information for the task and also to investigate alternative approaches for solving the issue of overfitting on the 3C Challenge dataset.

Abstract

The international collaboration has become usual in the research activity. Moreover, international collaboration tends to lead papers to have higher citations than papers with national collaboration. This fact has been previously studied finding a difference of impact in several areas. However, some reasons that could influence this difference of impact have not been studied for the Library and Information Science (LIS). Thus, in this contribution we analyze 22,127 papers from the years 2015 to 2019. These papers were classified under three classes: local, national, or international collaboration. They were analyzed separately by means of science mapping analysis and performance measures. The results show that there is a difference in impact as well as thematical differences among the collaboration types.

Introduction

In the last years, the increase of complexity of the science, and the need of being competitive, has led countries to cooperate with other countries. Therefore, the research policies implemented by countries have encouraged the mobility of researchers as well as the funding of international projects (Sugimoto et al., 2017; Suresh, 2012). Consequently, the researchers need to collaborate with foreign colleagues in order to achieve a higher scientific impact (Chinchilla-Rodríguez, Sugimoto, & Larivière, 2019; Larivière, Gingras, Sugimoto, & Tsou, 2015). According to Adams (2013), that new trend in collaboration is known as the fourth age of research, which is driven by "international collaborations between elite research groups".

Due to the interest growth in assessing research, to implement new research policies, new tools dealing with the overwhelming amount of research output have been created to understand the science development or to detect patterns on it (Bornmann & Mutz, 2015; Fortunato et al., 2018; Milojević, 2015). Therefore, bibliographical networks (Batagelj & Cerinšek, 2013) and science mapping analysis tools help scientists of science on this task (Cobo, López-Herrera, Herrera-Viedma, & Herrera, 2012; Moral-Muñoz, Herrera-Viedma, Santisteban-Espejo, & Cobo, 2020).

There are several studies analyzing the consequences that international collaboration may have in academic impact. Indeed, the difference between the impact of academic collaboration has been studied previously in several areas, and, in general, international collaboration entails a higher impact rather than other types of collaboration (Gazni, Sugimoto, & Didegah, 2012; Persson, 2010). It has also been studied in particular areas (Khor & Yu, 2016; Polyakov, Polyakov, & Iftekhar, 2017; Rousseau & Ding, 2016; Sooryamoorthy, 2017) as well as in Library and Information Science (LIS) (Asubiaro, 2019; Sin, 2011; Sooryamoorthy, 2017).

Nonetheless, other influences that might affect the impact of academic research have been studied, such as publishing in open access (Gabrielle Breugelmans et al., 2018), the leadership impact (Chinchilla-Rodríguez et al., 2019) or if this increase in impact occurs in all the research fields (Polyakov et al., 2017). Moreover, it has been studied that government funding is statistically nonsignificant in international collaboration in the OCDE countries (Leydesdorff, Bornmann, & Wagner, 2019). Furthermore, the thematical landscape has been studied previously in the LIS category using co-word and co-citation analysis (Galvez, 2018; Hu, Hu, Deng, & Liu, 2013; Olmeda-Gómez, Ovalle-Perandones, & Perianes-Rodríguez, 2017). However, the themes treated in the academic collaboration and its possible influence in the impact difference of academic collaboration on LIS field have not been studied.

Thus, the goal of this contribution is to analyze the thematical differences or similarities that might affect the academic impact differences between types of collaboration that other studies have confirmed in the specific ambit of the LIS category. To do so, the papers of this category published during the period 2015-2019 have been downloaded from Web of Science and analyzed by means of science mapping analysis and performance analysis. The main hypothesis of this contribution states that one of the reasons for the difference in academic impact of the Library & Information Science category are the themes treated.

The rest of the contribution is organized as follows. First, the methodology used to carry out the analysis of the metadata is explained. Then, the results obtained are presented and described. Next, the discussion regarding all the results from a global perspective and the findings of the study are shown. Finally, the conclusions and future work are presented.

Methodology

This section describes the methodology followed to carry out the analysis. In order to find out the differences or similarities between the types of collaboration, it is necessary to define them. According to previous studies (Chinchilla-Rodríguez et al., 2019; Gazni et al., 2012), there are three types of collaboration: local (intra-institutional collaboration), national (collaboration with colleagues from same country) and international collaboration (collaboration with colleagues from foreign countries).

In order to perform any bibliometric analysis, the first step is to obtain the data to be analyzed. It can be done by retrieving the data from the several bibliographical databases available, such as Scopus, Web of Science, Dimensions or ScholarMetrics, among others. The analysis that will be performed needs the following metadata: author's keywords, author's affiliations, and publications year. Therefore, the bibliographical database must offer this kind of metadata.

For this study, the Web of Science database was selected to download the papers metadata. The query to perform is filtered by the year, the paper category, the database editions, and the document type. The limits were the following:

- Documents between 2015 and 2019, both included.
- Documents under the "Information Science & Library Science" category.
- Documents indexed on the Science Citation Index ™ Expanded (SCI) or Social Sciences Citation Index ® (SSCI).
- Articles or reviews.

Therefore, the advanced query to perform against the Web of Science database is WC="Information Science & Library Science" AND PY=2015-2019 AND DT= (ARTICLE OR REVIEW)"

To conduct the bibliometric analysis presented in this contribution, we have used the software SciMAT. One of the advantages of using SciMAT is that it is the only science mapping analysis tool with the de-duplication feature (Cobo, López-Herrera, Herrera-Viedma, & Herrera, 2011a; Cobo et al., 2012; Moral-Muñoz et al., 2020). Moreover, it allows us to plot the detected themes in a strategic diagram which is a useful tool to uncover the differences among the different corpus and the differences of themes covered in each one.

The next step is to process the author's keywords to join the ones that represent the same concept. This step also involves the removal of terms with a broad meaning, known as stop words.

Once the author's keywords have been cleaned, the dataset is divided into the three types of collaboration mentioned above. It is done by computing the number of unique countries and organizations in the affiliation.

- The local (intra-institutional level) papers must satisfy the number of organizations and countries to be one.
- The national collaboration papers must satisfy the number of organizations to be more than one and to only have a single country.
- Finally, the international collaboration papers are classified under this tag when two or more countries are collaborating in them.

We should point out that mentioned sets are mutually exclusive.

After the split is performed, the analysis can be carried out. Firstly, the performance measures of each collaboration type are computed, and a comparison of academic impact in terms of citations is done. According to Thelwall (2016), citations should be averaged using the geometric mean, since they follow a discretized lognormal distribution. Moreover, the hypothesis will be checked by means of science mapping analysis and overlapping of the keywords between collaboration types.

Next, for each collaboration type, a bibliographical co-words network using the author keywords of each document will be built. In this network, the nodes will be the words and the edges will represent if those two keywords appear together in the papers or not. The network has two attributes: the frequency of a node, namely how many times such keyword appears in the documents; and the second, which is the co-occurrence frequency of two nodes (or the weight of an edge), which means the number of times that the two keywords appear together in a document. Next, a normalization process over the co-occurrence frequency is made by means of the equivalence index (Cobo, López-Herrera, Herrera-Viedma, & Herrera, 2011b; Van Eck & Waltman, 2009). Once this step is done, clustering is performed applying the Leiden algorithm (Traag, Waltman, & van Eck, 2019). The Leiden clustering algorithm has been employed because it offers some guarantees such as well-connected communities, which is an advantage over other clustering algorithms (Traag et al., 2019).

Once the clusters (themes) are detected, some measures related to academic impact can be computed. It is done by performing the union of all the documents under the nodes of the clusters, and then, computing the measures over that set of documents. In this study, the number of documents, the citation average, the h-index and the mean normalized citation score (MNCS) (Waltman, van Eck, van Leeuwen, Visser, & van Raan, 2011) will be computed for each theme detected in the three collaboration types. Moreover, these themes can be plotted out in a strategic diagram by computing the internal and external cohesion of the clusters, according to their density and centrality. Hence, the diagram classifies the themes in four categories: motor, basic and transversal, highly developed and isolated, and emerging or declining (Cobo et al., 2011b). It should be point out that a theme encapsulates a cluster. That is, a theme represents a set of strong connected keywords (sub co-word network), which received the name of the most central one.

In addition to this comparison, to give a performance perspective, the number of most cited keywords colliding among the three collaboration types will be measured and plotted out in a line chart. The number of shared keywords between the collaboration types will allow us to compare whether they are treating the same topics or not. The colliding keywords will be measured by the Jaccard index (Cobo et al., 2011b) for the *n* most cited keywords, with several values of *n*.

Results

The download was performed on October 6th, 2020 using the advanced query explained in the Methodology section, and it retrieved 22,127 records.

Performance analysis

The output of the performance analysis of the data by types of collaboration is shown in Table 1. The papers with no collaboration represent the half of the total, and national and international papers are the rest with similar amounts. A difference of impact can be noticed in the geometric mean of citations since it becomes higher when the collaboration level increases.

Table 1. Descriptive measures by collaboration type datasets

Metrics	*Local*	*National*	*International*
H-index	70	61	75
Citations (geometric mean)	4.14	5.13	6.3
Citations (standard deviation)	17.17	15.05	23.39
Citations (median)	3	4	5
%Papers	49.98%	23.39%	26.63%
Number of papers	10,158	4,755	5,413

We should point out that the sum of the papers of the three collaboration types is not equal to the total number of downloaded papers. This is due to 1,801 papers did not have the affiliation, i.e., neither the country nor the organization.

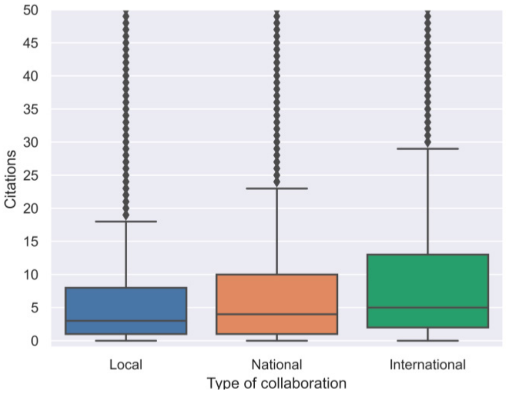

Figure 1. Boxplot diagram of local, national, and international collaboration citations.

In addition, as shown in Figure 1, the maximum of citations without outliers is higher when the collaboration level increases. Moreover, the outliers are more reduced in the national and international collaboration in comparison with the local collaboration type. The 25% of most cited papers increase when the academic collaboration is higher, this can be noticed by the 3rd quartile being higher in each of the collaboration types.

Themes in the collaboration types

A science mapping analysis has been made on each collaboration type to study the thematical differences and similarities between the collaboration types. The clusters detected for each collaboration type are shown in the strategic diagrams (Figures 2-4). For each of those clusters the number of documents, the citations average, the h-index and the MNCS have been computed. They are shown in Tables 2-4.

Prior to describing the results, is important to clarify that in the rest of the paper, the name of the themes will be in *italic*. Also, it is important to point out that concepts related to themes are nodes under the detected clusters.

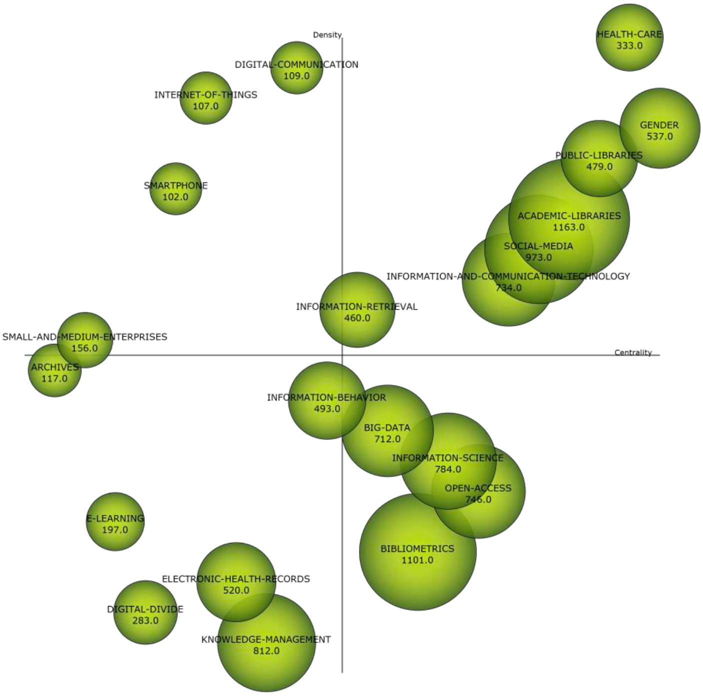

Figure 2. Local collaboration strategic diagram.

As we can see in Figure 2 and Table 2, the local collaboration is focused on some of the following themes. The theme *academic libraries*, which is related to information literacy, collaboration, and higher education. *Bibliometrics*, which is about citation analysis, altmetrics, and social network analysis. Additionally, we can see *social media*, which is delved into topics such as social networks, social networking sites, and political communication. Also, new technologies such as the *big data* theme have a place in this collaboration type, focusing on concepts such as e-government, transparency, open data, and developing countries. Another important theme is *information and communication technology* that is related to content analysis, digital media, and journalism.

The themes with the strongest impact are *internet of things* that is delved into digitalization, academic librarians, and blockchain, which is a new technology too; and *digital divide*, which is related to cloud computing, user experience and customer relationship management, obtains a high impact in this collaboration type. These last two themes have a MNCS of 2.32 and 1.41 respectively, as shown in Table 2. In contrast, the themes that achieve less impact are *academic libraries* and *information science* with a MNCS of 0.63 and 0.68, respectively.

Table 2. Local collaboration cluster measures.

Cluster names	*#Docs*	*Citations average*	*h-Index*	*MNCS*
ACADEMIC-LIBRARIES	1,163	5.44	29	0.63
BIBLIOMETRICS	1,101	10.03	41	1.14
SOCIAL-MEDIA	973	10.23	42	1.25
KNOWLEDGE-MANAGEMENT	812	9.27	35	1.14

INTERNET-OF-THINGS	107	13.36	18	2.32
SMARTPHONE	102	7.52	14	0.91

Furthermore, the national collaboration, as shown in Figure 3 and Table 3, puts its attention on the following themes: *bibliometrics*, which is focused on the same topics as the local collaboration type; *electronic health records*, which add new technologies to the health context such as machine learning and natural language processing; *academic libraries*, which is related to the same concepts as the local collaboration; and *social media*, which is focused on the same topics as in the local collaboration too. The stronger themes in terms of impact are *electronic* *health records* and *patient portals* with a MNCS of 1.56 and 1.63 respectively, as shown in Table 3. *Patient portals* theme is delved into mobile health and electronic health. Otherwise, the themes with lower impact are *academic libraries* and *ontology*. The *ontology* theme is related to information retrieval, data sharing and interoperability topics.

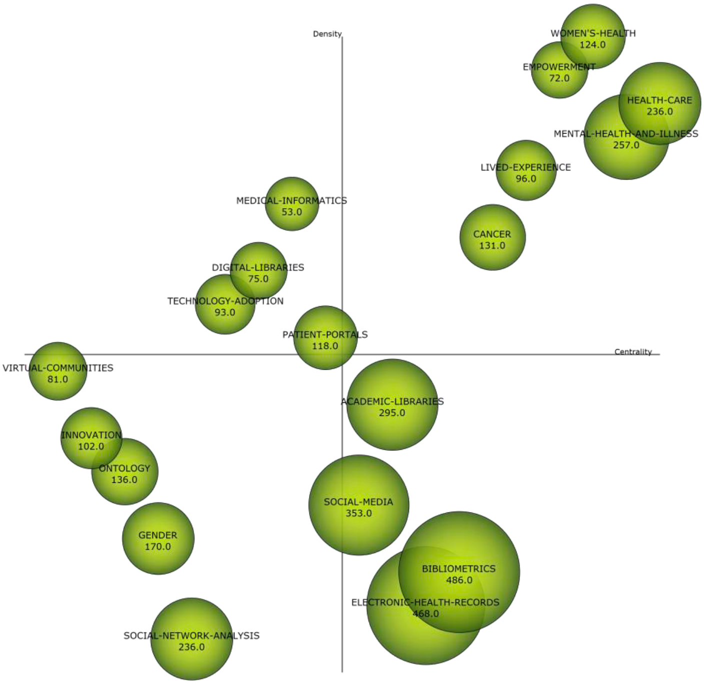

Figure 3. National collaboration strategic diagram

Moving to the international collaboration side, as shown in Figure 4 and Table 4, the themes have some similarities but also many differences with the other collaboration types: *bibliometrics*, but this time it is very related to data mining, content analysis and text mining; *developing countries*, focusing on topics such as information and communication technology and small and medium enterprises; *social media*, which relates to the same concepts as the other collaboration types; *knowledge management*, which is delved into knowledge sharing, innovation and systematic literature review; and themes focused on new technologies like *sentiment analysis*, *big data*, *natural language processing* and *machine learning*.

The theme with the stronger impact is the *literature review,* which is about information system and enterprise architecture, and obtains a MNCS of 3.13, as shown in Table 4. Also, the new technologies themes obtain a high impact. In contrast, more traditional themes like *higher education* and *health care* obtain a lower rate of MNCS, 0.97 and 1.27, respectively.

Thematical similarities and differences

Aiming to study the differences and similarities of the themes treated in each collaboration type, the results of the most cited keywords overlapping in terms of the Jaccard index are shown in Figure 5. The computation was done for the *n* most cited keywords, for exponentially increasing values of *n* until 10^7, which includes all the keywords in the datasets.

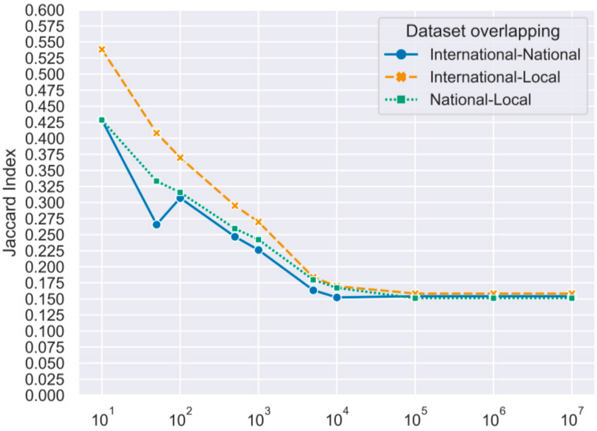

Figure 5. Jaccard Index between datasets keywords for n in 10, 50, 100, 500, 1000, 5000, 10000, 100000, 100000

As Figure 5 reveals, there is a moderate sharing of the most cited keywords between the international and local collaboration that is in line with the strategic diagrams obtained from the science mapping analysis. Moreover, the national and international collaboration is less shared than the international-local. Finally, the national and local collaboration share fewer keywords than the other ones, but it has a similar slope that is not as pronounced as the others. Therefore, the international and local collaboration are the most similar in terms of most cited keywords than the others.

Discussion

Once the proposed analysis has been done, an overview of the impact and the thematical differences and similarities between the collaboration types of the LIS category is given. First, according to previous studies (Gazni et al., 2012; Persson, 2010; Sin, 2011), international collaboration yields a higher impact in terms of citations. It is also demonstrated in our study by the results of the geometric mean (4.14 < 5.13 < 6.3) for local, national, and international collaboration, respectively. This fact is also supported because 25% of most cited papers of each collaboration type are more cited when researchers collaborate with international colleagues.

Regarding the research conducted, there are some thematical similarities as well as many differences between collaboration types. The similarities that can be noticed are: *bibliometrics*, which is present on the three collaboration types and obtains a similar impact in the three. It is delved into citation analysis, altmetrics and social network; moreover, *social media* theme is quite similar, and it is very related to social networks, but in the international collaboration it is a stronger theme in terms of MNCS; *health care* is very similar too, focusing on topics such as education, culture, and patient safety. In fact, there are several health-related themes in the three collaboration types: *empowerment*, which is about physical activity and mental illness; *gender*, which is about how gender relates to health, race, and information technology. All of them get around the same impact at the three collaboration types. Furthermore, *academic libraries*, which is related to collaboration and information literacy, is similar too. Nevertheless, in the international sphere, computer science (data mining, text mining) plays an important role. In fact, the MNCS of *academic libraries* is shot up in the international collaboration type, and doubles the impact acquired in the local and national collaboration types.

Additionally, there are many differences. While in the local and national collaboration, artificial intelligence topics are more spread through the themes, in the international collaboration type they form four themes: *natural language processing*, *big data*, *sentiment analysis* and *machine learning*, with a really high MNCS, almost all of them doubling the average citation rate of the area. Moreover, *literature review*, which is in the international collaboration type, is delved into enterprise architecture and information systems and it has the highest impact (MNCS = 3.13). Also, there are other themes with a significant impact: *social networking sites* and *collaboration*. However, these two themes are very spread in other themes at the local and national collaboration types.

The differences concluded in the last paragraphs are confirmed by the study of the overlapping keywords. The international and local collaboration datasets share less than 2/3 of 10 highest cited keywords. If this number is exponentially increased by the power of 10, the sharing quickly decreases to a value around 1/3 and then converges to 1/6 approximately for all the keywords. The rest of the collaboration datasets comparisons suffer the same situation, but they are less shared and converge to near the same value. This fact supports our performance analysis on the strategic diagrams which pointed out a difference between the themes of the different collaboration networks.

Although the findings reported in this contribution highlights the differences between the collaboration types, some limitations should be highlighted: only one database (Web of Science) was considered; only the period 2015-2019 was included. To the extent of our study, future research must include other databases and a wide period to reach a larger number of documents.

Conclusions

In this contribution, we present a research about the thematical differences and similarities in the Library and Information Science category between the 2015 and 2019 years (both included). Our study reveals that there are impact differences when a researcher collaborates with international colleagues rather than limiting the collaboration to the same institution or collaborating with colleagues from the same country. In fact, the more collaboration, the more impact is achieved in general. This fact has been pointed out and demonstrated in other areas and temporal periods (Chinchilla-Rodríguez et al., 2019; Gabrielle Breugelmans et al., 2018; Gazni et al., 2012; Polyakov et al., 2017). Furthermore, when this difference is detected, there is a difference between the themes in the collaboration types. The difference is mainly related to artificial intelligence being applied broadly in the field as well as *literature review*, *collaboration*, and *social networking sites*, acquiring a very high attention. However, there are also some similarities like *social media*, *health care* and *bibliometrics* themes. Nonetheless, while this difference in impact has been found in our study and we have analyzed the thematical differences, it also can be due to external factors, such as publication place, funding (Asubiaro, 2019), research leadership (Chinchilla-Rodríguez et al., 2019) or publishing in open access (Gabrielle Breugelmans et al., 2018). Therefore, future research on this topic should consider these other variables in order to demonstrate what we are stating in this study.

Assessing the potential effect of a unified system of journal classification based on citation impact indicators: the new Qualis

Eloisa Viggiani[1], Alexandre Prestes Uchoa[2] Jano Moreira Souza[2]

Abstract

In 2018, CAPES ' Evaluation Directorate proposed a new methodology for Qualis, the journal classification system used to score the scholarly output of Masters and PhD programmes in Brazil, which used a system with varied composite criteria specific to each Evaluation Area. A unified criterion without distinction by areas was proposed, based on WoS, Scopus and GS citation impact indicators. We explored the potential effect on the publication scores of programmes and Evaluation Areas if a such a new system was adopted and, through correlational analysis using various characteristics of journals and programmes, we found signs that the reasons for the negative effects may have different origins and, therefore, can be mitigated through different actions. We found that the Sports Education, Nursing, and Agricultural Sciences areas would see the strongest decrease in their publication scores and that at least 96% of their programmes would be negatively affected. Journals published by Brazilian universities and societies, which may have important functions for the programmes, such as training of early career researchers, were the most downgraded. Our study brings insights to the improvement of the proposed classification system, and to the publishing strategy of programmes.

Introduction

The problem of assessing research output from different subject fields has long been studied in the context of Performance-based Research Funding Systems (PRFS) (Hicks, 2012) and the reliability and validity of citations as performance indicators has been debated for the past decades (Aksnes, Langfeldt and Woulters, 2019). Citation indicators and other bibliometric methods are believed to provide benefits in terms of robustness, validity, functionality, cost, and time of execution, when applied to the natural and formal sciences (Abramo and D´Angelo, 2011), though it is recognised that journals that are not covered by the main international bibliographic databases may have important functions for certain research fields and local research communities, such as knowledge gap-filling, knowledge bridging, introduction of new concepts and methods, and training of early career researchers, (Chavarro and Ràfols, 2019).

Many PRFS have addressed the issue by using a formula of weighted publications according to the rank or citation impact of the publication channel, such as the Norwegian Model, which attempts to comprehensively cover all the peer-reviewed scholarly journals in all areas of research in one single indicator, and where the bibliographic data are delivered by the institutions themselves through a CRIS system (Sivertsen, 2018). Nevertheless, PRFS are not static, and many have undergone major redesign (Hicks, 2012).

Other main research strands around the use of indicators in evaluations study the potential effects of evaluation exercises on publication practices, such as strategic behaviour by research communities, goal displacement, "gaming" of indicators, and the potential biases against interdisciplinary research (de Rijcke et al., 2016).

Background and purpose

Changes to the National Evaluation of Graduate Programmes in Brazil

The national evaluation of the graduate programmes in Brazil is performed by the Federal Agency for Support and Evaluation of Graduate Education (CAPES) every 4 years, and is a metrics-informed peer review process, through Evaluation Area committees, currently divided into 49 Areas (Oliveira and Amaral, 2017).

In 2018, CAPES ' Evaluation Directorate initiated a series of actions aiming to improve the instruments used in the evaluation. The main motivation was to increase the focus on the quality of the training of doctors and masters and on the excellence of Brazilian graduate studies. A new framework for multidimensional assessment was proposed, considering: i) teaching and learning, ii) internationalization, iii) knowledge production, iv) innovation and knowledge transfer, and v) economic and social impact, and relevance. Working groups started in 2019 to elaborate the definition of concepts, variables and indicators representing each of the evaluation dimensions (CAPES, 2020).

Of special interest to our study is the proposed methodology for a unified Qualis journal classification for all Evaluation Areas, hereafter identified as “Qualis 2019”. We will briefly describe the former Qualis system, the proposed changes, and their justification. Nevertheless, it is important to highlight that many other indicators are taken into consideration in the overall evaluation framework, related to other functions that Master and PhD programmes need to fulfil.

The former Qualis System

The Qualis journal classification system was created in 1988 to allow the analysis and evaluation of the scholarly output reported by degree programmes in all disciplinary areas. Until the last national evaluation exercise performed in 2017, covering the period from 2013 to 2016, the criteria for journal classification was determined by each Evaluation Area Committee. The Committees were also responsible for continuously updating their Qualis journal list, and minor revisions to the criteria were not uncommon.

A recent study by Oliveira and Amaral (2017) found that 81% of the Evaluation Areas used the Impact Factor and 56% made use of SJR/Scimago. Many Areas classified journals based on their presence in regional or field specific databases, such as SciELO, RedALyC, LatIndex, PubMed, PSYCINFO, and BIOSIS. The Evaluation Areas also considered titles which were evaluated for their local or regional impact, the importance of the content developed and the objectives of the research. For example, within the area of Agricultural Sciences, the development of literature, teaching of local history among others, in which the less dissemination does not mean lack of quality or prestige (Oliveira and Amaral, 2017). This system, from now on identified as “Qualis 2017”, resulted in 49 different lists of journals and corresponding strata, published by CAPES as a web page with multiple filters (“Plataforma Sucupira”, [n.d.]).

The main objections to Qualis 2017 were around the concentration of publications in low visibility/low impact journals, the difficulty of comparisons and benchmarking, and management issues. Pires et al. (2020) argued that as an effect of the Qualis system used until 2017, Brazilian degree programmes concentrated their publications in a restricted number of journals, which were classified in the top levels of Qualis, regardless of their performance in terms of international visibility and citation impact. Perlin, Imasato, and Borenstein (2018) found that when a potentially predatory journal enters Qualis, the number of publications from Brazilian programmes tends to increase, meaning that researchers are less likely to challenge its quality and visibility. The authors also found that even experienced researchers, with significant career time and many publications in non-indexed journals are publishing in questionable journals. According to Barata (2016), the system produced incommensurable results, hampering the integration between the Evaluation Areas, and resulting in lack of communication between key stakeholders. The author justified the need for a unified Qualis classification system as the only way to give greater visibility to Brazil´s scientific production and encourage the publication of quality research in all areas of knowledge.

The new Qualis System

In this new system proposed by CAPES in 2019, each journal would receive only one classification, based on field normalized citation impact percentiles, calculated using indicators from WoS (Impact Factor) or Scopus (CiteScore). The first step would be to assign each journal to a subject field (or "Mother Area") corresponding to the Evaluation Area whose programmes reported the highest number of publications during the evaluation period, and then consult the corresponding indicators. When both indicators from WoS and Scopus are available for a journal, the highest percentile value among them is to be considered. When neither is available, the value of Google Scholar´s h5 index is used in a model of regression making a relationship between h5 and CiteScore and estimating a corresponding percentile value. (CAPES, 2019a). Based on this method, a journal list was created, with all the titles previously classified in Qualis 2017, and their corresponding classification when using Qualis 2019. This list was presented to the Evaluation Areas Committees during the mid-term review in 2019 for their input and feedback. Currently, there is a working group reviewing this list and the final version is expected to be published in 2021.

The purpose of this study is to explore the Evaluation Areas (EAs) which would potentially be affected by the replacement of a journal classification system with distinctions between disciplinary fields (Qualis 2017) by a unified classification system based on citation impact indicators (Qualis 2019). Our goal is to identify characteristics of the main downgraded journals and of the programmes which would see a decrease in their publication score. Though acknowledging that a pure bibliometric approach is not sufficient to assess the suitability of the proposed unified system, our study aims to contribute to its refinement and improvement, and to support programmes in reviewing and/or adapting their publication strategies.

Methodology

Data Sources

The source of metadata regarding the programmes and their scholarly output were produced by CAPES' Sucupira system and are openly available in CAPES' open data repository (http://dadosabertos.capes.gov.br). Each register contains the Evaluation Area, programme name and identification number, programme degree level (Academic Master, Professional Master, Academic Master and PhD, or Academic PhD), programme start year, grade received in the 2017 evaluation exercise, institution, number of publications, publication year, journal name, and journal ISSN. The retrieved dataset contains 714,459 registers for the years 2017 and 2018, which reported a total of 1,245,755 publications in 16,272 unique journals, authored by faculty and students from 4,442 programmes, offered by 246 Brazilian institutions. The criteria for journal classification adopted by each EA were also obtained from Sucupira System. The Qualis 2017 journal classifications were published by CAPES as a web page with multiple filters ("Plataforma Sucupira", [n.d.]). As a result, only isolated parts of the classification could be consulted at a time. Additionally, there was no print or download feature. For practical reasons, we decided to use the files released by (GOUVEIA, 2017). This dataset consists of independent CSV files, each one for an Evaluation Area with all its corresponding journals and respective strata. The Qualis 2019 journal classification, although not officially released yet, could be easily found in the websites of many universities as a single text file. After comparing the content of the files of three different websites and making sure they were identical, their content was converted into a table.

Qualis 2017 and Qualis 2019 strata and scoring systems

In the Qualis 2019 system there are 8 strata, corresponding to one citation impact octile each, and the scoring is equally divided into the strata. In the Qualis 2017 system, there were 7 strata, with a rule limiting the number of journals classified in the upper strata, as can be seen in Table 1, which contains the classification strata, scores, and journal distribution quartiles for Qualis 2017 and Qualis 2019.

Table 1. Qualis 2017 and Qualis 2019 classification strata, scores, and corresponding journal distribution quartiles.

Qualis 2017		*Journal Distribution Quartiles*	*Qualis 2019*	
Score	Strata		Strata	Score
1.000	A1	Q1	A1	1.000
0.850	A2		A2	0.875
0.700	B1	Q2	A3	0.750
			A4	0.625
0.550	B2	Q3	B1	0.500
0.400	B3		B2	0.375
0.250	B4	Q4	B3	0.250
0.100	B5		B4	0.125
0	C		C / NP	0

Identification of most affected Evaluation Areas and Programmes

A total publication score was calculated for each Evaluation Area and each programme, using both the Qualis 2019 and the Qualis 2017 scoring system, and their difference was used to determine which Evaluation Areas and which programmes would be more positively or negatively affected by the new classification system. We selected the three most negatively affected Evaluation Areas (EAs) for the following analysis.

Analysis of Qualis 2017 criteria and journal up- or downgrade

The 2017 Area Documents were consulted to verify the criteria for journal classification adopted by the EAs. The criteria were categorised as follows:

- **CI** = used citation impact indicators from WoS, Scopus and/or Google Scholar.
- **COV** = considered the coverage by databases, such as: SciELO, PubMed, LatIndex, and RedALyC. This category also included the coverage by WoS, Scopus or Google Scholar, when no citation impact indicators were used.
- **DF** = criteria applied only to journals with a selected disciplinary focus or gave those journals some advantage over multidisciplinary journals and journals considered from unrelated disciplines.
- **BR** = criteria applied only to Brazilian journals or gave those journals some advantage over the others.

For each EA, we calculated the percentage of journals and publications which continued to be classified in the same quartile and of those which were upgraded or downgraded, when using the Qualis 2019 classification. The average number of articles per title was calculated to identify if there was a higher concentration of articles on the titles that remained in the same quartile or on those up- or downgraded.

Characteristics of main downgraded journals

For all journals which published 10 or more articles from the selected Evaluation Areas in 2017 and 2018, namely the "main downgraded journals", we identified the journal´s publisher, country, and type of organisation (university, scientific society, or commercial publisher), and calculated the percentage of journals and publications published by:

- Brazilian universities, scientific societies, and commercial publishers, which potentially have the function of knowledge gap-filling, knowledge bridging and introducing new concepts and methods to local communities of research and practice.
- Brazilian universities, which could also have the function of training early career researchers.

Since one of the most affected Evaluation Areas reported the presence of potentially predatory journals in their Qualis 2017 list, we also calculated the percentage of their publications.

Identification of Programmes Characteristics

We investigated various characteristics in search of possible reasons for the publication practices that, in the final analysis, would lead to low scores in case of using exclusively a citation impact indicator. Having in mind that each Evaluation Area has its own characteristics inherent to its scientific field, our strategy focused on aspects related to the time of existence, experience, degree of multi or interdisciplinarity of teams, and whether these could be related to decreases in the score of publications. Regarding the programme´s experience, we verified the percentage of faculty graduated over 20 years ago and calculated the programme´s time of existence (years), with the following age quartiles:

- Q1 = programmes with up to 2 years of existence
- Q2 = between 2 and 7 years
- Q3 = between 7 and 13 years
- Q4 = more than 13 years

The programme´s multidisciplinarity was assessed by verifying the percentage of faculty graduated in a programme belonging to a different Evaluation Area. The balance was assessed by the grade received by the programme in the last evaluation exercise. It is worth mentioning that this was considered an especially useful measure of balance, because despite being an aggregation which includes the publications, the programme grade also considers other important indicators of education, research, and third mission, such as number of students per faculty, theses, dissertations, and patents. Grades range from 1 to 7, where 1 is the lowest and 7 is the highest grade. Other contextual characteristics were also analysed, such as number of faculty members, proportion of permanent vs. visiting faculty, and geographic region (in Brazil), but no significant relation to the decrease in publication scores was found.

Findings

Most affected Evaluation Areas

Out of the 49 Evaluation Areas, 15 would see a decrease in their average publication score if the new Qualis 2019 system was implemented, affecting more than 50% of their programmes. The most negatively affected Evaluation Area would be Sports Education, regarding both the decrease in the average publication score (-2318), as well as in the proportion of programmes which had their publications scores decreased (100%), followed by Nursing (-1594, 99%), and Agricultural Sciences (-1700, 96%). Figure 1 shows the average difference in the Evaluation Area publication score and the percentage of programmes which would have a decrease in their publication score, when using Qualis 2019 and Qualis 2017, for the 49 Evaluation Areas.

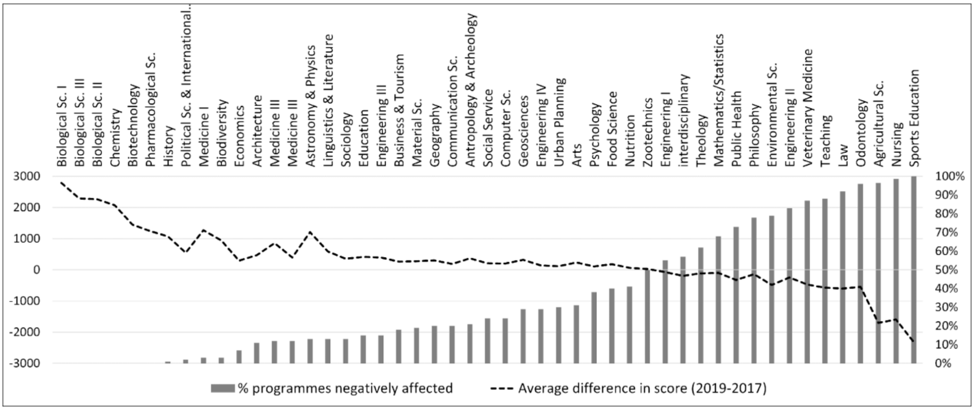

Figure 1: Average difference in the publication score of the Evaluation Areas when using Qualis 2019 and Qualis 2017, and the percentage of their programmes which would have a decrease in their publication score with the new system.

We selected the 3 most negatively affected Evaluation Areas for further analysis: Sports Education, Nursing, and Agricultural Sciences.

Evaluation Area Sports Education

The criteria for journal classification adopted by the Sports Education Area for the Qualis 2017 used impact citation indicators from WoS (SCIE and SSCI) for the 1st and 2nd journal quartiles, but only for journals that met the EA´s disciplinary focus, which included the subject categories “Sport Sciences”, “Rehabilitation”, “Audiology & Speech-Language Pathology”, “Hospitality, Leisure, and “Sport & Tourism” in WoS. The highest possible classification for journals from other disciplines was in the 2nd quartile. For the 3rd and 4th journal quartiles, the Sports Education area opted for a combination of coverage by SciELO, Pubmed, CINAHL, RedALyC and/or LatIndex. As expected, due to the different criteria, we found that a significant proportion of journals would be upgraded, as well as downgraded, if Qualis 2019 was adopted, as can be seen in Table 2.

Table 2. Qualis 2017 criteria for the Evaluation Area Sports Education and journal classification by Qualis 2017 and Qualis 2019.

Journal Quartile	*Qualis 2017 Criteria*	*Journals classified by Qualis 2017*	*Journals classified by Qualis 2019*		
			Upgraded	*In same quartile*	*downgraded*
Q1	CI+DF	281	-	178 (63.3%)	103 (36.7%)
Q2	CI+DF	182	53 (29.1%)	69 (37.9%)	60 (33.0%)
Q3	COV	215	110 (51.1%)	51 (23.7%)	54 (25.1%)
Q4	COV	190	69 (36.3%)	121 (63.7%)	-

CI = Citation impact indicators; DF = Disciplinary focus; COV = covered by database(s)

We found that the most significant reason for the decrease in the EA´s publication score is that the potentially downgraded journals are the ones which concentrated the highest number of publications from the Sports Education area. Even though the criteria adopted in 2017 did not include any advantage for Brazilian journals, we found that among the 10 journals with more publications from the Sports Education Area, 8 are Brazilian journals, and all would be downgraded with the adoption of Qualis 2019. We found 79 main downgraded journals responsible for 41.5% of the area´s output, of which 40 are Brazilian journals (2476 publications, 26.8%), predominantly published by universities (22 journals, 1410 publications, 15.2%) and societies (16 journals, 958 publications, 10.4%). Among the non-Brazilian journals, the majority of the titles belongs to commercial publishers (23 journals, 832 publications, 9%). Among these, we also found titles from the most prestigious international publishing houses, though they were the ones with the smallest decrease.

All 67 programmes belonging to Sports Education would see some degree of decrease in their publication score if Qualis 2019 was adopted and the strongest decreases would be among the 4 programmes which received grade 6 in the last evaluation, followed by the 2 programmes which received grade 7. These programmes represent only 11% of the total, so the decrease of the Evaluation Area´s total publication score would come mostly from the accumulated contribution of numerous programmes with lower grades, as seen in Figure 2 (left). Regarding the programme´s experience, the strongest decrease in publication scores was found in programmes with 7 to 13 years of existence, followed by programmes with more than 13 years, as seen in Figure 2 (right).

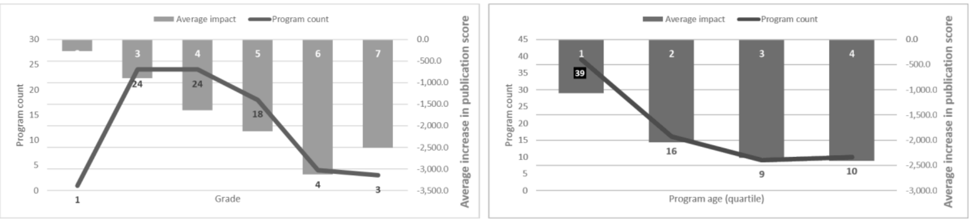

Figure 2: Relation between average decrease in programme´s publication score and grade received in the last evaluation exercise (left), and programme´s years of existence (right) for the Evaluation Area Sports Education. Lines represent number of programmes.

On the other hand, programmes in the Sports Education Area with more experienced faculty seem to be less affected than those with a higher proportion of faculty graduated more recently, as can be seen in Figure 3, which relates the average decrease in the programme´s publication score and the percentage of faculty graduated 20 years ago or more.

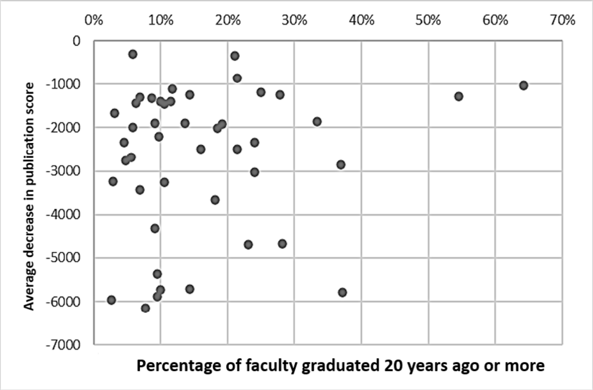

Figure 3: Average decrease in the publication score of programmes when using Qualis 2019 and percentage of faculty graduated 20 years ago or more for the Evaluation Area Sports Education.

Evaluation Area Nursing

The criteria for journal classification adopted by the Nursing Area for Qualis 2017 contemplated impact indicators from WoS, Scimago for the assignment of journals to the 1st quartile, but his criterion was only valid for journals in the subject category “Nursing” in WoS or Scopus. For the remaining quartiles, the Nursing Area considered the coverage by field specific databases, such as CUIDEN, a database published by Ciberindex, Medline, CINAHL, LILACS, BDENF, LatIndex, SciELO, and Rev@Enf.

Despite having adopted a similar criterion for the top journal quartile as in Qualis 2019, the Nursing Area would see 31.6% of journals in this quartile being downgraded with the adoption of the new classification system. An even higher proportion of journals would be downgraded from the 2nd quartile (58.7%) and from the 3rd quartile (44.2%), as can be seen in Table 3.

Table 3. Qualis 2017 criteria for the Evaluation Area Nursing and journal classification by Qualis 2017 and Qualis 2019.

Journal Quartile	*Qualis 2017 Criteria*	*Journals classified by Qualis 2017*	*Journals classified by Qualis 2019*		
			Upgraded	*In same quartile*	*downgraded*
Q1	CI+DF	155	-	106 (63.4%)	49 (31.6%)
Q2	COV	126	24 (19.0%)	28 (22.2%)	74 (58.7%)
Q3	COV	156	30 (19.2%)	57 (36.5%)	69 (44.2%)
Q4	COV	175	80 (45.7%)	95 (54.3%)	-

CI = Citation impact indicators; DF = Disciplinary focus; COV = covered by database(s)

Additionally, we found that the publications from the Nursing Area were highly concentrated in a small number of journals. No criterion to benefit Brazilian journals was adopted in Qualis 2017, but the main downgraded titles are predominantly published by Brazilian universities (9 journals, 1233 publications, 14.1%) and Brazilian societies (7 journals, 242 publications, 2.8%). 42.7% of the EA´s reported output was concentrated in 10 Brazilian journals, of which 5 would be downgraded by 1 or 2 quartiles.

Out of the 74 programmes in Nursing, 73 would have a decrease in their weighted publication scores and similarly to what was found in the Sports Education Area, the most significant decreases are again among the programmes which received higher grades in the last evaluation exercise, and among programmes with more than 13 years of age. Here again, the accumulated contribution of numerous programmes with lower grades has led to the overall decrease in the Evaluation Area´s total publication score, as seen in Figure 4 (left). However, differently from the Sports Education Area. However, we did not find a relation between the programme´s years of existence, which suggests that the decrease in the Nursing Area´s publication score is not affected by characteristic, as seen in Figure 4 (right).

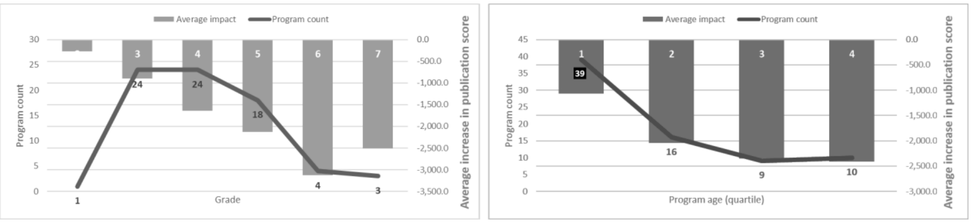

Figure 4: Relation between average decrease in programme´s publication score and grade received in the last evaluation exercise (left), and programme´s years of existence (right) for the Evaluation Area Nursing. Lines represent number of programmes.

A stronger relation was found regarding the multidisciplinary of the programmes´ faculty body. Programmes with a higher percentage of faculty members graduated in other disciplinary fields would be the ones less negatively affected by the adoption of Qualis 2019, possibly due to a selection of journals from other disciplinary fields, which may have been under classified by the Nursing Area in Qualis 2017. c

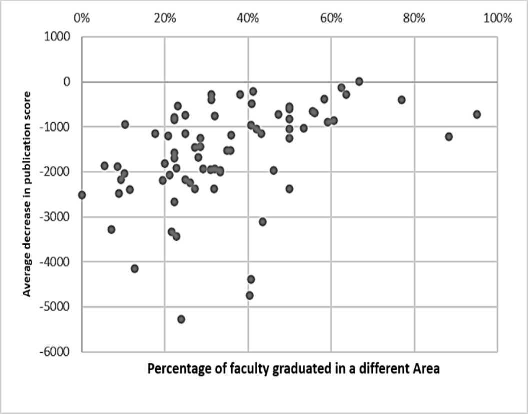

Figure 5: Average decrease in the publication score of programmes when using Qualis 2019 and percentage of faculty graduated in a different Area the Evaluation Area Nursing.

Evaluation Area Agricultural Sciences:

The Agricultural Sciences Area adopted citation impact indicators from WoS or Scopus for the classification of journals into the 1st and 2nd journal quartiles. For the 3rd and 4th quartiles, the EA considered the coverage by SciELO and the following field specific databases: CAB (Commonwealth Agricultural Bureau), BIOSIS (Biological Abstracts), and AGRIS (International System for Agricultural Science and Technology). We found that the majority of journals would remain in the same quartile with the adoption of Qualis 2019, as illustrated in Table 4.

Table 4. Qualis 2017 criteria for the Evaluation Area Agricultural Sciences and journal classification by Qualis 2017 and Qualis 2019.

Journal Quartile	*Qualis 2017 Criteria*	*Journals classified by Qualis 2017*	*Journals classified by Qualis 2019*		
			Upgraded	*In same quartile*	*downgraded*
Q1	CI	492	-	407 (82.7%)	85 (17.3%)
Q2	CI + DF	400	108 (27.0%)	183 (45.8%)	109 (27.3%)
Q3	CI + COV	264	79 (29.9%)	108 (40.9%)	77 (19.2%)
Q4	COV	474	160 (33.8%)	314 (66.2%)	-

CI = Citation impact indicators; DF = Disciplinary focus; COV = covered by database(s)

Nevertheless, in all journal distribution quartiles there was a significantly higher concentration of articles per titles among the downgraded journals, and this is the predominant factor for the decrease in the EA´s publication score. We found 89 main downgraded journals, with 7713 publications, representing 27.6% of the EA´s output for 2017 and 2018. Despite not having a criterion to benefit Brazilian journals in 2017, 33 main downgraded journals are published by Brazilian universities (3278 publications, 11.7%), and 17 by Brazilian societies (1924, 6.9%). 13 journals by non-Brazilian commercial publishers identified by the EA as potentially predatory published 1486 articles in 2017 and 2018, representing 5.3% of the area´s output, and may indeed be a source of concern for the EA.

Programmes with higher grades (5 to 7) in the last evaluation exercise would see the strongest decrease in their publication scores, as well as programmes with more than 13 years of existence, as can be seen in Figure 6.

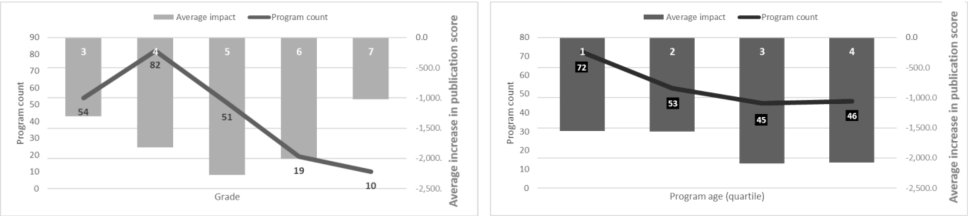

Figure 6: Relation between average decrease in programme´s publication score and grade received in the last evaluation exercise (left), and programme´s years of existence (right) for the Evaluation Area Agricultural Sciences. Lines represent number of programmes.

It is worth noting the high proportion of programmes which received high grades in the last evaluation exercise that would see a decrease in their publication scores with the adoption of Qualis 2019, and the degree in which this would happen. The same is valid for long standing programmes, especially those with more than 13 years of existence, and for programmes with well experienced faculty, which could be affected because of their selection of journals.

No meaningful relation was found between the potential decrease in the publication score of programmes in the Agricultural Sciences and either the percentage of faculty graduate in different Areas nor in the percentage of faculty graduated 20 years ago or more, as seen in Figure 7.

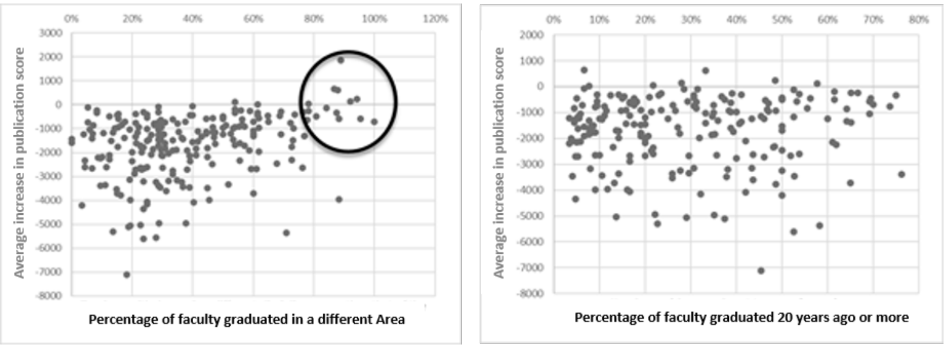

Figure 7: Average decrease in the publication score of programmes when using Qualis 2019 and percentage of faculty graduated in a different Area (left) and percentage of faculty graduated 20 years ago or more (right) for the Evaluation Area Agricultural Sciences. Each dot represents a programme. Programmes with no faculty graduated in a different Area were omitted.

Discussion and conclusions

The 3 Evaluation Areas which would experience the highest decrease in their publication scores if Qualis 2019 was adopted are Sports Education, Nursing, and Agricultural Sciences. These EAs used a combination of citation impact indicators from WoS and Scopus and the coverage by regional and/or field specific databases for journal classification in 2017, which resulted in significant changes in the journals´ classification strata and consequently, in the publication score of programmes with the adoption of a system based on citation impact from WoS, Scopus and GS. Nevertheless, in all 3 areas, part of the journals maintained their classification level in both systems, meaning that they have met both the bibliometric approach as well as their areas´ understanding of relevance and quality.

Despite not having adopted any criterion to benefit Brazilian journals, most of the potentially main downgraded journals are published by Brazilian universities and societies and may serve local communities by bringing new concepts and methods, knowledge bridging and knowledge gap-filling. Journals published by Brazilian universities, notably underfunded, may also have the function of training of early career researchers, which is part of the programmes´ educational mission. Further considerations are needed around what actions could be taken regarding these journals, especially because they concentrated the highest proportion of articles from the Evaluation Areas addressed in this study. If one understands that these journals serve specific needs of the programmes, the methodology for the new Qualis system could be adjusted for that purpose, although this means departing from a more universal and general system. Alternatively, strengthening these journals´ by means of directed resources and support, so they have a better chance to improve their editorial quality standards, could fulfil that goal. Although it is not guaranteed that by improving their quality they would consequently be indexed by the main bibliographic databases.

At the same time, this study showed signs that there may be programs that, even with an eventual adjustment in the categorization of certain journals, will still need to review their publication strategies. Further investigations are needed to understand why the journals chosen might be of relevance to the programmes and can precisely characterize each case to allow targeted, more effective, and reasonable actions like training of researchers and libraries on journals search, selection, and publishing options, targeted funding of submissions and subscriptions, even on article writing and translation.

Future studies can also focus on the upgraded journals, and the underlying reasons for many of them having been under classified in Qualis 2017, such as not meeting the stated disciplinary focus of the EA. It is important to understand the potential effects of any change on publication and research practices of each EA to ensure that its disciplinary (or multi- inter-transdisciplinary) goals are neither unintentionally distorted nor hindered by a new journal classification system only for the sake of simplicity.

In summary, multiple factors play a role in the publication pattern of the graduate programmes in Brazil and in the characteristics of local journals. Addressing them is important to ensure the robustness, validity, and functionality of the new Qualis system, and to maintain an alignment with the multidimensional approach proposed by CAPES, that considers teaching and learning, internationalization, knowledge production, innovation and knowledge transfer, economic and social impact, and relevance. Another important consideration is that the new Qualis which is expected to be finalised by mid-2021 will be used to evaluate the research output from 2017 to 2020 and so, whatever changes are implemented, the results should be interpreted with caution, since both researchers and programmes coordinators were working under the conditions of the previous criteria and will need time to adapt to the changes.

Abstract

Twenty funding programs from many countries were selected for they cover, or not, a range of support mechanisms fueling, to varying degrees, cross-disciplinarity (XDR). Their publication outputs were then used to test the usefulness of quantitative indicators to capture their anticipated degree of XDR. This assumes that the programs have been sufficiently successful to produce XDR outputs to a degree that matches the qualitative assessment. Publication sets were delineated through grant databases or funding acknowledgements. The quantitative assessment relied on the use of two indicators of disciplinary diversity, 1) the Rao-Stirling index applied to references to measure intellectual integration (interdisciplinarity); and 2), a novel variation on the Rao-Stirling index applied to authorships (multidisciplinary collaboration). The quantitative results highlighted the current emphasis placed on multidisciplinary collaboration in the funding landscape for XDR, as programs producing XDR papers were scoring high either on multidisciplinary collaboration alone or on both dimensions, but never on interdisciplinarity alone. The XDR indicators were rarely above expectations for non-XDR programs, whereas they were mostly above, to varying degrees, for XDR programs. The results also showed that the XDR programs were either more or less successful than anticipated, or highlighted the challenge of making precise qualitative characterizations.

Introduction

Recent work has highlighted problems in the application of currently available bibliometric indicators of interdisciplinarity and cross-disciplinarity (here, we will use the term "cross-disciplinarity", abbreviated to XDR to encompass all modalities of interdisciplinarity, multidisciplinarity or related practices that are currently measurable with bibliometric indicators). Various teams have reported (Hackett et al., 2021; Leydesdorff & Bornmann, 2020; Locatelli et al., 2021) that findings from bibliometric indicators of XDR did not converge with observations from qualitative or case study work (Hackett et al., 2021). Schneider and Wang, reviewing multiple indicators of XDR, concluded that none of the currently available bibliometric approaches are fully satisfactory for capturing practices in XDR (Q. Wang & Schneider, 2019). The work by Locatelli et al (using mixed methods with bibliometrics being just one evidence stream considered) make it clear that the problems in aligning quantitative findings with existing classifications or findings from qualitative approaches extend beyond the specific realm of bibliometric research.

The recent findings reported above contradict the prior experiences of the authors, who, as analysts working for a commercial bibliometric service provider, have been able to deploy XDR indicators in the formal program evaluations of a number of funding initiatives. The authors have found two bibliometric indicators, disciplinary diversity in authorships (DDA) and disciplinary diversity in references (DDR), to be of value in characterizing the scientific output of funding programs and hypothesizing on their likely mechanisms for steering research practices.

The authors note that there is a clear expansion in the number of currently operating funding programs seeking out measurements on the degree to which supported projects have achieved the XDR outcomes expected from the funding mechanism. On this basis, this paper is motivated by a pragmatic aim to support the managers of a large number of existing programs (Gleed & Marchant, 2016; Rylance, 2015) and other policymakers in developing capacity for the critical assessment of their XDR initiatives. We cannot touch here on the question of how the expansion of XDR funding programs impacts the scientific system more broadly; or if, when and how it is desirable to deploy XDR research funding – although the authors have recently reported that XDR research may be associated with greater odds of policy-relevant outcomes than monodisciplinary research (Pinheiro, Vignola-Gagné, & Campbell, 2021).

In this paper, we aim to test whether our own observations can be generalized by applying these measures across a large number of funding programs, expected to account for different mechanisms to support (or not) XDR; from purely excellence-driven investigator-level grants to initiatives that support highly diverse, transdisciplinary collaborations. We argue that breaking down publication sets by funding programs is currently the best possible approach in trying to evaluate the robustness of XDR indicators. We contend that in no other level of analysis (individual researcher; department; institution; networks, to take just a few example) can there be such a sustained orientation towards XDR practice as that which can be achieved in a dedicated funding program. Funding programs are also a major, and quite possibly the most important socio-organizational mechanism through which XDR is being promoted towards and adopted by researchers. Additionally, developing approaches for measuring XDR outcomes of funding programs is of practical relevance in the context of applied bibliometrics.

We provide a preliminary test of the usefulness and validity of XDR indicators for evaluating the XDR-fostering potential of funding programs. We draw on descriptive statistics, comparing expected XDR practice levels based on qualitative appraisal of program design characteristics and instruments, against measurements obtained through our two XDR indicators. A starting hypothesis here is that funding is the most likely and possibly effective mean through which researchers are exhorted to engage in more XDR research. While some researchers certainly come to engage in XDR practices as part of their intellectual or networking trajectories, our assumption is that funding provides the logistic basis for acting on this ambition.

The methods section will detail the indicators of interdisciplinarity and multidisciplinarity used, with more extensive detail for the second as it amounts to a novel variation of the Rao-Stirling computation applied to publication authorship characteristics. The method section will also include a brief description of the funding programs selected for inclusion in this exercise. Findings are presented at the level of the individual funding programs retained, for DDA, DDR and other relevant dimensions. Findings from follow-up investigations are also presented to test specifically the expectation that various groupings of publications (e.g., by research area) could achieve exhibit intellectual integration (DDR) independently of team-based collaboration (DDA). In this paper, this was done by measuring XDR for Scopus topics of prominence. We conclude with a discussion of these findings and next steps.

Methods

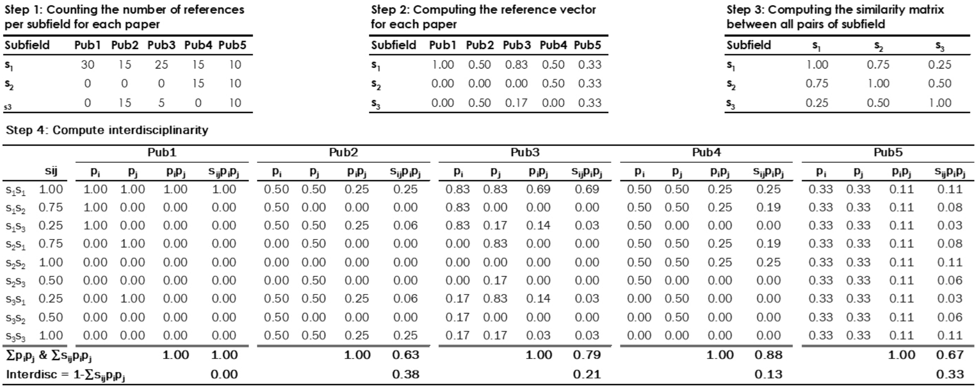
XDR indicators

Cross-disciplinarity at the paper level was captured through two lenses (see also Pinheiro et al., 2021): disciplinary diversity of cited references (DDR; tracks diversity of integrated knowledge) and disciplinary diversity of contributing authors (DDA). The former is equivalent to the integration metrics of Porter and Rafols (2009), relying on a hybrid (journal- and article-based) version of the Science-Metrix classification of science to classify a paper's cited references by subfield (see below for more details) (Rivest, Vignola-Gagné, & Archambault, 2021). Using their method, each paper in Scopus is assigned a DDR score from 0 (i.e., completely following predominant citation patterns) to 1, the latter being extremely interdisciplinary (i.e., diverging completely from normal citation patterns, integrating knowledge from areas that others do not). Per their method, a paper's DDR score is computed as:

$$Interdisciplinarity = 1 - \sum_{i,j} s_{ij} p_i p_j$$

Where p_i and p_j are the respective proportions of references in subfields i and j in a paper's reference list. The summation is taken over all cells of the subfield-by-subfield similarity matrix, accounting for all subfields in Science-Metrix taxonomy. s_{ij} is the similarity between subfields i and j and captures how close (or distant, by taking 1-sij as in the above formula) the integrated subfields are in a given paper. The similarity matrix between subfields was obtained by computing the cosine similarity between each pair of subfields, each subfield being represented by an ordered vector of 174 dimensions (one per Science-Metrix subfield). The values populating a given subfield vector represent the proportion of instances in which it was co-cited with each of the 174 subfields in the whole of Scopus. Table I depicts the computation for five papers in a system with three subfields (e.g., s1 = forestry, s2 = applied mathematics, and s3 = optics; the similarities in the example are fictive).

Table I Illustration of the computation of a paper's interdisciplinarity/DDR score



Step 1: Counting the number of references per subfield for each paper

Subfield	Pub1	Pub2	Pub3	Pub4	Pub5
s_1	30	15	25	15	10
s_2	0	0	0	15	10
s3	0	15	5	0	10

Step 2: Computing the reference vector for each paper

Subfield	Pub1	Pub2	Pub3	Pub4	Pub5
s_1	1.00	0.50	0.83	0.50	0.33
s_2	0.00	0.00	0.00	0.50	0.33
s_3	0.00	0.50	0.17	0.00	0.33

Step 3: Computing the similarity matrix between all pairs of subfield

Subfield	s_1	s_2	s_3
s_1	1.00	0.75	0.25
s_2	0.75	1.00	0.50
s_3	0.25	0.50	1.00

Step 4: Compute interdisciplinarity

		Pub1				Pub2				Pub3				Pub4				Pub5			
	sij	p_i	p_j	p_ip_j	$s_{ij}p_ip_j$	p_i	p_j	p_ip_j	$s_{ij}p_ip_j$	p_i	p_j	p_ip_j	$s_{ij}p_ip_j$	p_i	p_j	p_ip_j	$s_{ij}p_ip_j$	p_i	p_j	p_ip_j	$s_{ij}p_ip_j$
s_1s_1	1.00	1.00	1.00	1.00	1.00	0.50	0.50	0.25	0.25	0.83	0.83	0.69	0.69	0.50	0.50	0.25	0.25	0.33	0.33	0.11	0.11
s_1s_2	0.75	1.00	0.00	0.00	0.00	0.50	0.00	0.00	0.00	0.83	0.00	0.00	0.00	0.50	0.50	0.25	0.19	0.33	0.33	0.11	0.08
s_1s_3	0.25	1.00	0.00	0.00	0.00	0.50	0.50	0.25	0.06	0.83	0.17	0.14	0.03	0.50	0.00	0.00	0.00	0.33	0.33	0.11	0.03
s_2s_1	0.75	0.00	1.00	0.00	0.00	0.00	0.50	0.00	0.00	0.00	0.83	0.00	0.00	0.50	0.50	0.25	0.19	0.33	0.33	0.11	0.08
s_2s_2	1.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.50	0.50	0.25	0.25	0.33	0.33	0.11	0.11
s_2s_3	0.50	0.00	0.00	0.00	0.00	0.00	0.50	0.00	0.00	0.00	0.17	0.00	0.00	0.50	0.00	0.00	0.00	0.33	0.33	0.11	0.06
s_3s_1	0.25	0.00	1.00	0.00	0.00	0.50	0.50	0.25	0.06	0.17	0.83	0.14	0.03	0.00	0.50	0.00	0.00	0.33	0.33	0.11	0.03
s_3s_2	0.50	0.00	0.00	0.00	0.00	0.50	0.00	0.00	0.00	0.17	0.00	0.00	0.00	0.00	0.50	0.00	0.00	0.33	0.33	0.11	0.06
s_3s_3	1.00	0.00	0.00	0.00	0.00	0.50	0.50	0.25	0.25	0.17	0.17	0.03	0.03	0.00	0.00	0.00	0.00	0.33	0.33	0.11	0.11
Σp_ip_j & $\Sigma s_{ij}p_ip_j$				1.00	1.00			1.00	0.63			1.00	0.79			1.00	0.88			1.00	0.67
Interdisc = $1-\Sigma s_{ij}p_ip_j$					0.00				0.38				0.21				0.13				0.33

Per this example, one can see that subfields 1 and 3 are the least similar (or most dissimilar), and that subfield 2 is most similar to subfield 1, while at the same time being more similar to subfield 3 than subfield 1 is to subfield 3. Thus, the combination of subfields 1 and 3 should contribute most to DDR, followed by subfields 2 and 3, and then subfields 1 and 2. Of course, if only one subfield is cited in a paper (either subfield 1, 2 or 3) as in publication #1, DDR will equal 0 (monodisciplinary paper). Publication #2 strictly cited the two most distant subfields (i.e., 1 and 3) in equal proportions. This resulted in the highest DDR score (0.38) across the five publications shown in the example. Publication #3 also strictly cited subfield 1 and 3, but in very unequal proportions. Accordingly, its DDR score (0.21) is lower than for publication #2 (0.38). Publication #4 strictly cited subfields 1 and 2 in equal proportions. Since they are the least distant (or most similar) subfields, its score (0.13) is lower than for publication #2 (0.38) even though they both have their references uniformly distributed across cited subfields. Finally, publication #5 is the only one to have cited all three subfields, and this in equal proportions. Due to the balanced integration of a greater variety of disciplines, it scores higher than publication #3 and #4, but not more than publication #2. This is because although publication #2 only cited two subfields instead of three, the average distance between the integrated disciplines in publication #2 is higher than in publication #5—that is, the additional subfield cited in publication #5 reduces the overall "intellectual" distance in the pool of referenced work.

In computing DDR, the proximity between integrated subfields is computed as the cosine similarity matrix between subfields, relying on the subfield co-citation network in the whole of Scopus (using peer-reviewed publications; i.e., journal articles, conference papers and reviews). The classification used to categorise publications by subfield can have an impact on the resulting DDR scores. It is important for such a classification to offer enough granularity to enable the detection of relevant disciplinary mixes. For example, carrying out the analysis at the level of large scientific domains (e.g., natural sciences, engineering, health sciences, social sciences and humanities) would disregard significant differences in scientific culture, methods and tools within each of those domains (e.g., between biology, chemistry and physics within the natural sciences). At the other end of the spectrum, too much granularity would introduce noise in the analysis, detracting our attention from those disciplinary mixes that matter most. For example, in most cases of funders promoting cross-disciplinary work, it would appear irrelevant to know that an entomologist working on species X collaborated with an entomologist working on species Y, but it would matter to know that an entomologist working on the ecology of species X collaborated with a geneticist to study the population genetics of species X. Selecting the appropriate classification to study DDR is not a trivial choice. Ideally, one wants to pick a structure that somewhat reflects the current division of staff in academic departments at higher education institutions. One such classification was developed by Science-Metrix (Archambault et al., 2011) and was recently recognised as the most accurate journal-based classification of scientific papers (Klavans & Boyack, 2017).

In its most recent version, generalist journals publishing papers in diverse fields (e.g., Nature, Science, PNAS, PLOS One) were reclassified in the most appropriate category at the paper level using a machine learning algorithm. The updated classification tree now includes 174 subfields distributed across 20 fields and 5 domains. All 174 subfields are used in computing DDR.

Since the similarity matrix was built using all years in Scopus (since 1996) irrespective of a paper's publication year, recent papers may naturally have a greater tendency towards higher DDR scores than older ones. What was a rare disciplinary connection in 1996 may now be quite common. For this reason, DDR was normalized by publication year to uncover, for each year, those papers that stand out on DDR. Additionally, subfields are not all equally covered in Scopus, meaning that the proportion of a paper's references that are unclassified, and thus overlooked in computing DDR, varies across them. To eliminate the effects of these coverage biases, DDR was also normalized by subfield. As a result, the emphasis was placed on those publications that stand out most on the DDR scale within each subfield and year.

The latter XDR indicator, DDA, measured diversity as reflected in the prior disciplinary background of a paper's co-authors (team multidisciplinarity). Authors were disambiguated using Scopus author IDs, which produce reliable results at scale (Campbell & Struck, 2019). Science-Metrix subfields were assigned to authors on a given paper based on their prior publications enabling the disciplinary background of authors to evolve through time. Percentage shares of prior publications by Science-Metrix subfield were integrated in a combined vector (see also (Zuo & Zhao, 2018) for a related approach).

Some of the limitations linked to inferring the disciplinary profiles of authors using this approach can already be highlighted. First, a large portion of researchers (e.g., students, some of which later left academia) published very few Scopus-indexed publications (or even only one publication). For these researchers, the assignation of a subfield vector is based on scant data. Thus, the resulting vector may not be representative of their “true” disciplinary background. As an example, researchers with few prior publications in Scopus may be assigned subfields other than their own. This could happen if they previously provided methodological support to the research teams of their previous publications (e.g., a graduate student in computer sciences providing support to biology papers). In other cases, graduate students could have had no previous publications, in which case they would not contribute to the score even though they effectively contributed to the paper. Despite these limitations, we observed a positive correlation between normalized DDA and DDR whose moderate strength (Pearson coefficient = 0.38) is in line with our expectation. While DDA should be conducive to DDR, it may not always lead to high DDR and DDR can in theory result from the work of a single researcher.

Compared to DDR, where each of a paper’s references are assigned a unique subfield, authors can be assigned multiple subfields in computing a paper’s DDA score. This is a key difference requiring adaptation to the Rao-Stirling diversity index. Once all authors on a paper are assigned a subfield vector, a subfield vector for the paper is created in two steps (see Table 2 for examples in a 3-subfield system). First, the authors’ subfield vectors are averaged together. Then, the averaged vector is subtracted from the authors’ subfield vectors, and the absolute differences are kept. Conceptually, what remains are the distances between the authors’ disciplinary profiles and the average disciplinary profile of the publication. If all authors share the exact same profile (i.e., no between-author variation in disciplinary profiles), and this even if within-author variation is present as for publication #1 in Table 2, differences will be null, leaving all authors’ subfield vectors empty, which is to say that the paper will score 0 on the DDA scale (i.e., to be interpreted as monodisciplinary). Otherwise, the differences will, once averaged across authors, reflect the paper’s disciplinary diversity stemming from the within- and between-author disciplinary diversity (see publication #2 in Table 2).

In measuring DDA, emphasis is placed on the collaborative aspect, which is the common denominator of most funding programs promoting cross-disciplinary research. Accordingly, within-author diversity (an author active in more than one subfield) will not contribute to the paper’s DDA score if there is no difference across authors' disciplinary profiles or if there is only one author (all single-author papers will score 0). It is important to recall that a single-author paper, even if authored by a researcher who previously published in diverse subfields, even distant ones, may not itself have resulted from the integration of knowledge from different subfields. A diverse publication profile for an author may simply result from him or her having changed discipline while approaching research in his or her new field in a traditional way (i.e., adopting the research practices of this new field in a monodisciplinary way). The DDA indicator aims to capture the disciplinary diversity across the co-authors of a paper, not the disciplinary diversity of an author’s publication profile. If a single-author paper is produced by a researcher with a diversified publication profile, the odds of the researcher integrating knowledge from different disciplines in producing this paper is probably higher than for a researcher with a “narrow” publication profile. However, this should be captured through DDR, not DDA.

The above approach for producing a paper’s subfield vector using author information runs the risk of counting as monodisciplinary all papers produced by, for example, two authors, a biologist and a physicist, who always published together, resulting in the exact same subfield vector for each of them (e.g., 50% in biology and 50% in physics). This, even though they truly provided distinct disciplinary inputs to their common work. This is a key limitation of the proposed metric. In practice, however, such cases are very unlikely. Given the number of subfields in the classification used (i.e., 174), most authors will publish in many subfields over their career (so more senior authors are likely to have more variation in their subfield vectors) making it unlikely for any given paper’s authors to share exactly the same subfield vector.

To compute the DDA of a given paper, the Rao-Stirling index as depicted above for DDR is applied to its resulting subfield vector obtained using the above procedure with author disciplinary profiles. Briefly, a paper’s reference vector (obtained in step 2 for DDR) is substituted by its paper’s subfield vector. Contrary to a paper’s reference vector, note that the sum of values across subfields for a paper’s subfield vector based on authors may add up to more or less than 1 (see publication #2 in Table 2). This implies that the adapted Rao-Stirling index for DDA is not bounded between 0 and 1 as for DDR. Instead, it ranges from 0 (in theory) to infinity (in practice, it rarely exceeds 1).

To ensure that the disciplinary profiles of a paper’s authors are adequately captured, DDA is only computed for papers with at least two effective authors (i.e., authors with an assigned subfield vector). For a score to be computed, the effective number of authors must also represent at least 20% of the real number of authors. A DDA score is not computed for any paper not matching these two conditions. Single-author publications are by default monodisciplinary papers (see above explanations).

Once a paper’s DDA score is obtained, it is normalized (by year and subfield) in the same way as DDR (see above).

Table 2Illustration of the computation of a paper’s subfield vector based on its authors’ disciplinary profiles

Step 1: Computing the average disciplinary profile of the paper

	Publication #1				Publication #2			
	Author subfield vector			Paper's avg subfield vector	Author subfield vector			Paper's avg subfield vector
	A1	A2	A3		A1	A2	A3	
S1	0.50	0.50	0.50	=(0.50+0.50+0.50)/3 = 0.50	0.50	0.50	0.00	0.33
S2	0.50	0.50	0.50	0.50	0.50	0.50	0.00	0.33
S3	0.00	0.00	0.00	0.00	0.00	0.00	1.00	0.33

Step 2: Computing the paper's subfield vector from the differences between author subfield vectors and the paper's avg subfield vector

	Publication #1				Publication #2			
	Difference (Author subfield vector - paper's avg subfield vector)			Paper's subfield vector	Difference (Author subfield vector - paper's avg subfield vector)			Paper's subfield vector
	A1	A2	A3		A1	A2	A3	
S1	=ABS(0.50-0.50)=0.00	0.00	0.00	0.00	0.17	0.17	0.33	0.22
S2	0.00	0.00	0.00	0.00	0.17	0.17	0.33	0.22
S3	0.00	0.00	0.00	0.00	0.33	0.33	0.67	0.44

DDR and DDA are both evaluated in two forms: with indices based on averages of normalized scores and, by calculating shares of publications amongst the 10% most interdisciplinary or multidisciplinary within their subfield.

Selection of funding initiatives

The authors regularly lead bibliometric components of funding program evaluations for funder globally. This experience provides them with either direct or indirect insight into the administration of a number of funding programs worldwide. Additionally, the authors have also conducted desk research on multiple additional programs as part of comparator selection approaches. Selection of funding programs to be included as analytical groups in this analysis drew from this prior experience. Prior publications on the implementation of some of these programs also provided further support in characterizing their degree of XDR focus.

Funding programs to be included in the analysis were selected with the expectation that they represent different cases of funding mechanisms:

- “Generic” funding programs oriented towards **investigator-driven research** (expected to display low or average scores for both DDR and DDA): the Canadian NSERC Discovery program; the Australian ARC Discovery program; the NSFC National Program for Basic Research; and two “investigator-initiated research projects” programs from the US NSF Division of Molecular and Cellular Biosciences, on cellular dynamics and function (MCB-CDF); and on genetic mechanisms (MCB-GM).
- Funding programs supporting above all **individual scientific excellence** (expected to display low or average scores for DDA; and no fixed expectation for DDR): the European Research Council; the Fulbright Program (Senior Scholar program); the MacArthur Foundation (Fellowships and so-called “genius grants”).
- Funding programs supporting **individual XDR projects** (expected to display high DDR but low or average DDA): the Human Frontiers Science Program (HFSP) Cross-Disciplinarity Fellowships (CDF) competition (Science-Metrix, 2018); the NSF MCB Investigator-initiated research projects – systems and synthetic biology (MCB-SSB); and on molecular biophysics (MCB-MBP).
- Funding programs supporting **collaborative XDR consortia**, without an explicitly stated goal to support intellectual integration (expected to display high DDA, and low or average DDR): the SNFC Fund for Creative Research Groups; and the US NSF Research Coordination Networks (Garner, Porter, Newman, & Crowl, 2012).
- Funding programs supporting **transformative, transdisciplinary or highly integrative research conducted by diverse consortia** (expected to display both high DDA and DDR): the National Academies Keck Futures Initiative (NAKFI); Swiss SNSF National Centres of Competence in Research (NCCR) (Schneider, Buser, Keller, Tribaldos, & Rist, 2019), Sinergia and National Research Program (NRP) programs; US NSF Science and Technology Centers; and Synthesis Centers (Hackett et al 2021); and the Australian ARC Centres of Excellence (COE) initiative.

Constituting of publication sets by funding program

Three main strategies were used to assemble sets of publications associated to the funding programs under analysis:

- Publication sets were available from prior evaluation work and were initially assembled from a funder-curated author list (HFSP CDF program)
- Publication sets were constituted specifically for this analysis by retrieving curated publication lists from a public database (some NSF programs)
- Publication sets were constituted specifically for this analysis by querying Scopus acknowledgement records (remaining programs)

In matching publications to funding program bins, an important assumption made was that most papers (and indeed even many individual authors) are supported by multiple funding programs, concurrently. We expect most researchers with XDR funding to simultaneously hold funding from investigator-driven, monodisciplinary programs. In the aggregate, scores for papers funded by XDR programs should tend towards higher DDR/DDA scores, despite cases of single papers in the overall sample having contributed observations to both XDR and non-XDR programs.

Precision of the delineation of publication sets by querying Scopus funding acknowledgements was evaluated by randomly selecting 300 within the overall pool of publications retrieved in this manner and manually validating their match to funding programs of interest. Precision in this sample was measured at 99.0%.

Complementary search for funding programs

Initial results did not conform to expectations, especially in the absence of findings showing that funding programs can foster DDR without also fostering DDA. To demonstrate that it is theoretically possible to achieve high DDR in the absence of high DDA, DDA and DDR measurements were also taken for Scopus "topics of prominence" (Klavans & Boyack, 2017). Capturing instances of high DDR/low DDA for some topics would showcase that intellectual integration of diverse bodies of knowledge is possible outside the context of a partnership between researchers of different disciplines. In that case, the unexpected results for XDR programs could be explained by the simple fact that one of the easiest mechanisms to foster DDR is most likely through collaborative work spanning many disciplines (i.e., DDA).

Bootstrapping to calculate stability intervals for DDR and DDA measurements

Bootstrapping was used to produce stability intervals for the average DDR and DDA measurements for each group. A total of 1,999 re-samples were run to produce point estimates (at the 50th percentile of observations' distribution); lower boundary of the stability interval (measured at the 2.5th percentile) and upper boundary (recorded at the 97.5th percentile).

Results

Main benchmarking *of funding programs*

Most findings presented in Table 3 fell into two well defined groups: either non-XDR programs (first two blocks of programs in Table 3) which generally (5 out of 8 or 63%) did not foster XDR publications (DDA and DDR both between 0.95 and 1.05); and XDR programs that most often (9 out of 12 or 75%) fostered DDA, and generally also DDR, but often with a more notable effect on the DDA dimension (keeping in mind that variance on the DDA scale is generally greater than on the DDR scale).

Patterns in shares of publications falling in the 10% most interdisciplinary (DDR 10%) and multidisciplinary (DDA 10%) papers generally, but not always, followed those based on average DDR (simply DDR in Table 1) and DDA.

Four standard investigator-driven grant programs conformed to expectation: they displayed average scores for both DDA and DDR indices, or even lower (MCB-GM). The MCB-CDF program displayed a moderately high DDA score however (1.15).

From these results, we observe that high DDA can occur without high DDR (e.g., MCB-CDF, SNSF-Sinergia), which is in line with our interpretation of both phenomena (see particularly Figure 1). However, most of the time, high DDA is associated with high DDR, which seems logical as DDA would, on average, appear conducive to DDR. From a funder's perspective, high DDR did not come up in the absence of high DDA. This could be explained by the difficulty (most notably for funders) of promoting high DDR through a mechanism other than collaboration in teams of researchers from diverse disciplinary background (high DDA).

Follow-up identification of DDR-oriented topics of prominence

As an additional step to illustrate the independence between DDR and DDA (we saw in the methods that there is only a moderate positive correlation between them at the paper level in the full database, Pearson r = 0.38), Scopus topics of prominence were investigated with the specific goal of identifying topics with a higher DDR score than DDA score. That is, the intention was to find specialties where investigators and/or research teams tend to display average or low levels of disciplinary diversity but still integrate intellectual insights from a diversity of research fields. This design was operationalized as identifying all topics of prominence with an average DDR score 0.25 points above their average DDA score.

This stream of measurements identified more than 14,500 topics of prominence (from a total of more than 97,000 such topics available in Scopus) falling within the criteria specified above. Of these topics, 2,087 were associated with 1,000 publications or more. Table 4 presents the top 10 (on publication volume) topics of prominence retrieved in this step.

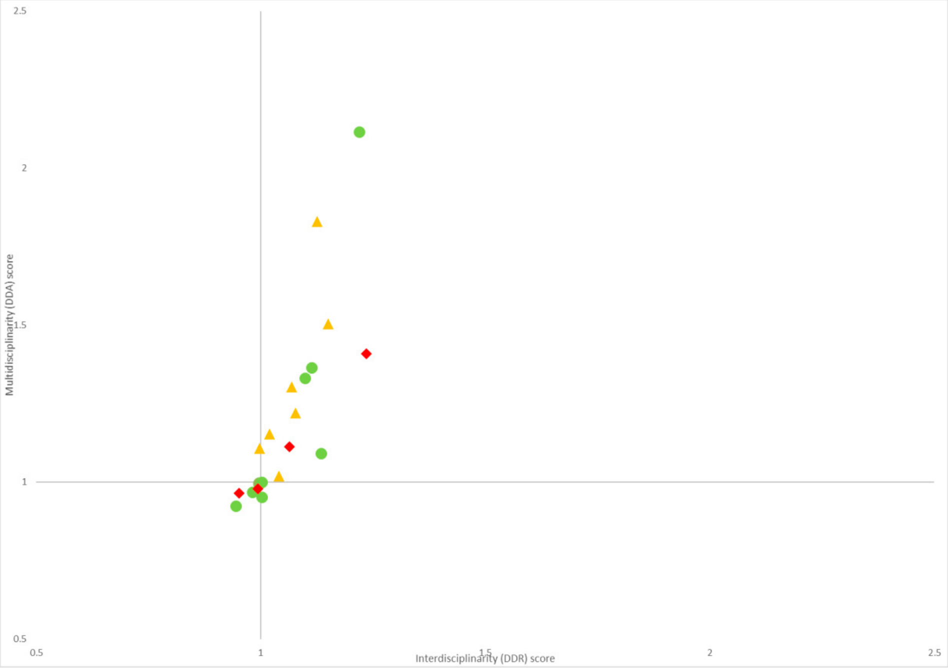

Figure 1. Distribution of 20 funding programs for their support of DDR and DDA research practices. Point shape denotes conformation to expectations. Circles denote funding programs conforming to expectations; triangles, programs deviating from expectations on one dimension; diamonds, programs deviating from expectations on both dimensions of interest.

Table 4 – Instances of Scopus topics of prominence with higher DDR than DDA

Topic of prominence	Count	DDR	DDR 10%	DDA	DDA 10%	Avg Refs	Avg auth	Med auth
Superconductors (materials) ; Superconductivity ; Iron-based superconductor	8,021	1.07	1.0%	0.60	1.9%	37	6	6

Activation analysis ; Catalysis ; Bond functionalization	7,220	0.59	0.0%	0.33	1.2%	69	4	4
Dark energy ; Models ; Holographic dark	6,544	1.53	11.1%	0.91	7.4%	54	2	2
Angular momentum ; Vortex flow ; Carrying orbital	6,256	0.96	2.9%	0.61	3.1%	22	4	4
Suburethral Slings ; Urinary Incontinence, Stress ; Subjective cure	6,200	0.88	0.4%	0.57	2.9%	18	3	3
Gamma ray bursts ; Afterglows ; Afterglow emission	6,071	1.15	4.3%	0.74	4.5%	44	7	3
Metamaterials ; Resonators ; Left-handed metamaterial	5,992	1.42	16.2%	1.07	10.3%	19	3	3
Nonexpansive mapping ; Strong convergence ; Pseudocontractive mappings	5,916	1.45	11.5%	0.82	5.8%	23	1	2
Multiple Myeloma ; Patients ; Diagnosed multiple	5,884	0.87	0.4%	0.56	2.6%	31	6	4

These findings at the topics of prominence aggregation-level provide some confirmation that DDR has some degree of independence from DDA in circumstances where individuals or monodisciplinary teams draw knowledge from a range of disciplines. Many of the topical publication sets in Table 2 display large gaps in scores between DDR and DDA, with DDR often being above expectation while DDA is below expectation. For instance, DDR scores were also often higher than previously observed at the funding program level (including scores ranging from 1.28 and 1.53). Dark energy physics (DDR of 1.53) may not be associated a priori with high interdisciplinarity, but it should be kept in mind that the associated publications' scores have been normalized against average levels of intellectual integration in the particular Science-Metrix subfields in which publications in this topic fell. These results, combined with those above for funding programs, support the idea that funders best leverage point to fuel DDR is likely through multidisciplinary collaboration (or DDA).

Limitations and discussion

Overall, the DDR and DDA indicators in their current specification appeared to successfully differentiate between 1) traditional grants for "investigator-driven" research, on the one hand (non-XDR programs); and 2) most competition for mission-oriented grants that included at least one component to support XDR practices (XDR programs), although these programs tended to score high on both dimensions, irrelevant of formal program design focus towards interdisciplinary, multidisciplinarity or a combination of both.

The mismatches between expectations and measurements are likely to be explained by one or a combination of multiple factors such as: XDR programs being more or less performing than one might expect from the mechanism(s) they implemented to fuel XDR, and the challenges of qualitatively gauging a program's expected level of XDR. In retrospect, and following additional desk research, this latter factor appears to have played a role. In some cases, the initial characterization of funding programs in terms of XDR clearly failed to reveal their cross-disciplinarity character. This was exemplified by the NSF program on Molecular Biophysics, which despite being initially described as "investigator-driven" on the program's website, was noted to include a "collaborative" grants component when extraction from the NSD award database was conducted. In the case of the HFSP CDF program, which one of the authors has evaluated, disaggregating the sub-dimensions of DDA and DDR (as done in Hackett et al., 2021) might have better captured the program's specificities, with an operationalization of DDR centered around balance and distance but not variety.

Some of the transdisciplinary programs included here aimed to produce non-academic outcomes as much as peer-reviewed publications. This observation raises the possibility that projects supported by XDR programs may produce rather conventional articles while simultaneously engaging in sustained relationships with local stakeholders and public engagement, to take just an hypothetical example.

It must also be considered that the design and formulation of policy instruments for fostering XDR will not always lead to successful implementation of these means. The SNSF-NCCR appeared to the authors as one of the programs with the strongest XDR designs in our initial desk research, but the article by Schneider et al also show the range of obstacles facing the successful implementation of such a program, and most notably, to ensure the participation of researchers in XDR practices. In can also be considered that prior evaluations by the authors of individual consortia within the SNSF NCCR program and within the ARC CoE program had shown individually selected projects with a clear focus towards XDR to have indeed achieved high scores on both the DDR and DDA dimensions.

It must be noted that "discovery" or excellence funding programs tend to be designed and implemented quite differently from the typical funding program explicitly aiming to support XDR. "Non-XDR funding programs" tend to be recurring, foundational granting programs that provide the largest shares of researchers within a given scientific system; XDR funding programs tend to be ad hoc, mission-oriented instruments with a narrower audience. It is currently unclear how these differing program design features may play into the findings recorded here.

The next steps for this research project are to input some of the findings presented here in a regression analysis that will be better control for confounding factors and help specify the relationship between DDR and DDA. To do so, the authors will also attempt to correlated DDR and DDA measurements with those obtained from other indicators such as "Div"(Leydesdorff, Wagner, & Bornmann, 2019) or the disaggregated components of DDR and DDA, as proposed by (Hackett et al., 2021; J. Wang, Thijs, & Glänzel, 2015).

A bibliometric strategy for identifying benchmark research units

Abstract

While normalized bibliometric indicators are expected to resolve the subject-field differences between organizations in research evaluations, size still matters. Furthermore, research organizations, policymakers and research funding providers tend to use benchmark units as points of comparison for a given research center in order to understand and monitor its development and performance. In addition to monitoring and evaluations, the identification of comparable benchmark organizations can also be used to pinpoint potential collaboration partners or competitors. Therefore, methods to identify benchmark research units are of practical significance. However, few studies have investigated this problem. This study aims to propose a bibliometric method to identify benchmarks. We define a benchmark as a well-connected research environment, in which researchers work on similar topics and publish a similar number of publications compared to a given research center during the same period. Three essential attributes for the evaluation of benchmarks are research topics, output, and coherence. We apply this strategy to a Swedish research center, and examine the effectiveness of the method.

Introduction

Few studies in the field of research evaluation and research policy have focused on identifying benchmark research organizations. One reason for this is probably that normalized bibliometric indicators are used to deal with differences in research-field and publication output between research organizations, and this solution may be seen as sufficient. However, size still matters, both when evaluating the research performance of organizations that change in size over time, and since researchers at a larger organization are more likely to benefit from peer- and organizational effects. Field-normalized citation indicators that work well for large organizations and across coarse field-classifications may also be misleading for smaller organizations with a narrower research focus, where comparisons against relevant benchmarks may be more accurate.

A key aspect in identifying benchmarks is defining the relevant attributes for comparisons. Even so, we only found two studies on this topic. Carayol et al. (2012) propose a method for selecting peer universities and departments, and Andersen et al. (2017) develop a bibliometric-based approach for choosing proper benchmarks. Even though both these studies lack a concrete definition of benchmarks, their perceptions of a benchmark unit can be gleaned from their proposed approaches. The approach by Carayol and colleagues (2012) implies that the quantity of scientific production and its impact are the two essential attributes for a benchmark. In addition to these two attributes, Andersen and colleagues (2017) stress the importance of research topics in the selection of benchmarks. More specifically, they hold that “the topicality or subject profile” of a benchmark unit should be approximately similar to the treatment.

Based on the previous studies, benchmark units should consist of researchers who work on the same topics, publish a similar number of papers in relation to the unit under evaluation during the same period. In addition to these factors, we suggest that a benchmark also needs to form a well-connected and coherent research environment, to function as a useful benchmark unit. In this study, we exclude research impact suggested by Carayol et al (2012) from the primary identification of benchmark units, but it can still be useful as a soft attribute to select from potential benchmarks. Accordingly, the main attributes to consider when detecting benchmarks to research organizations should be (i) research topics, (ii) output, and (iii) coherence.

Methodology

In this section, we go through the three attributes for the identification of benchmarks in turn below.

Research topics

Delineating the research topics of an evaluative organization is one of the most important procedures for the identification of benchmarks. In this study, research topics were defined as publication clusters, using the clustering method of Waltman and Van Eck (2012, 2013) based on direct citation links. The reasons for choosing this strategy were summarized in Wang (2018). Our employed clustering system assigned around 36 million publications (articles and reviews) into 5,053 clusters. These publications were published from 1980 to 2019 and covered by the Web of Science (WoS) database. It has a similar scale compared to the one used in Leiden Ranking (2020), which consists of around 4,000 clusters[1].

The research topics of a treatment unit are, then, described by the clusters that include the unit's publications. After mapping the distributions of the 15 Swedish research centers, we conclude that the distributions of publications over clusters are usually highly skewed, as shown in Fig.1. Most of these centers are not interdisciplinary oriented. It is of little significance to delineate the research profile of a treatment group using the clusters that have an extremely small number of its publications. In addition to this, one should notice that the size of clusters varies greatly in our clustering system. During the 38-year period, the largest cluster consists of around 56,000 publications, whereas the smallest has only 500 based on the parameters we set. Therefore, for an evaluative group, it would be more reliable to consider its relative number of publications in each cluster to define its dominant research topics.

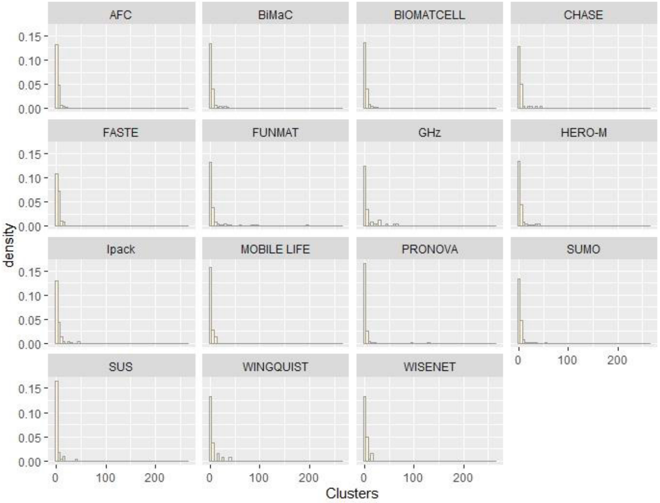

Figure 1. Distribution of publications over clusters for 15 research centers.

To be specific, let $p_{i,ts,\,te}^{k}$ denote the number of publications of evaluative unit i in cluster k from the year ts to te, then its total number of publications can be expressed as $P_{i,ts,\,te} =$

[1] More detailed information on the fields in Leiden Ranking is available at https://www.leidenranking.com/information/fields

$\sum p_{i,ts,te}^{k}$. Let $t_{ts,\,te}^{k}$ denote the total number of publications in cluster k from the year ts to te, and $a_{i,ts,\,te}^{k}$denote the share of publications for i in cluster k, then we have $a_{i,ts,\,te}^{k} = \frac{p_{i,ts,\,te}^{k}}{t_{ts,\,te}^{k}}$. To pinpoint dominant clusters for unit i, we intend to select the clusters with a high a. Let r denote the rank of a in decreasing order, and it hence satisfies $a_{i,ts,\,te}^{k(r-1)} \geq a_{i,ts,\,te}^{k(r)}$. Let $d_{i,ts,\,te}$denote the share of publications for unit i in the first nth clusters, then we have

$$d_{i,ts,\,te} = \frac{p_{i,ts,\,te}^{k(1)}+p_{i,ts,\,te}^{k(2)}+\cdots+p_{i,ts,\,te}^{k(n-1)}+p_{i,ts,\,te}^{k(n)}}{\sum p_{i,ts,te}^{k}} = \frac{\sum_n p_{i,ts,\,te}^{k(r)}}{\sum p_{i,ts,te}^{k}}. \tag{1}$$

To identify the dominant clusters, we require $d_{i,ts,\,te} \geq d_{min}$. In the meanwhile, we also need to avoid selecting the clusters with an extremely small number of unit i's publications, which requires $p_{j,ts,\,te}^{k(r)} \geq p_{min}$. By setting the parameter values, nth clusters can be selected to delineate the research profile for unit i.

Research output

After the selection of the dominant clusters, publications between year ts and te in the nth clusters can be aggregated into research organizations based on the affiliations of authors. Let $P_{j,ts,\,te}$ denote the publications of organization j in the nth clusters, which can be expressed as $P_{j,ts,\,te} = \sum_n p_{j,ts,\,te}^{k(r)}$. As discussed, for a research unit to be considered as a benchmark, it should have a similar number of publications with the treatment, that is $P_{j,ts,\,te} \in (P_{i,ts,\,te} - \Delta p,$ $P_{i,ts,\,te} + \Delta p)$.

Coherence

Researchers at a benchmark unit are expected to be connected to some extent. In this work, a weighted measure of the clustering coefficient (Opsahl & Panzarasa, 2009) has been applied to examine the extent to which researchers working at a benchmark unit are well connected. According to Opsahl and Panzarasa (2009), the clustering coefficient evaluates the total value of closed triplets in a weighted network in comparison with the total value of triplets. The higher the clustering coefficient, the more connected a network is. They have proposed several measures for calculating the weighted triplet value, including arithmetic mean, geometric mean, maximum and minimum, and further indicated the choice of the weighted measure should be based on the research question at hand. In our network, nodes represent researchers and links refer to the number of their collaborated publications. We assume that as long as researchers A and B, A and C have established collaboration relations respectively, B and C are then likely to collaborate. We hence choose the minimum measure. Let $h_{j,ts,\,te}$ denote the clustering coefficient of a benchmark unit, it should satisfy that $h_{j,ts,te} \geq h_{min}$.

In summary, a benchmark research unit should satisfy each of the following criteria: 1. $d_{i,ts,\,te} \geq d_{min}$ it should present similar research interests with the treatment; 2. $p_{j,ts,\,te}^{k(r)} \geq p_{min}$ it should have a certain amount of research output published in the main research topics of the treatment; 3. $h_{j,ts,te} \geq h_{min}$ it should be coherent.

Data

In this study, we applied the proposed method to identify benchmark units for some research centers that have been financed by Sweden's Innovation Agency (VINNOVA). Hero-m, at KTH-Royal Institute of Technology, was used as an example to further demonstrate our approach and to elaborate the results. This center aims "to develop tools and competence for fast, intelligent, sustainable and cost-efficient product development for Swedish industry.

Continuous scientific breakthroughs are exploited to enable design of materials from atomistic scales to finished products"[2]. Based on the information available on their webpage, we have collected 255 publications between 2007 and 2019, which belong to 62 clusters. As shown in Fig.1., the distribution of its publications over clusters is highly skewed and most of the publications are assigned in the top seven clusters. In addition to this, its coherence is 0.39.

Results

We used two sets of parameter values to examine the proposed method, as summarized in Table 1. The various combinations of parameter values would be useful to examine the sensitivity of the results. For the first set, we expect the first nth clusters, ranked by the share of Hero-m's publications over clusters, to have about 80% of Hero-m's total publications. Additionally, the dominant clusters are supposed to include no less than 5 Hero-m's publications. We further require the total publications of a benchmark in those dominant to be within the range between 0.7 and 1.3 times Hero-m's total publications. For the second set, Hero-m's publications in the dominant clusters should account for 60% of its total output and each dominant should include no less than 10 Hero-m's publications. Potential benchmarks are, then, the research organizations that have publications in these dominant clusters. More specifically, a benchmark should satisfy the criteria that its total publications are between 0.5 and 1.5 times Hero-m's publications, and its coherence is no less than 80% of Hero-m's values, which is 0.3.

Table 1. Two sets of parameter values

	Parameter set - 1	*Parameter set – 2*
d_{min}	212 (80%$P_{i,ts,\,te}$)	159 (60%$P_{i,ts,\,te}$)
p_{min}	5	10
Δp	53 (30%$P_{i,ts,\,te}$)	132.5 (50%$P_{i,ts,\,te}$)
c_{min}	0.39 ($c_{i,ts,\,te}$)	0.3 (80%$c_{i,ts,\,te}$)

The two sets of parameter values yielded 31 and 52 benchmarks respectively. For lack of space, Table 2 only presents the top ten most published benchmarks. The number of publications and coherence of each benchmark can be found in this table.

We acknowledge that our approach has a trade-off between precision and recall. Unfortunately, it is impossible to understand entire benchmarks for an evaluative unit, and hence the magnitude of the trade-off is very difficult to estimate. Nevertheless, we consider that precision is more important than recall in terms of the present research question. In other words, identifying appropriate comparable research units seems to be more meaningful in practical applications. It should be stressed that our approach is quite flexible, which allows researchers, policymakers, and other practitioners to adjust parameter values to detect benchmarks according to their specific purposes.

Validation

In this section, we further examine the effectiveness of the proposed method.

Examining the consistency of research topics

The Latent Dirichlet Allocation (LDA) was employed to generate underlying research topics from the publications of each identified benchmark. In our work, the abstract of publications was used to generate topics. Some frequently occurred terms were considered as stop words. Since Hero-m is not a multidisciplinary research center with broad and diverse research topics, we determined to generate simply two topics for this center and each identified benchmark. Furthermore, for each topic, we listed the first 20 terms according to their probabilities of the inferred topics. The result of LDA for both treatment and benchmarks are available online[3]. Comparing the results in the two tables, the topics of Hero-m and its benchmarks are rather similar, focusing on properties, structure, and calculation of materials. But we have also noticed that some benchmarks have one of the topics regarding nuclear, ray, radiation, and irradiation, for instance, one of the research focuses at Pacific Northwest National Laboratory[4] is relevant to nuclear materials. On closer examination, we found Hero-m has indeed a small number of publications on this topic, such as Li and Korzhavyi's study in 2015 (*Interactions of point defects with stacking faults in oxygen-free phosphorous-containing copper*) and Xu and colleagues in 2020 (*Nuclear and magnetic small-angle neutron scattering in self-organizing*

[3] The results of LDA are available online https://kth.box.com/shared/static/1m4m66v8gnku4lzi4k1voobbl90gsqvy.docx

[4] More detailed information on Pacific Northwest National Laboratory are available at https://www.pnnl.gov/materials-science

nanostructured Fe1− xCrx alloys). For this reason, organizations with a focus on nuclear materials, such as Pacific Northwest National Laboratory, have been identified.

Examining the robustness of different coherence measures

In this study, we have chosen the minimum statistic as a measure of coherence. However, it is unclear if our results are robust to other coherence measures. We have therefore applied the four different measures, to calculate coherence for the benchmark units identified with the use of the second set of parameter values. The shows high consistency of various coherence measures, which Pearson correlation coefficients are all above 0.95.

Discussion and future work

Besides the validation tests mentioned in the previous section, we have also examined the performance of using the WoS subject categories as research topics, instead of publication clusters. However, 69% of Hero-M's publications belong to the category, Material Science Multidisciplinary, which is a rather broad research topic and cannot precisely describe the research focus of the center. Thus, we believe a finer classification system must be used for this type of study. However, using a classification that is too granular can instead run the risk of creating self-referential categories, meaning that most publications in individual clusters are from one individual research group. By analyzing the share of organizations in each cluster, we found that, only in 21 clusters, a single organization accounts for more than 40% of the total publications. In other words, the applied classification system does not seem to present a self-referential problem.

In the next step, we would like to examine the performance of this method to interdisciplinary research centers and also examine other methods to evaluate cluster profiles between the focal unit and potential benchmarks.

Acknowledgments

We would like to thank Lennart Stenberg for his helpful comments and suggestions. We are grateful to VINNOVA for their support of this study. We also thank reviewers for their comments on this paper.

Abstract

Female representation among students and graduates in higher education is growing internationally. This is a promising trend for achieving gender balance in top positions in academia. But there is still a long way to go, as women accounted for 24 per cent in top positions at European higher education institutions in 2016. In this article, we examine the influence of international recruitment on gender balance in Norwegian academia. We draw on data from the Norwegian Register of Research personnel, linked with population statistics from Statistics Norway. These data show that 32 per cent of the researchers at Norwegian higher education institutions in 2018 were born abroad. The share of foreign full professors has increased from 16 per cent in 2001 to 27 per cent in 2018, while for postdocs there has been an increase from 31 to 69 per cent. In terms of gender composition, a higher percentage of the foreign-born researchers are male. The incidence of international recruitment differs significantly across academic fields and positions. These dimensions are further analysed from a gender perspective in this paper.

Introduction

Many countries have put gender balance high on the research policy agenda to utilize the pool of talent and improving the quality of research. During the last decades the gender balance in research and higher education has improved, but imbalances persist and vary across countries, sectors, academic positions, and disciplines, as manifested in reports such as the *She Figures 2018* (EC 2019). Women are particularly underrepresented in top academic positions. Moreover, the lack of gender balance is especially strong in some of the STEM-fields (Science, technology, engineering, and mathematics). This has been a matter of concern by governments in many countries as it is believed that the quality of work and innovation in these fields may increase with more women. There are multifaceted arguments for increased gender balance, ranging from ethical, and economic to legal arguments. The European Commission highlights gender balance from the perspective of avoiding waste of talent (2010) and has recently again emphasised the importance of gender equality to strengthen European research and innovation (EC 2020). In the Horizon Europe Strategic plan 2021–2024 the integration of gender equality is highlighted as a cross-cutting issue, especially concerning global challenges in which gender differences play an important role that determine the societal relevance and quality of research and innovation outcomes.

The lack of gender balance has several explanations. In this paper we address the issue by investigating the role of international mobility and recruitment from a gender perspective. The internationalization of science has accelerated during the last decades, caused by factors such as increased access to physical and digital communication. In addition, the labor market for researchers has been increasingly internationalized with positions that are often open for applicants from abroad. Most vacant positions at Norwegian higher education institutions (HEIs) are advertised internationally.

International mobility of academics is supported by most Western countries, even though there is an asymmetry of mobility flows, some countries and regions are more attractive than others depending on historical, political, and economic factors. Higher demands for high-quality tertiary education worldwide are coupled with specific policies to promote student mobility within a geographic region (as is the case in Europe). Attracting mobile students and researchers is a way to tap into a global pool of talent and support the development of innovation and production systems across OECD countries. On average 10 per cent of first-time entrants into tertiary education were international students in 2018 (Education at a Glance 2020). Also in the EU mobility has been a cornerstone of the European Research Area (ERA) and its success is determined by highly skilled people who move across borders to where their talent can be best employed; ERA Priority 3 (EC 2020).

Still there is little knowledge about the consequences of increased international mobility of researchers on gender balance. The EU MORE 3-survey (EC, 2017) among 10,000 European researchers revealed that women are more mobile at early stages of their career, while men are more mobile later. Other studies have looked into reasons for low representation of women at higher career-levels in academia by investigating driving forces for geographic mobility which influence men and women differently (Leemann 2010, Canibano 2016).

We have found no other studies that look at the impact of international mobility of researchers on gender balance within countries. Does such mobility improve the domestic gender balance or not? Obviously, this issue will arise differently among countries. And in a sense, it will be a zerosum game: Influx of female researchers from one country to another reduces the population of women in first country and increases it in the second, recipient country.

In our study we look at incoming mobility[1] to Norway. Norway is a small country which contributes to 0.4 per cent of global research and development (R&D) (OECD 2020a). Attracting the best talents and promoting diversity have been high on the political agenda when international recruitment is discussed in Norway (Vabø 2020). Norway may be an interesting country for analyzing this issue because the country is a small and open country with strong research links to the rest of Europe and the USA and facilitates the mobility and work of foreign researchers. As part of the EEA agreement, all EU citizens are allowed to work in Norway and also researchers from most other countries can easily get work permissions.

Approximately two thirds of the full professors in Norway obtain their professorship through a "professor by competence" system[2]. This implies that the recruitment of associate professors, as the recruitment pool for full professorships, is crucial to obtain gender balance in the top positions in Norwegian HEIs. In the current academic career system, the postdoc position is an important step on the career ladder to become an associate professor. We have thus selected these three positions for further analysis. We will also examine the gender balance among researchers born in Norway or abroad.

The following main research questions are addressed: a) What is the gender balance among the native and foreign researches across fields and over time? b) Has the international recruitment hampered the process of achieving gender balance in the Norwegian HE-system? In the study we will look at incoming mobility to Norway for the crucial career steps of postdoc, associate professor and full professor in different fields of research. The analysis covers 2007–2018.

[1] Our dataset contains limited information about outgoing mobility of Norwegian-born researchers, as we do not have information about Norwegians studying for a PhD abroad.

[2] The Norwegian scheme of promotion to professor after a competency assessment was introduced in 1993 and is part of the Act relating to Universities and University Colleges. The purpose was among other things to create a more fair system. Previously you could only become a full professor if you applied for, and got, a vacant professorship. A better career system, improved quality of higher education and research, and to increase the number of female professors were other goals. Today 66 per cent of new professors have their promotion through this system.

Data and method

The study is based on the Norwegian Register of Research personnel[3], operated by NIFU, combined with data of population statistics from Statistics Norway[4]. The dataset includes variables on country of birth, gender, position, and field of research. In the analyses each individual is classified as either Norwegian (native) or foreign based on country of birth. We provide descriptive overviews of changes in the career systems over time and by field according to these dimensions in a gender perspective. As a first step, we present an overview of the current situation in Norway (2018). Then we analyse individuals who have achieved new positions as full professors and associate professors. This population of researchers are of particular interest as they reflect the most recent developments.

Results

In Norway, international recruitment is highest for the temporary positions, such as postdoc and research fellow. In 2018, a total of 33 per cent of the researchers at Norwegian HEIs were born outside Norway. Approx. 70 per cent of full professors and associated professors were born in Norway, while at postdoctoral level the picture is opposite; more than 70 per cent of the postdocs were born abroad (Table 1). Almost half of the researchers at Norwegian HEIs were women (49 per cent). Among researchers born abroad the share was 45 per cent, while the share among native Norwegian researchers was 52 per cent. Women accounted for 31 per cent of the full professors and 49 per cent of the associate professors, while 45 per cent of postdocs and 54 per cent of the research fellows were female. The percentage of women is almost identical for native and foreign full professors (one percentage point difference), while there is a larger difference for postdocs and temporary research positions (11 percentage points).

Table 1. Full professors, associate professors and postdoctors by immigrant status[1] and share of women in Norwegian HEIs. 2018 (percentages).

Position	*Status*	*Share of total*	*Share of women*	*Share of men*	N=
Full professor	Native	70 %	31 %	*69 %*	3 021
	Foreign	30 %	30 %	*70 %*	1 096
Associate professor	Native	69 %	51 %	*49 %*	3 151
	Foreign	31 %	45 %	*55 %*	1 305
Postdoctor	Native	28 %	53 %	*47 %*	444
	Foreign	72 %	42 %	*58 %*	1 130

[1]Immigrant status relates to country of birth.

Source: NIFU, Statistics Norway

Our data show that in Norwegian HEIs the share of foreign researchers varies clearly between field of research. In 2018, 30 per cent of the researchers in humanities and the arts were born abroad, while social sciences had 23 per cent foreign researchers. The highest share of foreign researchers was found in natural sciences and engineering and technology (hence 49 and 50 per cent). In medical and health sciences, 27 per cent of the researchers were born abroad.

A closer look at full professors in 2018 shows that in humanities and the arts 36 per cent were female (38 per cent of the natives and 34 per cent of those born abroad), while in social sciences, 33 per cent of the native and 37 per cent of the foreign full professors were women. In

[3] The Register of Research personnel is part of the official Norwegian R&D statistics. The register covers researchers/university graduated personnel that participated in R&D at Norwegian HEIs, as well as research institutes and health trusts. The register includes information on position, age, gender, educational background and workplace. Personnel data is retrieved from the administration of the R&D-performing institutions per October 1st, and the registry goes back to the 1960s. Mobility, gender balance and career paths of the academic staff in Norway has thus been monitored through several decades through this rather unique database.

[4] Information on country of birth is retrieved from Statistics Norway. We also have information about which country foreign-born researchers immigrated from, if other than birth country.

engineering and technology, only 14 per cent of the full professors were women. The share of women was higher for the foreign full professors (16 per cent), compared to 13 per cent for the natives. We see the same trend for natural sciences, with 21 per cent female full professors born abroad, and 19 per cent of the native.

[1]Immigrant status relates to country of birth.
[2]Note that a number of new HEIs were included in the Register of Research Personnel in 2007, 2013 and 2017. Some of the new professors in these years are new entries in the database but held professor positions previously.
Source: NIFU, Statistics Norway

The female representation among the tenured personnel has grown steadily over time, as shown in Table 2, with figures for full professors and associate professors in Norway. The percentage of women has increased from 18 per cent for full professors in 2007 to 31 per cent in 2018. For associate professors, there has been an increase from 35 to 49 per cent in the same period.

In order to analyze this question further, we have looked specifically at researchers in new positions. This shows that the extent of international recruitment has increased significantly over time and the gender balance has improved. In 2007, 19 per cent of the new full professors were female and native, whereas 9 per cent were female and foreign. 11 years later, the share of female new full professors had increased to 42 per cent; 28 per cent native women and 14 per cent foreign women. For associate professors, there has been a notable increase in the share of foreign women (11 to 19 %) and men (14 to 21 %), while there has been a decrease in the share of native med (39 to 23 %). The share of native women has been relatively stable (34 to 37 %). The data shows that Norwegian men are still the largest group of new full professors, but the share of women, both native and foreign, is growing steadily. Native men are outnumbered by native women in the associate professor position, and they might soon be outnumbered by foreign-born men. A closer look at the recruitment of new full professors, see figure 1, shows that the share of foreign full professors has increased in all fields except medicine and health sciences. There is a significantly higher share of new male foreign full professors over foreign female, again with the exception of medicine and health sciences. At the same time, the share of new male native full professors seems to be decreasing in all fields, while the share of native female full professors is relatively stable in the STEM-fields and increase in medicine and health sciences. However, the share of men among the new full professors is still higher than the share of women in most fields, and especially in the STEM-fields.

When analyzing the population of native and foreign new full professors separately, the overall female proportion is 31 and 30 per cent, respectively in 2015–2018 (Table 3). However, at field levels, there is a better gender balance among the foreign full professors than the native in several of the fields, although the difference is not very large.

There is clearly a higher share of women, both native and foreign, among the new associate professors than it was for the full professors. This applies to all fields, but the differences were highest in 2015–2018 for engineering and technology and medicine and health sciences. For the first field, it was especially the share of foreign female associate professors that was higher, for the latter it was the share of native female associate professors. These results are not shown, but will be examined closer in the full paper.

Discussion

This study has shown that the Norwegian HE-system has undergone rapid changes in terms of internationalization, where the share of foreign researchers has grown considerably over the last years, especially at lower levels of the academic career ladder and especially within the STEM-fields. However, among foreign researchers the share of women is lower (45 %) than among the native Norwegians (52 %) and this might suggest that internationalization has slowed down the development towards gender balance.

However, there are significant differences in gender balance by field of research. Moreover, international recruitment is particularly prevalent in engineering and technology, where the gender balance is most skewed. Thus, the overall figures are affected by these patterns. When the issue is analysed at the level of fields, a different picture emerges. The female proportion of new foreign professors (2015-2018) is higher than the female proportion of native professors in all fields, except humanities and arts, while it is equal in medicine and health. Contrary to what would be expected from the overall results, this shows that the international recruitment has in fact contributed positively to the gender balance in Norway in the majority of the fields. The final analysis will include a more detailed mapping of both associate professors and postdocs. We will also look into statistics on applicants for vacancies at the Norwegian HEIs.

Acknowledgments

We would like to thank our colleague, Dag W. Aksnes who is the project leader of the BALANSEkunst project at NIFU, for comments on this early draft of the paper.

Abstract

Topic hierarchies can help researchers to develop a quick and concise understanding of the main themes and concepts in a field of interest. This is especially useful for newcomers to a field or those with a passing need for basic knowledge of a research landscape. Yet, despite a plethora of studies into hierarchical topic identification, there still lacks a model that is comprehensive enough or adaptive enough to extract the topics from a corpus, deal with the concepts shared by multiple topics, arrange the topics in a hierarchy, and give each topic an appropriate name. Hence, this paper presents a one-stop framework for generating fully-conceptualized hierarchical topic trees. First, we generate a co-occurrence network based on key terms extracted from a corpus of documents. Then a density peak search algorithm is developed and applied to identify the core topic terms, which are subsequently used as topic labels. An overlapping community allocation algorithm follows to detect topics and possible overlaps between them. Lastly, the density peak search and overlapping community allocation algorithms run recursively to structure the topics into a hierarchical tree. The feasibility, reliability, and extensibility of the proposed framework are demonstrated through a case study on the field of computer science.

Introduction

The last decades have witnessed a great accumulation of scientific documents, resulting in information overload for researchers. Aiming to improve this situation, a substantial number of bibliometric studies on topic extraction, knowledge mining, and text analytics have been undertaken, each looking for efficient ways to extract information from textual data and concise ways of presenting the knowledge found (Ba et al., 2019; Qian et al., 2020; Song et al., 2016; Wu et al., 2020; Zhang et al., 2018; Zhang et al., 2017). What many of those studies have shown is that, one, organizing research topics into curated hierarchical structures is an excellent way of quickly conveying a great deal of knowledge about the composition of a research field to those who are unfamiliar with it, and, two, constructing these arrangements is nontrivial and highly challenging. While very broad overviews of a field are not particularly difficult to generate, creating interactive topic maps that show fields at different and especially fine levels of granularity and disentangling the rising complexities of inter-/multi- disciplinary studies is another story altogether. In fact, all but the most rudimentary techniques still rely heavily on expert knowledge.

That said, advancements in natural language processing (NLP) are reducing this dependence, with methods capable of automatically identifying and stratifying the thematic concepts found in a dataset of literature. Among these methods, hierarchical latent Dirichlet allocation (hLDA) (Blei et al., 2010) is especially well-known. However, there are a couple of aspects of hLDA that could be improved. These include sometimes weak associations between the generated parent and child topics; and internal unigram incoherence within topics (Qian et al., 2020; Xu et al., 2018); a propensity to represent each topic as a conglomeration of unigrams and probabilities; and a tendency to label topics with appropriate names, which reduces the interpretability of the results. There are also alternative approaches of building topic hierarchies, such as taxonomy identification (Shang et al., 2020), ontology construction (Wong et al., 2012), and knowledge graphs (Yang et al., 2017). But, despite substantial efforts to the contrary, these techniques inevitably suffer from either an excessive number of parameters that need to be fine-tuned and/or issues with creating clean partitions between topics. Hard clustering algorithms like K-means or non-negative matrix factorization (Qian et al., 2020; Zhang et al., 2018), which most of these techniques are based on, struggle to find clear divisions between topics with high levels of overlap, convergence, or interactivity – characteristics that typify the process of scientific development.

Aiming to solve these issues, we propose a novel framework called *Hierarchical Topic Tree* (HTT) that operates in a recursive manner to reveal the topic hierarchies within a set of documents. The framework comprises a term co-occurrence network and two algorithms: DPS, a density peak search algorithm, modified to work with networks; and OCA, an overlapping community allocation algorithm. We assume that every topic consists of a core term, which becomes the topic's label, and a set of affiliated terms. Applying the density peak search algorithm to a term co-occurrence network reveals the density peak terms that meet some specific criteria for being used as a topic's label. The terms associated with every core topic term, i.e., the affiliated terms, are then determined and partitioned by the overlapping community allocation algorithm, which means terms can be assigned to multiple topics. These two steps are run recursively on partitioned subnetworks to identify deeper hierarchies in the term co-occurrence network until no core topic terms (topic labels) are found. To demonstrate the practical workings of the HTT framework, we conducted a case study on 6,267 academic articles published in the expansive field of computer science. The final results show a tree with six main branches and 120 sub-branches in a complex, but cohesive, hierarchical structure. The three main contributions our work makes include: 1) a density peak search algorithm that identifies and labels the topics in a corpus; 2) a community allocation algorithm that recognizes topic overlaps, which may indicate knowledge convergence; and 3) a model that requires two hyperparameters – a density threshold and an overlap threshold, which makes the process of tuning parameters easy and the model adaptable to a variety of cases.

The rest of this paper is organized as follows. The Related Works section next gives a brief review of the work on topic hierarchy identification. The Methodology section sets out the details of our proposed methodology. The Case Study section follows, presenting the data, results, and empirical insights derived from the computer science domain case. We then wrap our study with a conclusion, the study's limitations, and future directions of research.

Related Works

Hierarchies are instinctive, basal structures to humans that naturally aid our sensemaking of scientific knowledge composition. Blei pioneers the automation of topic hierarchy identification by developing the two perhaps most renowned algorithms in identifying topic hierarchies – the Chinese restaurant process (CRP) (Blei et al., 2004) and hierarchical latent Dirichlet allocation (hLDA) (Blei et al., 2010). However, the efficacy of the hLDA model largely depends on the pre-processing quality and may generate unsatisfactory results otherwise (Qian et al., 2020; Xu et al., 2018). The latter works pay efforts to modify topic hierarchy identification from different perspectives, including introducing the idea of recursive hierarchy detection (Wang et al., 2013), involving distance-dependent discrepancies for the CRP (Song et al., 2016), adding external ancillary information (Shang et al., 2020; Wang et al., 2015; Xu et al., 2018), and using alternative topic partition method like non-negative matrix factorization (Qian et al., 2020). But those studies either suffer from the need for a pre-defined tree structure or the lack of a labeling strategy. In practical terms, hierarchical structures vary hugely from discipline to discipline, especially for disciplines of vastly different forms, such as biomedicine versus artificial intelligence. As for the topic labeling strategy, most bibliometric approaches constitute topics as a set of semantically similar terms or records (Colavizza & Franceschet, 2016; Hou et al., 2018; Porter et al., 2020). Similarly, in mainstream topic modeling approaches, a topic is not represented with one all-encompassing label but, rather, as a bag of words or phrases and their corresponding probabilities. With both approaches, one still has to manually dive into the specific words, phrases, or even documents to infer the broad subject matter of the topic and decide on a name.

Density peak clustering was first proposed in *Science* by Rodriguez and Laio (2014). It is based on the premise is that the center of a cluster is more densely packed than the surrounding regions and that areas of high density tend to be relatively far apart. As a clustering method, density peak search has proven to be very fast and quite accurate. Compared to traditional K-means or density-based clustering algorithms like DBSCAN, density peak searches identify cluster centroids purely based on the one characteristic of density. There are no additional parameters and no multiple iterations, which means the clustering process is extremely efficient and highly robust to parameter selection. Du et al. (2016) have since improved this method by using average K-nearest neighbor (KNN) density to emphasize the importance of local density instead of the circle radius approach used originally. This notion of density accords with the characteristics a topic label should have in that a highly representative topic label will be strongly connected to its affiliated terms but as different as possible from other topic labels. This parallel motivated our idea to automatically name topics through a KNN-modified density peak-based clustering algorithm.

Methods

Concept definitions and problem formulation

Definitions of the main concepts referred to in the methodology are as follows.

- Topic term: Nominal phrases extracted from scientific documents via a series of natural language processing and cleaning steps.
- Topic: A set of topic terms with their corresponding probabilities headed by a core topic term. Term overlaps under the same parent topic are allowed for different topics.
- Hierarchical topic tree (HTT): HTT is both the name of our methodology framework and the final output. As an output, an HTT is a tree-structure that consists of topic nodes residing on different layers of a tree, as illustrated in Figure 1. The length from the root node to the nodes on the deepest layer is called the tree depth. A higher layer topic is a parent topic, and its connected topics in lower layers are called child topics. Child topics under the same parent topic are siblings. The associations between a parent and child topic are assumed to be stronger than the associations between siblings.

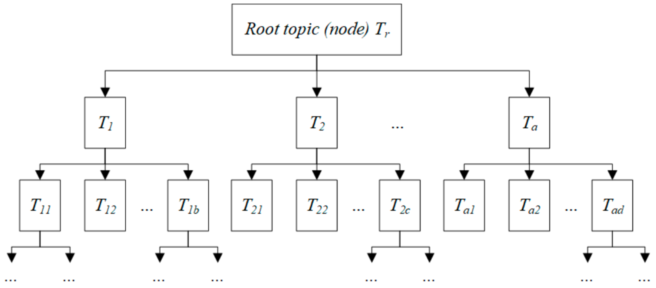

Figure 1. An example HTT

Problem formulation: The study aims to: 1) identify research topics with different granularities and construct a topic tree automatically from a collection of scientific documents; 2) label every topic with an appropriate name; and 3) detect topic overlaps.
HTT accomplishes these goals through the following steps.

Term clumping and network construction

The process begins by extracting topic terms from a corpus of documents. This is done with VantagePoint[1] and a term clumping process (Zhang et al., 2014). With the extracted terms in hand, the next step is to construct a weighted co-occurrence network of topic terms, denoted as $G = (V,\ E)$. V is the set of nodes representing the extracted topic terms, and E is the set of edges representing term co-occurrence. The graph is formulated according to the following equation:

$$w_{V_iV_j(i\neq j)} = \begin{cases} \dfrac{1}{CF(V_i, V_j)} & if\ V_i\ and\ V_j\ co-occur\ in\ at\ least\ one\ document \\ 0 & otherwise \end{cases}$$

where $w_{V_iV_j(i\neq j)}$ is the edge weight of $E_{V_iV_j(i\neq j)}$ and $CF(V_i, V_j)$ is the co-occurrence frequency of V_i and V_j.

Density peak search (DPS)

This algorithm is designed to identify core terms for topic labels. The primary concern when applying density peak clustering to network data is finding appropriate proxies for the distance and density measurements. Bai et al. (2017) use r-step topological distance as a proxy. However, this strategy necessitates a redundancy parameter r and a weighted parameter t, both of which need to be fine-tuned and both of which reduce the model's adaptability. Therefore, we opted to develop a new distance proxy, although still based on the topological distance between nodes:

$$d_{V_iV_j} = \begin{cases} w_{V_iV_j} & if\ V_i\ and\ V_j\ are\ connected \\ SPL_{V_iV_j} & if\ \ V_i\ and\ V_j\ are\ unconnected\ a\ path\ exits\ between\ them \\ \text{NA} & if\ no\ path\ exists\ between\ V_i\ and\ V_j \end{cases}$$

where $SPL_{V_iV_j}$ is the length of the shortest path from node V_i to V_j.

Generally, the co-occurrence network of high-frequency terms is fully connected, which means there will be at least one path from V_i to V_j. Hence, using the proposed new distance proxy, the kernel local KNN density and distance to the nearest denser point of every term can be calculated as:

$$\rho_{V_i} = \exp\left(-\frac{1}{K}\sum_{j\in KNN(V_j)} d(V_i, V_j)^2\right)$$

[1] More details could be found at www.vantagepoint.com.

$$\delta_{V_i} = \begin{cases} \max\limits_{V_j}(d_{V_iV_j}) & if\ \rho_{V_i} = \max(\rho_{V_i}) \\ \min\limits_{V_j\,\epsilon\,V_{\rho_{V_j}>\rho_{V_i}}}(d_{V_iV_j}) & otherwise \end{cases}$$

In the few cases where the co-occurrence network includes several unconnected components, we will generate a virtual root node for the final HTT. Then each component will be processed separately as a branch of the virtual root node.
The original DPC algorithm identifies the cluster centroids with higher values of ρ and δ by observing the $\rho - \delta$ plot. However, when applying this algorithm to a real-world dataset, the boundaries of centroids and other terms are not always that clear. Therefore, in HTT, these selection criteria are quantitative. V_c denotes the potential centroids of all the communities, and the criteria for selecting the final centroids are formulated as follows:

1) Density peak: The selected centroids should be density peaks, denoted as:

$$\rho_{V_c} = \max_{V_i \in KNN(V_c)} \rho_{V_i}$$

in which $KNN(V_c)$ denotes the K-nearnest neighbor nodes of V_c.

2) Sparsity: To guarantee the identified centroids are sparse to each other, we set the node's distance to its parent node as a quantitative minimum threshold, which also indicates the associations of child nodes are weaker than the associations with their common parent node. This criterion is expressed as follows:

$$\delta_{V_c} > d_{V_rV_c}$$

in which V_r denotes the parent node of V_c.

Initially, there is no root node to measure whether a node meets Criterion 2). Hence, we will only use Criterion 1) to identify root nodes. If only one node meets criterion 1), it will automatically become the root node. Otherwise, a virtual root node is generated, and the n identified nodes would become children to the virtual root.

Overlapping community allocation (OCA)
The next step is to distinguish overlapping topics between communities and ensure they are given proper multiple assignments. Thus, every node is assigned a probability vector $p_{V_i} = \{p_{i,1,} p_{i,2,} p_{i,3,} \dots, p_{i,n}\}$, which reflects the probabilities that V_i belongs to core terms identified. Specifically, the probability that node V_i belongs to a community (topic) with the core term V_c is calculated as follows:

$$p_{i,c} = \frac{\min\limits_{V_j \in V} d(V_j, V_c)}{d(V_i, V_c)}$$

In disjoint community allocation, node V_i will be exclusively allocated to its closest centroid c if $c = argmax_t\{p_{i,t}, t = 1,2,3, \dots, n\}$. However, our aim is to allocate a node to more than one potential community with high probabilities. Hence, we employ an overlap threshold σ to decide multiple communities the node V_i could belong to. The rule applied is that if $\frac{p_{i,t}}{p_{i,c}} > \sigma$, node V_i will be assigned to both community t and c. The output of this step is n overlapping communities with their assigned terms and probabilities.

Recursive hierarchy detection

The previous steps partition the network into n subnetworks, with each subnetwork comprising a core topic term and representing a sibling topic on the second layer. To extend the hierarchy into deeper layers, new subcommunities are detected by recursively applying the modified DPS and OCA algorithms to the partitioned subnetworks. When partitioning the parent networks into subnetworks, terms that belong to more than one topic, i.e., community overlaps, are excluded. This is because our approach aims at revealing hierarchies that exclusively belong to the parent topic. The recursive loop ends when no further core topic terms are detected in any subnetwork or the term number in the subnetwork is less than K.

The output of this step is the final HTT, with each node represented by a core topic term and linked to a set of terms. Topic overlaps containing terms shared by sibling topics are detected as well. This recursive process is illustrated in Figure 2, where each color represents a different stratum in the hierarchy. From top to bottom, the HTT has a root topic and one or multiple layers of topics generated by the iterations of DPS and OSA algorithms. Topics generated in the same iteration are siblings to each other and share a mutual parent topic.

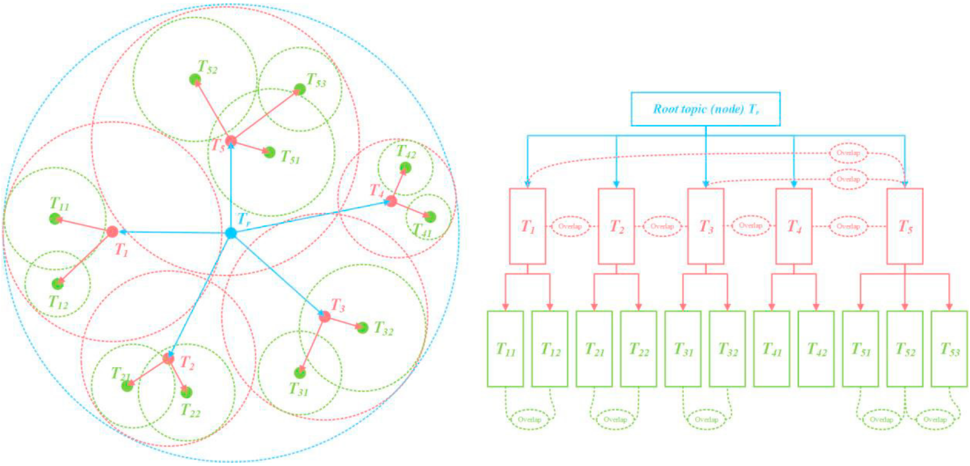

Figure 2. The recursive process of hierarchy construction

Methodology evaluation

According to criteria from previous studies, a well-curated hieratical topic structure should meet at least two characteristics: semantically coherent topics and high-quality parent-child topic relationships (Qian et al., 2020; Shang et al., 2020; Xu et al., 2018). Hence, we designed two indicators - topic coherence and parent-child association index (PCAI) to quantify the two characteristics. Additionally, we calculate the weight loss ratio of network edges to measure the information loss in the HTT process. Please note that the topics mentioned in this section contain overlapping terms, the association strength between two topics means the total sum of the edge weight's reciprocal of the pairwise terms from the two topics, the internal topic association of a topic strength refers to the total sum of the edge weight's reciprocal of pairwise terms from the topic itself.

- Topic coherence: Previous studies employ pointwise mutual information (PWI) to measure the topic coherence, but we consider it does not provide an intuitive and universal measure of topic coherence because its value range is -∞ to +∞ and its values vary hugely in multiple studies (Qian et al., 2020; Wang et al., 2013; Xu et al., 2018). Hence, in the current study, we measure the coherence of a topic via calculating the proportion of its total internal association strength against its total association strength with itself and its siblings.

$$Coherence_{T_i} = \frac{1}{|T_i|} \sum_{V_m \in T_i} \frac{\sum_{V_n \in T_i, m \neq n} CF(V_m V_n)}{\sum_{T_j \in children(parent(T_i))} \sum_{V_k \in T_j} CF(V_m V_k)}$$

- Parent-child association index (PCAI): This indicator is only applied to parent nodes in the final HTT (including the virtual root node if it exists). For every parent node, the PCAI equals the ratio of the total pairwise association strength among its children topics over the total association strength of itself and all children topics subtracted by 1.

$$PCAI_{T_i} = 1 - \frac{\sum_{T_m, T_n \in children(T_i), m \neq n} \sum_{V_p \in T_m^K, V_q \in T_n^K} CF(V_p, V_q)}{\sum_{T_j \in children(T_i)} \sum_{V_x \in T_j^K, V_y \in T_i^K} CF(V_x, V_y)}$$

- Information loss index: This index measures the overall information loss when the co-occurrence network being transformed into a hierarchical tree structure. The smaller value of information loss reflects the model's better performance of retaining information.

$$Information\ loss\ index_{T_i} = \frac{\sum_{T_m, T_n \in children(T_i), m \neq n} \sum_{V_p \in T_m, V_q \in T_n} CF(V_p, V_q)}{\sum_{V_x \in T_i, V_y \in T_i, x \neq y} CF(V_x, V_y)}$$

Case Study: The hierarchy of research topics in computer science

To demonstrate the methodology, we conducted a case study on the field of computer science, decomposing its many and varied research interests into topic hierarchies.

The corpus comprised 6,267 highly-cited papers published between 2010 and 2021 retrieved from the Web of Science (WoS) Core Collection database spanning the mainstream research topics regarding this domain. WoS is a well-curated multidisciplinary database with 74.8 million scientific publications from over 21,100 journals. Category information is assigned to every journal, and articles with the top 1% of citations received per field are flagged[2]. The search strategy used to assemble the corpus was as follows:

(WC = "Computer Science") AND LANGUAGE: (English) AND DOCUMENT TYPES: (Article), Refined by: ESI Top Papers: (Highly Cited in Field), IC Timespan=2010-2021
WC: Web of Science Category;

Data pre-processing

Before applying our methods to the dataset, we ran VantagePoint's natural language processing (NLP) function to extract the raw words and phrases from the titles and abstracts. We then executed a term clumping process that removes noise and consolidates synonyms to arrive at a final list of topic terms. From this list, we selected terms with a frequency greater than 2. The

[2] https://clarivate.com/webofsciencegroup/solutions/essential-science-indicators/

stepwise cleaning results are given in Table 1. The final output was a term co-occurrence network consisting of 2,134 terms.

Table 1. Stepwise cleaning results

Step	*Description*	*# Terms*
1	Raw terms retrieved with NLP	132,846
2	Consolidated terms with the same stem, e.g., “information system” and “information systems”	116,898
3	Removed spelling variations, removed terms starting/ending with non-alphabetic characters, e.g., “Step 1” or “1.5 m/s”, removed meaningless terms, e.g., pronouns, prepositions, and conjunctions	114,459
4	Removed general single-word terms, e.g., “information” *	96,245
5	Consolidated synonyms based on expert knowledge, e.g., “co-word analysis” and “word co-occurrence analysis”	84,828
6	Eliminated all terms occurring less than 5 times	2,134

*Note: Given that most single-word terms take on additional context when used in multi-word phrases, e.g., “information” vs. “information systems”, we opted to remove generic single-word terms. Further, some multi-word terms were consolidated into a single-word form in Step 2 (e.g., “classification method” became “classification”). Non-general single-word terms were retained.

Parameter selection

Before generating the HTT, we selected appropriate values for the KNN density parameter K and the overlap threshold σ. Optimal values of K were determined through a sensitivity analysis by monitoring the number of initially identified core topic terms against K. The corresponding plot is presented in Figure 3.

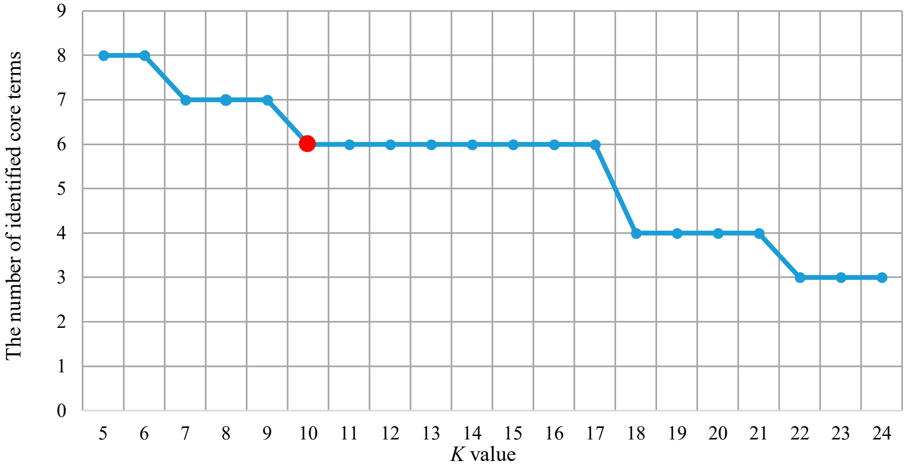

Figure 3. The plot of *K* against the number of identified core topic terms

HTT returned six initial core topic terms at every setting of K between 10 and 17. Therefore, to detect as many topics as possible, we set K to 10 and the overlap threshold σ to 0.8.

Tree generation

With the co-occurrence network as input to the DPS and OCA algorithms, the graph was recursively partitioned into subnetworks of topics in different layers, and the overlaps between topics were evaluated and assigned accordingly. The algorithms stopped at the eighth iteration, yielding a nine-level HTT of computer science research. Figures 4 and 5 illustrate the HTT and detailed terms in topics and their overlaps, respectively.

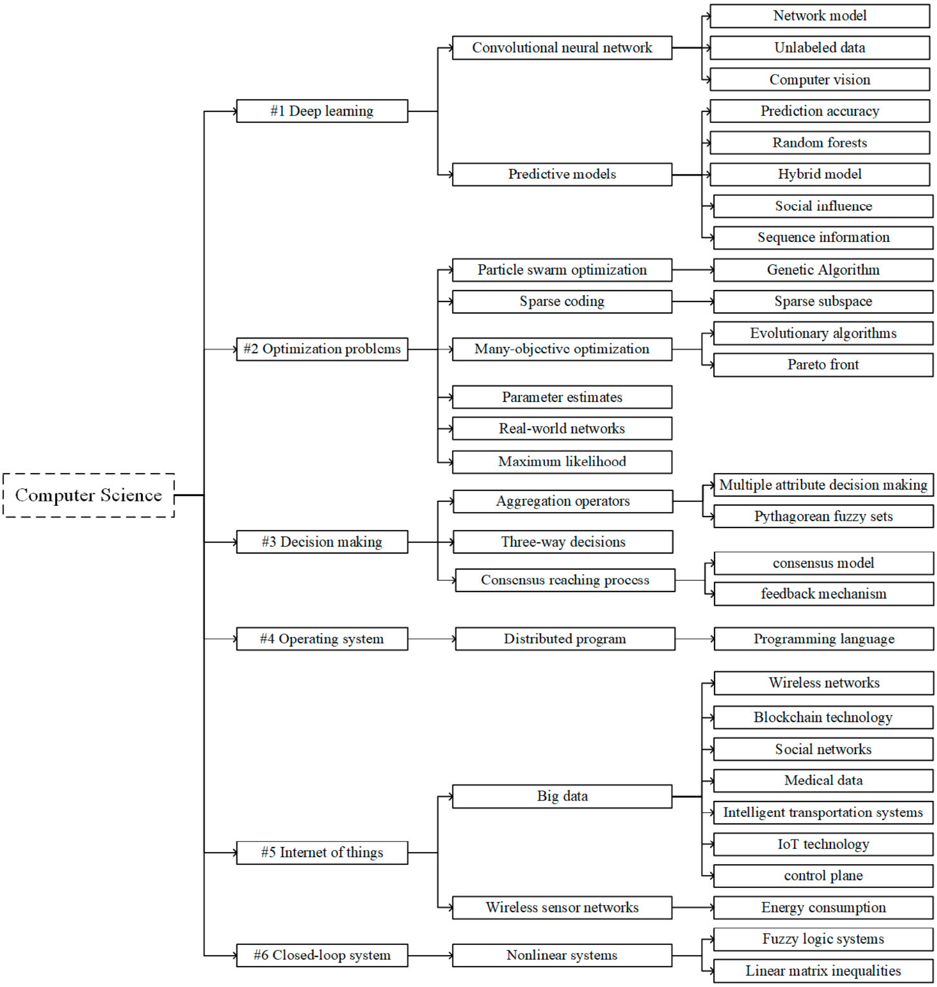

Figure 4. The HTT for computer science[3]

Evaluation and discussion

To evaluate the performance of HTT in this case, we calculated the average topic coherence, PCAI, and information loss of the final HTT, with their values presented as 0.619, 0.847, and 6%, respectively. The high PCAI value indicates our methods yield solid and reliable relationships between parent and their corresponding child topics. The low average information loss index suggests that the HTT evenly retains more than 93% of the information in every hierarchy construction process. The topic coherence is above 0.6, which is acceptable in partitioning the tangling research topics in the computer science domain that includes many multi-disciplinary interactions and knowledge convergence.

In Figure 4, the six topics in the first tier reflect six relatively separate research directions, which result from the idea of DPS that each core label should be topologically distant from each other. Simple observation confirms that the selected label terms with high density are also representatives of the terms they lead. Drilling down into each of the six initial parents, *#1 Deep learning* branches off into topics that pertain to various neural network techniques, such as convolutional neural networks and recurrent neural networks, and onwards to the tasks they are used to solve in the real world, e.g., computer vision, image classification, etc. The lower branch of this topic groups the models and metrics associated with deep learning, such as random forest and prediction accuracy. *#2 Optimization problem[s]* spans the different techniques, algorithms, and research objects associated with optimization and its sub-problems. *#3 Decision making* captures the models, strategies, sub-problems relevant to decision intelligence and its processes. #4 *Operating system[s]* groups the research topics surrounding computing architectures and software, which is a fundamental aspect of computer science. #5 *The Internet* *of Things* (IoT) connects big data and sensor technology with its many spheres of application. Last, #6 *Closed-loop system[s]* leads the branch of topics concerning the convergence of computer science with engineering and control systems.

We also generated insights into cross-direction convergence from the topic overlaps in Figure 5. The overlapping terms between #1 and #2 include “data mining”, “classification accuracy”, and “classification tasks”, which are universal concepts for both deep learning and optimization studies. Overlapping terms of #2 and #4 describe two programming tools (R, MATLAB) and computer performance (enhanced performance, CPU time). This overlap indicates a direction of solving optimization problems using computer operating system-based applications. Likewise, the other overlapping terms all indicate different kinds of topic convergence. Intriguingly, “machine learning” was also assigned to this overlapping section. Conventionally, deep learning would be regarded as a sub-topic of machine learning; however, the two terms are close neighbors in this term co-occurrence network, and “deep learning” has a higher KNN density. What this reflects is that deep learning has overshadowed its precursor technologies to become the more dominant research focus. Interestingly, this outcome raises questions over the temporal associations users attach to hierarchies and how the HTT framework prioritizes attention over evolution. This is a question we leave to future study.

Conclusions

This paper presents an end-to-end framework called HTT for identifying topic hierarchies from a co-occurrence network. The methodology combines density peak search and overlapping community allocation to provide a solution that extracts the topics from a corpus, identifies topic overlaps, arranges the topics in a hierarchy, and gives each topic an appropriately descriptive name. In HTT, the core term to each topic in a co-occurrence network, to be used as its label, is determined by the term’s density peak characteristics, while overlapping community allocation detects overlaps among different topics. Recursive implementation of these two algorithms generates a hierarchical topic tree. A case study on the topic hierarchies in computer science demonstrates the feasibility and reliability of the proposed methodology.

In future studies, we plan several improvements to the HTT framework. These include: 1) Automatic parameter tuning: To further improve the adaptability of the methodology, we plan to change the DPS and OCA algorithms into nonparametric functions. Then, optimal values of K and σ could be selected automatically via a maximum entropy model or other approaches. 2) Leveraging additional forms of similarity: Co-occurrence networks are a classical input in bibliometric approaches, but they have also been criticized for their tendency to include too many irrelevant keyword pairs. Other forms of similarity, or combinations of similarities, such as semantic similarity based on topological distance, may prove to be a more effective proxy for the density peak search process. We plan to test these ideas in a future study. 3) HTT for streaming data. We also intend to build a variant of HTT that considers the temporal relationship between topics and how the research topics evolve over time.

Abstract

We examine the ability of different approaches to discern the topics and the cognitive structure of research into cardiovascular disease (CVD). Since our work is still in progress, we consider only two approaches, namely a citation-based journal map and a topic model, to create maps of CVD research. We compare the results and detect commonalities and differences. We discuss the advantages and disadvantages of these methods and explore reasons behind different results. The results show that the journal map and the topic model generate a relatively similar overall structure of CVD research. The journal map provides an easily understandable intellectual structure of CVD research, while the topic model provides more detailed information on topics and structure. These findings suggest that these two mapping techniques are complementary to a certain extent. The journal map does not suffer from the problem of synonymy and polysemy brought by topic modelling. Meanwhile, the topic model provides more detailed information than the journal map. Also, these findings point to the suitability of both approaches. The journal map is suitable for describing the overall structure of CVD research, and the topic model is suitable for representing more detailed information of topics of CVD research.

Introduction

Science mapping is often used to inform science policy about developments in a research field. Different methodologies for mapping have been developed (Petrovich, 2020). These mapping methods involve different data models and clustering algorithms, and each mapping method exhibits certain advantages and disadvantages, these properties of approach determine different characteristics of the intellectual structure of a research domain (Velden et al., 2017, Chang et al., 2015). Therefore, a concern emerged and is steadily growing: to what extent are results determined by properties of the knowledge structure or by the approaches used (Glaser et al., 2017)? In response to this question, some researchers proposed presenting approaches and comparisons that can address key unresolved theoretical and methodological issues (Glaser et al., 2017). Given that different meaningful and legitimate perspectives on a result produced by a specific approach are possible, rather than aiming at creating the 'best' solution with the highest accuracy, we compare two disparate methodological approaches (Boyack, & Klavans, 2010, Klavans, & Boyack, 2017). There have been few comparisons among approaches. The few studies conducted have shown some similarities yet also significant differences across methods (Velden et al., 2017). However, two of the most widely used methods, namely citation-based clustering and topic model, have not yet been compared. Also, there is a lack of discussion on the advantages and disadvantages of approaches, and addressing this gap would help to get a comprehensive understanding of the suitability of each approach.

In this work, our analysis aims at providing researchers with a better understanding of the strengths and downsides of different approaches. We are particularly interested in how the information obtained from these methods compare to each other, what aspects of results are similar or different, and the reasons behind the possible differences. We propose to use several bibliometric methods to describe the topics and the cognitive structure of a research domain, then compare and detect in what aspects results agree or differ. Next, we discuss the advantages and disadvantages of these methods and explore reasons behind different results.

In this study, we describe the topics and the cognitive structure of the research on CVD, following the delineation of the field provided by Gal et al. (2019), this delineation was created by an expert in cardiology, Prof. Sipido, and collaborators. CVD is an area in which there is an ongoing debate about research priorities and thus where an understanding of intellectual structure is essential. Many stakeholders believe current research is too focused on clinical and biomedical approaches, at the expense of more public health, prevention, and social determinants. The main contribution of our study is that it can answer the question to what extent results are determined by properties of knowledge structure and approaches we use (Glaser et al., 2017). It also contributes to knowledge on the suitability of data models and algorithms for the identification of topics.

Since our research is still in progress, in this study, we consider only two methods, namely citation-based journal map and topic modelling. We characterized the mapping obtained using these two methods, in terms of the content of mapping and the topology of the mapping. As the next step in our project, we plan to also consider mappings generated by other approaches, such as article-level clustering maps, term maps, and maps of MeSH descriptors.

Data

Data was collected from the Web of Science (WoS) database. We used the in-house version of the WoS database at the Centre for Science and Technology Studies (CWTS) at Leiden University. The dataset was established using a hybrid information retrieval strategy, combining lexical and citation-based methods, adopted from Gal et al. (2015). The dataset includes articles, letters, notes, and reviews from 1991 to 2019. It contains 1,079,177 documents from 7,159 journals. The data was retrieved in July 2019.

Methods

Journal map

We applied VOSviewer to build a journal map based on bibliographic coupling links between journals. We collected 7,159 journals from 1991 to 2019 and then removed journals of the subject category 'Multidisciplinary science '. 82 journals were removed, e.g., ‘PLOS ONE’, ‘Scientific Reports’, etc. In the end, we got 7,077 journals. Next, we selected the 400 journals with the largest number of CVD publications. These journals contain 73% of all publications included in the dataset. We then calculated their bibliographic coupling data for constructing a journal map. We removed some general journals, such as ‘Circulation’, ‘American Journal of Cardiology’, etc. Because of their general nature, the inclusion of these journals in a journal map does not contribute to the understanding of the intellectual structure of CVD research.

We aim to compare insights obtained from different approaches, and for this purpose, we prefer to have a relatively fine-grained clustering of the journals in the journal map. Therefore by comparing results produced by choosing different values for the resolution parameter of the clustering techniques used by VOSviewer, we finally chose a value of 1.5 for the resolution parameter. The final map can be seen in Fig.1A. (For map with full detail, please visit https://bit.ly/3gASryG.)

Topic modelling

We trained the Latent Dirichlet Allocation (LDA) topic model contained in the Gensim package to process data. Due to the large-scale final data set, we randomly sampled 10% of the publications with100,286 records. Before training the LDA model, text data was pre-processed. The natural language processing tools were applied to pre-process data. After pre-processing text data, we obtained a dictionary containing 126,784 unique nouns and noun phrases. The LDA model parameters were set to α=50/K, β=0.1 (the default value of β), and Gibbs sampling was run for 2000 iterations in the analysis of the corpus. K indicates the number of topics, and α and β indicate the hyperparameters in the LDA model. K needs to be determined by users, in order to select a suitable number of topics, we repeated experiments of setting the different values of K. We found that terms had a higher probability and better discrimination for K=15. Labels could be obtained by selecting a few meaningful terms among the most frequent (or relevant) terms within every topic. Fig. 1B shows the visualization result of LDA. (If you are interested in the mapping with full detail, please go to https://bit.ly/3rn0h1c to download a file and open the file in your web browser.)

Results

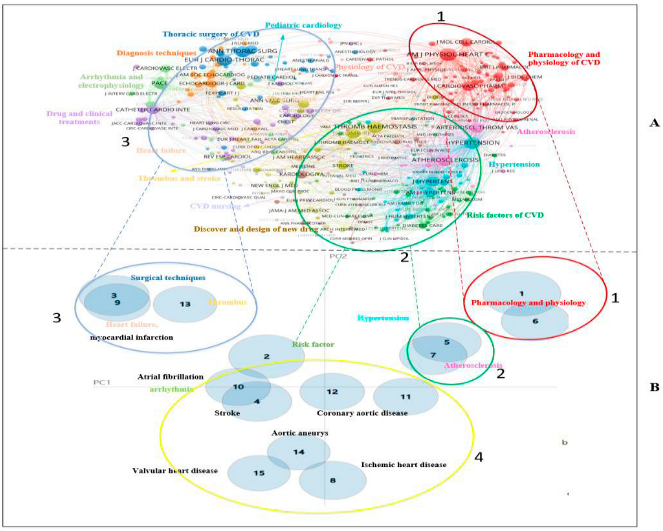

Figure 1. Comparison of journal map and topic modelling map

In Fig. 1A, each journal is represented by a circle, and the distance between two journals approximately represents the relatedness of the journals in terms of bibliographic coupling links. Colors represent clusters of strongly related journals. In Fig. 1B, every circle represents one topic. The distance between the two circles approximately represents the relatedness between topics. We interpreted and compared the map from two aspects: 1) the content of every cluster and topic, 2) the topology of the map.

The research content of clusters and topics

As shown in Fig. 1A, there are 16 specific clusters related to CVD. By interpreting journals within every cluster, we identified various aspects of CVD research: pharmacology and physiology of CVD (cluster 1, red), risk factors of CVD (cluster 2, green), thoracic surgery of CVD (cluster 3, blue), thrombosis and stroke (cluster 4, yellow), drug and clinical treatments (cluster 5, purple), hypertension (cluster 6, blue-green), diagnosis techniques including CT and echocardiogram (cluster 7, orange), discovery and design of new drug (cluster 8, brown), atherosclerosis (cluster 9, pink), physiology of CVD (cluster 10, light red), arrhythmia and electrophysiology (cluster 11, light green), rheumatic heart disease (cluster 12, light blue), CVD nursing (cluster 14, light purple), pediatric cardiology (cluster 15, light blue-green), and heart failure (cluster 16, light orange).

As shown in Fig. 1B, there are 15 specific topics related to CVD. By interpreting terms within every topic, we identified various issues of CVD research. In Pharmacology and physiology (topic 1 and topic 6), research on cell signalling, gene transcription, and animal models are prominent. Risk factor (topic 2) mainly focuses on smoking, diabetes, obesity, BMI, and alcohol. Surgical techniques (topic 3), such as heart bypass, coronary artery bypass graft, and percutaneous transluminal coronary angioplasty. Stroke and its prevention measures (topic 4), with research on life quality and drug prevention. Hypertension (topic 5). Atherosclerosis (topic 7). Ischemic heart disease (topic 8), with research on diagnosis technique and drug prevention. Heart failure and myocardial infarction (topic 9), with research on diagnosing these diseases. Atrial fibrillation and arrhythmia (topic 10) the topic mainly focuses on diagnosis technique and surgery measure. Coronary aortic disease (topic 12). Treatment, therapy, and drug of thrombus (topic 13). Aortic aneurysm (topic 14), which pays attention to the diagnosis technique and surgery measure. Valvular heart disease (topic 15), with research on surgery measure and diagnosis technique.

The topology of the journal map and the topic model mapping

As shown in Fig. 1A, from the overall view, the journal map identifies three main different categories of research: 1) basic research, 2) risk factors of CVD/population, and 3) clinical research (Axel et al., 2018, Gal et al., 2019). Basic research is loosely connected to clinical research, which reveals that there is a gap between basic research and clinical research. In the basic research category, cluster 1 and cluster 10 are closely linked. In the risk factors of CVD category, the relationship of clusters 2, 6, and 9 are strongly interrelated. Meanwhile, cluster 4 is close to cluster 9, because thrombus can lead to atherosclerosis. In the clinical research category, Clusters 5, 11, 7, and 3 are closely linked. These clusters mainly focus on surgery and CVD diagnosis techniques.

As shown in Fig. 1B, from the overall view, the topic modelling map identifies four groups. According to the classification of topics of Gal et al (2019), group 4 can be classified into the clinical research area, which talks about the diseases of CVD. The topic modelling map reveals a similar pattern as the journal map. In basic research, topic 1 and topic 6 are closely linked, and these two clusters are loosely connected to other topics. In clinical research, the relationship of topic 3, 9, and 13, is close. These clusters pay attention to CVD diseases and surgical and drug treatment of these diseases. In risk factors of CVD, Topic 5 and 7 are closely connected, mainly focus on hypertension and atherosclerosis. Topic 2 is loosely connected to topics 5 and 7, while topic 2, 4, and 10 are closely connected.

Comparison between journal map and topic modelling map

Through the comparative analysis of different results produced by different methods, we can get a deeper understanding of the ways in which specific properties of the approaches we used to create differences between our results (Glaser et al., 2017).

In terms of content, the journal map method and topic modelling method both identified the pharmacology and physiology of CVD, risk factors, surgical techniques, and some main diseases of CVD. However, there are also differences, the topic modelling discerned more risk factors, surgical techniques, and CVD diseases than the journal map. Because topic modelling map is created based on document-level data rather than journal-level data. Also, by contrast, text data are probably clearer to users than the bibliographic references data that identified clusters of same content (Zitt et al., 2011). In addition, the journal map may identify some groups that do not appear in the topic model, like the discovery and design of new drug, CVD nursing. Because terms within these clusters are scattered among different CVD disease topics. The reason behind the phenomenon is that terms remain universal on linguistic factors, not confined to scientific databases. While citation-based journal map may prefer to cite the journals from the same corpus (Zitt, 2015).

In terms of topology, both maps show that pharmacology and physiology of CVD are far from other clusters or topics, especially, from surgical treatments. This distance suggests that there are gaps between basic science and clinical research. We discovered some differences as well. From the overall view of these two maps, the journal map provides a clear overall intellectual structure of CVD. Because the intellectual structure of research can be directly read from the organization of bibliographic references. While text data associations, even in full text, do not usually make the knowledge flow apparent due to the polysemy, synonymy used. (Zitt et al., 2011, Zitt, 2015). In the journal map, hypertension, atherosclerosis, and risk factor have a strong connection. However, the risk factor is far from hypertension and atherosclerosis in the topic modelling map. The reasons for this phenomenon may be that textual information can indicate similarities that are not visible to bibliographic reference, and vice versa (Janssens et al., 2008).

Discussion and conclusion

This paper presents the preliminary results of an ongoing project. We created a citation-based journal map and a topic model map to analyze the intellectual structure of CVD research. We compared these two maps from their content and topology. And detected in what aspects results agree or differ and explored reasons behind different results. We found three significant results regarding comparing different maps:

- These two maps may identify relatively similar clusters or topics. However, the topic model map provides more detailed information than the journal map. One reason is that the topic model is created based on document-level data, rather than journal-level data. Another reason is that text data is probably clearer to users than the bibliographic reference data that can identify clusters with the same content (Zitt et al. 2010). That means the topics identified through topic model provide more detailed information that can be used to get a deeper understanding of clusters found on the basis of a journal map.
- The journal map may identify some groups that do not appear in the topic model. Because in topic modelling terms within these clusters are scattered among different CVD disease topics. The reason behind the phenomenon is that terms remain universal on linguistic factors, not confined to scientific databases. While citation-based journal map may prefer to cite the journals from the same corpus (Zitt, 2015).
- These two maps show a gap between basic science and clinical research. Also, the journal map shows an easier to understand overview structure of CVD research because bibliographic references appear as tracers of intellectual connections, the intellectual structure of research can be directly read from the organization of bibliographic references.

Through comparing these two maps, we have a better understanding of the properties of the methods, which can help us learn the suitability of the methods. Topic model processes text data, however, the occurrence of synonymy, polysemy, and common terms may cause problems and may make it difficult to interpret topics' meaning. Therefore require complex semantic processing and pre-processing. By contrast, the journal map is a citation-based method. It does not need too complicated processing, and it can provide a clear intellectual structure of research. However, the journal's bibliographic references provide less detailed information. Our work shows that these two methods are complementary to a certain extent. The journal map describes the intellectual structure of CVD research in a way that is easy to understand, and it does not suffer from the problems of synonymy and polysemy. At the same time, the topic model provides more detailed information, which makes up for the limitations of the citation-based journal map.

This research is still in progress, and therefore there are a lot of possibilities for improving and extending the research. In this paper, we used only two methods to map CVD research. In the future, we plan to add more approaches, including maps based on article-level clustering, MeSH descriptors, and terms. These methods could be combined with our journal map and topic model, which may provide a richer understanding of the CVD field and of the properties of the different methods.

Acknowledgments

Interdisciplinarity vs. Unidisciplinarity: A Structural Comparison of Multi-generation Citations and References

Jiawei Xu[1], Chao Min[2], Win-bin Huang[1] and Yi Bu[1]

[1]*{imxujiawei, huangwb, buyi}@pku.edu.cn*

Abstract

This paper compares the structural characteristics between the citation/reference cascades (networks containing multi-generation citations and references) of interdisciplinary and unidisciplinary papers. By constructing multiple citation/reference cascades for each publication in the American Physical Society (APS) dataset, we found that: (1) for papers having a similar number of references, interdisciplinary papers tend to have a smaller and less 'radioactive' knowledge foundation than unidisciplinary papers, though the knowledge foundation of interdisciplinary papers is more heterogeneous; (2) for papers having a similar 'direct' scientific impact, unidisciplinary papers have a relatively greater 'indirect' impact, which indicates that the scientific impact of unidisciplinary papers is 'deeper' and more persistent; and, (3) compared to unidisciplinary papers, there exists at least a short time in which interdisciplinary papers trigger more follow-up discussions.

Introduction

Interdisciplinary research is found to facilitate knowledge integration and scientific innovation (Klein, 1990; Rafols et al., 2012). Yet, some researchers also hold the view that "the general superiority of interdisciplinarity over disciplinary knowledge" has not been fully proved (Jacobs & Frickel, 2009, p. 60). Within this debate, a considerable number of studies have focused on interdisciplinarity, many of which have paid special attention to the relationship between the interdisciplinarity of a single publication and its scientific impact. For instance, Larivière and Gingras (2010) found that publications in physics citing citation-intensive disciplines tend to obtain higher citation scores. Chen, Clément Arsenault and Larivière (2015) showed that the top 1% most-cited papers present higher levels of interdisciplinarity. These studies suggest to us that there might be a positive correlation between the level of interdisciplinarity of a publication and its 'direct' scientific impact, calculated by citation count-related indicators. Nonetheless, for two publications having a similar 'direct' impact, one might have a greater 'indirect' impact (quantified by using multi-generation citing publications) than the other. And the publication that triggers more follow-up discussions seems more invaluable.

To this end, in this paper, we adopt an existing citation network structure, namely citation cascade (Min, Sun & Ding, 2017; Min et al., 2021a) and reference cascade (Min et al., 2021b). For a given focal publication, its citation cascade contains its first-, second- (i.e., citing publications' citing publications), …, and *n*th generation citing publications, as well as their citing relationships. Symmetrically, its reference cascade includes its first-, second-, …, and *n*th generation references. Rousseau identified the concept of multi-generation citations and references dating back to 1987 (Rousseau, 1987), a concept which has inspired many further studies (Hu, Rousseau & Chen, 2011; Hu & Rousseau, 2016). Investigating citation cascades helps understand forward citation behaviour details and how a particular study inspires later research, regardless of whether this influence is direct or indirect. As for reference cascades, they include backward citation nuances in terms of knowledge foundations (e.g., scale, interlock-wise structure, etc.). This paper employs these two cascades and compares the 'indirect' scientific impact and knowledge foundation of interdisciplinary and unidisciplinary publications by adopting many structural-level measurements, such as structural virality, average clustering coefficient and network density.

Data and methods

Data

We adopt the American Physical Society (APS) dataset that covers 541,448 publications from 1893 to 2013 and the nearly 3 million citing relations among them. As a balance to guarantee a relatively long citation window and a sufficient number of publications, we particularly select all publications in 1996, 1997 and 1998 in our following empirical study.

All publications in or after 1975 are assigned one or more codes within the Physics and Astronomy Classification Scheme (PACS). These codes are adopted to identify fields in physics. There are several levels in the PACS. For simplicity, we employ the top-level codes (representing 10 fields) in our study to present the specialties of publications.

Methods

Citation cascade and reference cascade

From the structural perspective, citation cascade and reference cascade are generated through citing relations. For a given focal publication, its citation cascade comprises its citing publications (first-generation citations), its citing publications' citing publications (second-generation citations), …, and *n*th-generation citations. A reference cascade is symmetric; that being said, the reference cascade of a given publication contains its references (first-generation references), its references' references (second-generation references), …, and *n*th-generation references. Thus, reference and citation cascades tend to be more informative than traditional bibliometric indicators, e.g., number of citations and its normalised variants (Bornmann & Daniel, 2008).

Previous scientometricians have focused on the conceptualisation and operationalisation of citation cascades (e.g., Min et al., 2017; Min et al., 2021a), described as "the constitution of a series of subsequent citing events initiated by a certain publication" (Min et al., 2021a, p. 110). Similarly, reference cascades contain a series of proceeding citing (referencing) events initiated by a certain publication.

We defined all publications in 1996, 1997 and 1998 as the 'initial publication set' ***I***. And, for every publication in ***I***, we created its citation cascade and reference cascade using all the citing relations in the APS dataset. We stipulate that, if the depth of a publication's reference or citation cascade is less than four, this publication, as well as its cascades, will be removed from our following empirical study. To this end, 29,310 publications remain.

Quantifying interdisciplinarity

As mentioned above, each publication has one or more PACS labels from the 10 labels. Following Porter and Chubin (1985), the references' PACS labels are used to measure how interdisciplinary a publication is. We characterise the degree of interdisciplinarity of one specific publication following Figure 1. As shown, we first examine the PACS labels of all references of i and adopt the Reverse Simpson Index (RSI_i) as an indicator:

$$RSI_i = 1 - \sum_{j=1}^{R} {p_j}^2$$

where R represents the number of fields publication i's references come from and p_j the proportion of field j among all fields. Per Simpson (1949), RSI is "a measure of the concentration of the classification" (p. 688). The greater the RSI is, the higher the degree of interdisciplinarity. In practice, we define the top 20% ranked publications in terms of RSI as interdisciplinary papers and the bottom 20% as unidisciplinary papers[1]. This results in 5837 and 5834 publications in each group, respectively[2].

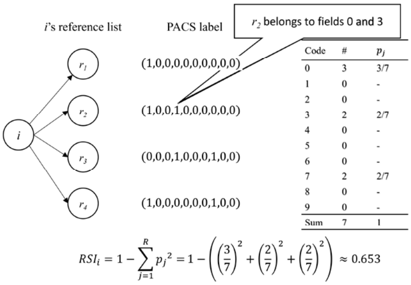

Figure 1. Illustration of quantifying interdisciplinarity of a publication *i*.

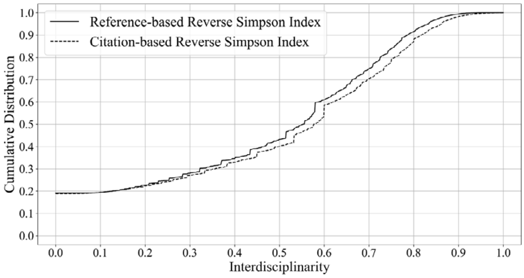

Figure 2. The cumulative distribution of the two interdisciplinarity indicators.

Matching

To reveal the differences regarding interdisciplinarity and unidisciplinarity, we set up two groups of publications. For each unidisciplinary publication, we try to find a 'similar' publication in the interdisciplinary group. To this end, we employ a one-to-one matching and stipulate that one publication cannot be matched with multiple publications. When implementing this matching process, we follow the below rules:

(1) This pair of publications have at least one same PACS field;
(2) For a given unidisciplinary publication, we only keep a certain interdisciplinary publication that has >90% field similarity[3];
(3) Compared with the higher cited publication (regardless of which groups), the lower cited publication has at least 90% as many citations, i.e., their numbers of citations have a ≤10% difference;
(4) Compared with the higher citing publication (regardless of which groups), the lower citing publication has at least 90% as many as references;
(5) This pair of publications have the same document type; and
(6) This pair of papers were published in the same journal in the same year.

Finally, we obtained 822 pairs of publications. The matched groups (822*2=1644 publications) are hereafter abbreviated as interdisciplinarity and unidisciplinary groups.

[1] According to Figure 2, there are ~20% publications with an *RSI* of 0.0. We therefore set the bottom 20% as unidisciplinary publications. Correspondingly, the top 20% are defined as interdisciplinary ones.

[2] Because there might be more than one publication exactly at the 20% threshold, we have to include all of these publications in practice. This is why there are minor differences regarding the number of publications in the two groups.

[3] For each publication, we construct a 10-dimension vector that contains its PACS code; each dimension represents one of the 10 fields under physics. If a publication has a certain field label, this dimension will be marked as one; otherwise, zero. We compare two publications' field similarity by calculating the cosine similarity of the two vectors.

Measurements

For each publication in the unidisciplinarity or interdisciplinarity group, we construct three citation cascades with different generations, i.e., citation cascade with the first two, three and four generations, as well as three reference cascades with different generations, i.e., reference cascade with the first two, three and four generations. We calculate the below indicators particularly:

- Structural popularity (SP): For citation cascades, SP represents the range to which knowledge is diffused; in terms of reference cascades, it indicates the scale of knowledge foundation. We utilise the number of nodes in a cascade as a measurement.
- Structural virality (SV): SV measures the knowledge diffusion depth of the publication. We use the average depth of the publication's citation cascade to represent it.

$$SV = \frac{1}{|T|-1} \sum_{v \in T, v \neq i} d(v, i),$$

T is the cascade initiated by publication i, $|T|$ is the number of nodes in T and $d(v, i)$ is the shortest path between v and i.

- Average clustering coefficient (ACC): ACC reflects the goodness of clustering in a network. Specifically:

$$ACC = \frac{1}{|V|} \sum_{v_k} C(v_k)$$

where V is the node set and $C(v_k)$ is the clustering coefficient of node v_k:

$$C(v_k) = \frac{number\ of\ closed\ triads\ connected\ to\ v_k}{number\ of\ triples\ of\ vertices\ centered\ on\ v_k}$$

- Network density (ND): ND describes the proportion of the potential connections in a network that are actual connections.

$$ND = \frac{2|E|}{|V|(|V|-1)}$$

where E is the edge set. The higher the ND is, the more connections the network has.

Results and Discussion

To statistically test whether the interdisciplinary and unidisciplinary publications have significant differences regarding the aforementioned indicators, we employ the Wilcoxon signed-rank test. As shown in Table 1, in terms of reference cascades, papers from the two groups have shown significant differences in SP and ACC when we select the first three and four generations in the cascade. As for citation cascades, we observe a significant difference for SV and ND for the first two and three generations. We did not find any significance in the first four generations for citation cascades, partly because of, at least conceptually, the insufficient topical similarity between a focal publication and its fourth-generation citing publications.

Table 1. Wilcoxon signed-rank test results.

Indicator	SP	SV	ACC	ND
Reference Cascade (first 2 generations) Sig.	0.149	-	0.240	0.379
Reference Cascade (first 3 generations) Sig.	**0.027***	-	**0.000*****	0.652
Reference Cascade (first 4 generations) Sig.	**0.005****	-	**0.000*****	0.406
Citation Cascade (first 2 generations) Sig.	0.108	**0.007****	0.269	**0.048***
Citation Cascade (first 3 generations) Sig.	0.105	**0.036***	0.076	0.069
Citation Cascade (first 4 generations) Sig.	0.208	0.117	0.198	0.139

Notes. SP=Structural popularity; **SV**=Structural virality; **ACC**=Average clustering coefficient; **ND**=Network density. $^{*}p<0.05$, $^{**}p<0.01$, $^{***}p<0.001$. All significant results under the 0.05 threshold are **bolded**.

We are particularly interested in the indicators that show statistically significant differences. In this research-in-progress paper, we present four of them in Figure 3, representing SP and ACC for reference cascades (sub-figures A and B, respectively) and SV and ND for citation cascades (sub-figures C and D, respectively). Figure 3(A) indicates the cumulative distribution of reference cascade SP (first four generations). We can see that, when SP<400, the unidisciplinarity and interdisciplinarity groups distribute closely and that there are more interdisciplinarity papers whose SPs are between 400 and 1100. Yet, when SP is greater, unidisciplinary papers dominate. As SP of reference cascades represents the knowledge foundation of the focal publication, Figure 3(A) reveals that interdisciplinary publications tend to have a smaller amount of knowledge foundation than unidisciplinary publications.

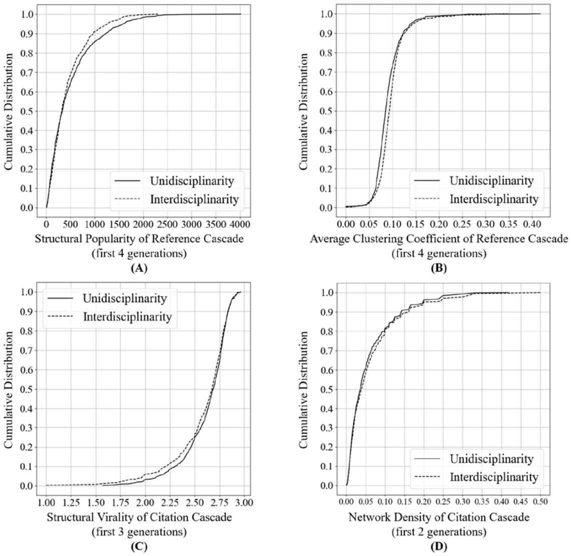

Figure 3. The cumulative distribution of the four structural indicators.

Figure 3(B) shows the cumulative distribution of reference cascade ACC (first four generations), and it demonstrates that an interdisciplinary paper's reference cascade is more similar to an interlocked network, which reveals that an interdisciplinary paper's knowledge foundation is more 'interlocked', though interdisciplinarity reflects the diversity of references.

As to citation cascade, Figure 3(C) presents the cumulative distribution of citation cascade SV (first three generations), in which we find that there are more interdisciplinary publications with a lower SV value. As SV is quantified by the average 'distance' between the focal publication and other publications in the citation cascade, this demonstrates that interdisciplinary publications have a more 'direct' or 'shallow' impact while unidisciplinary publications have a more 'indirect' or 'deep' impact.

Nonetheless, citation cascade ND (first two generations) displays the opposite pattern – we observe more interdisciplinary publications that have a greater value of ND (Figure 3(D)). Figure 3(D) reveals that there are more connections between the publications in the citation cascade of an interdisciplinary paper, and that interdisciplinary research may intrigue researchers and results in more discussions.

Conclusions

In this paper, we implement a structural comparison between the reference/citation cascades of unidisciplinary and interdisciplinary papers. With a sophisticated matching process, our study suggests that interdisciplinary papers tend to have a smaller knowledge foundation and a more 'shallow' or 'direct' impact on the follow-up research. Nonetheless, interdisciplinary papers contribute to the interactions between researchers. We speculate that interdisciplinary research may be relatively pioneering and there are fewer prior works for researchers to build on. Due to this characteristic of interdisciplinary research, policy makers should even more strongly encourage interdisciplinary research and devote more resources to it. Also, more future works are needed to explore the features and mechanisms of interdisciplinary research.

There are some limitations in our study. First, we do not set up any restriction when constructing the cascades, e.g., publication year of forward citations. Future work may consider involving a temporal dimension as a filter and set up different thresholds to examine differences. Second, since our experiment is implemented only in the discipline of physics, we cannot generalise the conclusions to other domains. In the future, we are going to apply the current empirical study in a more comprehensive, cross-discipline bibliographic dataset. Finally, only a few constraints are taken into account in our matching experiment, which may influence the reliability of the experiment. Many other factors could be controlled in our future study, such as the number of co-authors in a publication and their affiliations.

Acknowledgments

We acknowledge the two anonymous referees as well as the organisers for their useful comments. We also acknowledge the American Physical Society (APS) for publicly share the dataset for research.

Abstract

Identifying rising stars in scientific fields is critical to many kinds of applications. Traditional talent evaluation methods are inapplicable for the recognition of rising stars. Moreover, existing recognition methods demonstrate some problems and limitations. This paper proposes a ranking-based method: RStarRank, which recognizes rising stars with machine learning algorithm. In other words, this method generates a prediction model through learning preliminary features of many beginners and their future H-index to predict sequential probability of young talents' growth into academic leaders. This paper takes the computer science subject for empirical study. The results show that, the prediction accuracy can reach over 90% for 10-year model and over 84% for 5-year model, RStarRank has been verified to have a certain validity and has a higher prediction accuracy than other similar algorithms. Finally, this paper summarizes and describes deficiencies of the proposed method.

Introduction

Young scientists are emerging forces that can advance future scientific development. Identifying scientific rising stars is critical for the recruitment of research institutions, cultivation of youth talents, award assessment, and selection of peer reviewers, etc. However, there are few related studies on this problem at present. Generally, identifying rising stars is an academic evaluation issue. Traditional academic evaluation methods are mainly applicable to evaluate and recognize scientific talents with longer careers, making it difficult to recognize rising stars. Consequently, studying the recognition of rising stars will help to meet practical needs, and promote the evaluation of scientific talents, thus offsetting deficiencies in evaluating and recognizing scientific youth talents.

This paper aims to study rising stars and identifying them among young talents. After summarizing deficiencies of existing studies, this paper provides RStarRank, a new method based on ranking and machine learning algorithm. Then, an empirical analysis is conducted. Finally, this paper summarizes deficiencies of RStarRank and describes outlook for future study.

Related Work

Compared to researchers with longer academic careers, beginners carry some unique characteristics, making it difficult to recognize beginners simply with traditional recognition and evaluation method. Li (2009) firstly stated the issue of recognizing rising stars in 2009. According to the framework on which they are based, they are divided into 3 types in this paper, including ranking-based, classifying-based, and clustering-based method.

Ranking-based method

By establishing indicators and indicator system representing features of rising stars (possibly unknown), the ranking-based methods calculate "comprehensive indicator value" of each beginners and rank them to obtain a set of rising stars. Some ranking algorithms are PubRank, StarRank and CocaRank (Ning, Liu & Kong, 2017) (Ning, Liu, Zhang & Wang, 2017) (Daud, Aljohani, Abbasi, Rafique, Amjad, Dawood & Alyoubi, 2017) (Zhang, Liu, Yu, Zhang & Zhou, 2017) (Wijegunawardana, Mehrotra & Mohan, 2016). (Zhang, Ning, Bai, Wang, Yu & Xia, 2016) (Zhang, Xia, Wang, Bai, Yu, Bekele & Peng, 2016).

Classifying-based method

This method classifies beginners into those who may become highly influential scholars and those who may not. Through learning indicator features of the said two groups, this method generates a prediction model for recognition and prediction. This method mostly uses supervised learning (Billah, 2013) (Daud, Ahmad, Malik, M. S., & Che, D. 2015), to predict rising stars.

Clustering-based method

Tsatsaronis et al (Tsatsaronis, Varlamis, Torge, Reimann, Nørvåg, Schroeder & Zschunke, 2011) (Panagopoulos, Tsatsaronis & Varlamis, 2017) regarded the recognition of rising stars as a clustering issue. They classified scholars into four levels, i.e. well-established, rising stars, stable publication rate, and declining authors. Tsatsaronis et al used unsupervised learning method for scholar clustering, and conducted feature description for the obtained four types based on basic features, thus recognizing rising stars.

Table 1. Advantages and weaknesses of three methods for rising stars identification

Method	*Advantages*	*Weaknesses*
Ranking-based method	Reflects the potential of scholars to become rising stars. Capable of recognizing a number of stars.	The selection of feature indicators is critical. Some algorithms are highly complex due to feature indicator processing.
Classifying-based method	The results are definite, i.e. classifying the beginners into rising stars or those who are not.	The feature indicators and thresholds are particularly critical. It is impractical to simply classify beginners into two types.
Clustering-based method	Beginners are classified into several types.	The clustering results may be inconsistent with this assumption. Therefore, clustering results may not be highly interpreted.

Problem exists

Classifying-based method divides beginners into two categories, the two groups is greatly affected by the selection of the index threshold, thus the identification may fail once the index threshold is selected unscientifically or unreasonably. While clustering-based method relies on the clustering of the characteristics of academic beginners and the clustering results might be contradictory to the assumptions. The ranking-based method assumes that academic newcomers demonstrate different levels of potential and probability to become rising stars, which conforms to the objective law. Therefore, this paper selects ranking-based method to conduct the research. However, problems still exist:

- The definition of the key issues of identifying rising stars do not match the actual application scenario and there is a lack of reasonableness. For the definition of beginners in scientific research, some intercepted all authors for a period of time, some selected the authors that are not in the Top 3%. None of these definitions fit the actual application scenario. For the setting of the "future" observation time, some studies set it as 3-10 years, which is too short to assess their achievements.

- Methods are not universally applicable in different fields. The indicators of scholars' academic achievements vary substantially across fields. For example, citations in the medical field are often much higher than those in other fields.
- These methods require a large amount of data and high computing cost. Most methods require a large data set and complex data processing, such as heterogeneous information networks. Other methods rely on complex data indicators, such as PageRank value, etc.
- The prediction accuracy needs to be improved. The existing accuracy verification of ranking-based method mainly compares the authors' indicators of H-index, number of papers, and frequency of citations. Judging from the scale and effect of the current verification, the verification method and its accuracy are to be improved.

Method for rising star identification: RStarRank

Problem definition

In this study, the identification of academic star is considered to identify the Top K academic beginners most likely to grow into academic rising stars, namely:
For beginners $a_i(a_i \in \mathrm{A}), |\mathrm{A}| = \mathrm{N}$ in academic beginners set A, the academic career of a_i starts at time T1, p_i represents the probability of a_i to become a rising star at time T2, $X_i(X_i \in R^m)$ represents the feature index vector of a_i during time period (T1~T2), m represents the number of eigenvalues, y_i represents the H-index of a_i during time period (T1~T3), and Y represents the H-indexes of all beginners in set A.

This study aims to obtain P' on the basis of X_i using prediction model M by training the machine learning algorithm to learn the correlation between X_i and y_i. Here, P' represents the prediction probability sequence from large to small of all beginners in set A; P represents the probability sequence from large to small of all beginners in set A, which is calculated using Y. This is based on the assumption that the higher the H-index is, the higher the possibility that the scholar will become an academic rising star. In this study, H-index of a scholar in the 30th year of his/her academic career is used as a reference index, reflecting his/her level of research achievements to a certain extent. The corresponding relationship between P and Y is shown in Formula 1.

$$Order_{ij} = \begin{cases} 1, & if\ (y_i > y_j)\text{or}(y_i = y_j \text{ and } SN_i > SN_j), \\ & a_i \text{ ranks in front of } a_j \text{ in sequence P} \\ -1 & if\ (y_i < y_j)\text{or}(y_i = y_j \text{ and } SN_i < SN_j)\ , \\ & a_j \text{ ranks in front of } a_i \text{ in sequence P} \end{cases} \qquad \text{(Formula 1)}$$

For $\forall a_i, a_j \in \mathrm{A}$, $Order_{ij}$ represents the relative position of a_i, a_j in the sequence P, SN_i represents the author number of a_i, $Order'_{ij}$ represents the relative position of a_i, a_j in sequence P'.
This research aims to make P' overlaps with P, i.e., $\forall a_i, a_j \in \mathrm{A}, Order'_{ij} = Order_{ij}$. Therefore, it is needed to maximize the value of $\delta(\mathrm{P}, \mathrm{P}')$.

$$\delta(\mathrm{P}, \mathrm{P}') = \sum_{a_i, a_j \in \mathrm{A}}^{Order'_{ij} = Order_{ij}} Order'_{ij} * Order_{ij} \qquad \text{(Formula 2)}$$

The process of RStarRank is shown in Figure 1.

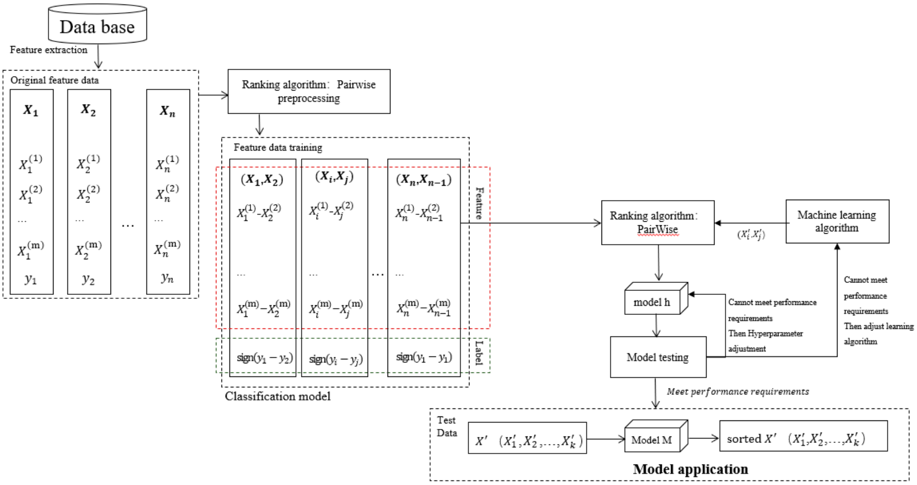

Figure 1. RStarRank Flow Chart

Specific issues involved are more clearly defined as below.

Standards for academic beginners. As rising stars have shorter academic careers, this paper considers the length of academic careers as the criteria to identify beginners. So, beginner a_i should initially publish paper at time T1, i.e. T1 is the starting point of his/her academic career.
